Abstract

Estimates of the seasonal and interannual exchanges of carbon dioxide (CO2) and methane (CH4) between land ecosystems north of 45°N and the atmosphere are poorly constrained, in part, because of uncertainty in the temporal variability of water-inundated land area. Here we apply a process-based biogeochemistry model to evaluate how interannual changes in wetland inundation extent might have influenced the overall carbon dynamics of the region during the time period 1993–2004. We find that consideration by our model of these interannual variations between 1993 and 2004, on average, results in regional estimates of net methane sources of 67.8 ± 6.2 Tg CH4 yr−1, which is intermediate to model estimates that use two static inundation extent datasets (51.3 ± 2.6 and 73.0 ± 3.6 Tg CH4 yr−1). In contrast, consideration of interannual changes of wetland inundation extent result in regional estimates of the net CO2 sink of −1.28 ± 0.03 Pg C yr−1 with a persistent wetland carbon sink from −0.38 to −0.41 Pg C yr−1 and a upland sink from −0.82 to −0.98 Pg C yr−1. Taken together, despite the large methane emissions from wetlands, the region is a consistent greenhouse gas sink per global warming potential (GWP) calculations irrespective of the type of wetland datasets being used. However, the use of satellite-detected wetland inundation extent estimates a smaller regional GWP sink than that estimated using static wetland datasets. Our sensitivity analysis indicates that if wetland inundation extent increases or decreases by 10% in each wetland grid cell, the regional source of methane increases 13% or decreases 12%, respectively. In contrast, the regional CO2 sink responds with only 7–9% changes to the changes in wetland inundation extent. Seasonal, the inundated area changes result in higher summer CH4 emissions, but lower summer CO2 sinks, leading to lower summer negative greenhouse gas forcing. Our analysis further indicates that wetlands play a disproportionally important role in affecting regional greenhouse gas budgets given that they only occupy approximately 10% of the total land area in the region.

1. Introduction

Northern high latitudes (north of 45°N) account for about half of the world’s wetlands although their distribution and total area are uncertain (e.g., Bridgman et al 2000, Lehner and Döll 2004). These wetlands contain a large amount of soil carbon (Gorham 1991, Vitt et al 2000, Turunen et al 2002, Warner and Asada, 2006, Tarnocai et al 2009) due to low rates of decomposition under anoxic conditions...
Traditionally, northern wetlands have been recognized as persistent long-term sinks of carbon (e.g., Smith et al. 2004). However, they may switch from current sinks to future sources due to changes in soil temperature, moisture, and disturbance regimes (McGuire et al. 2009, 2012).

To date, the uncertainty of contemporary carbon budgets of northern wetlands is still one of the largest remaining gaps in assessing boreal carbon budgets (e.g., Apps et al. 1993, Bond-Lamberty et al. 2006, McGuire et al. 2009, Fisher et al. 2014). One of the challenges is to quantify the responses of CO2 and CH4 dynamics in highly heterogeneous landscapes to changes in soil thermal and hydrologic regimes caused by changes of climate and land cover in the region. Simultaneous quantification of fluxes of these gases in wetland ecosystems generally has been slow to be incorporated into biogeochemical modeling efforts (Yu 2006). Studies of regional carbon dynamics have primarily focused on quantifying either CO2 exchanges in uplands (e.g., Clein et al. 2000, 2002, Lafleur et al. 2001, Zhuang et al. 2003, Carrasco et al. 2006, Balshi et al. 2007) or CH4 emissions from wetlands (e.g., Segers and Laffelaar 2001, Walter et al. 2001, Grant et al. 2002, Zhuang et al. 2004, Petrescu et al. 2010, Melton et al. 2012). Only a few process-based models have been developed to simulate both CO2 and CH4 exchanges, but most of those models have only been applied to a limited number of peatland sites (e.g., Potter et al. 2001, Zhang et al. 2002, Fan et al. 2012).

Although a few studies have focused on quantifying the radiative forcing of both CO2 and CH4 exchanges in northern ecosystems (e.g., Frolking et al. 2006, Zhuang et al. 2006, 2007, Frolking and Roulet 2007), they have not considered how changes in wetland inundation extent affect the simultaneous exchange of CO2 and CH4 between land and the atmosphere. With the emerging data on seasonal and inter-annual variation in wetland inundation extent (Prigent et al. 2001, 2007, Papa et al. 2010), it is now feasible to evaluate how this variation influences greenhouse gas exchanges in the region.

Here, we conduct such a study with a process-based biogeochemistry model, the Terrestrial Ecosystem Model (TEM, Zhuang et al. 2004, 2006). Our study focuses on analyzing how inter-annual variations in wetland inundation extent from 1993 to 2004 influence net land fluxes of CO2 and CH4 to the atmosphere. Specifically, we compare model simulations driven with three wetland distribution datasets including two synthetic, static wetland distribution products that were developed using various approaches including ground survey and satellite information (Matthews and Fung 1987, Lehner and Doll 2004) and a satellite-based dynamic inundation product with a monthly time step (Prigent et al. 2007). The comparisons evaluate the impacts of wetland and upland area changes on the net ecosystem carbon exchange, net methane emissions, and their global warming potentials (GWPs) in northern high latitudes.

2. Method

2.1. Overview

Below we briefly describe our methods consisting of: (1) a description of TEM and its modifications to better represent carbon dynamics in wetland ecosystems; (2) our representation of the variations in wetland extent in this study and how it differs from earlier efforts; (3) our representation of the spatial and temporal variation of other environmental factors that influence carbon dynamics in the northern high latitudes; (4) our calculations of regional CO2 and CH4 fluxes from the region; and (5) our evaluation of the importance of considering changes in wetland extent on these fluxes. More detailed descriptions of the methods can be found in the supplementary material.

2.2. Model description

The TEM uses spatially-referenced information on climate, elevation, soils, and vegetation to make monthly estimates of vegetation and soil C and nitrogen (N) fluxes and pool sizes. The model is well documented and has been used to examine high latitude terrestrial CO2 and CH4 dynamics (e.g., Zhuang et al. 2003, 2004, 2006, 2007, Euskirchen et al. 2006, Balshi et al. 2007, Sitch et al. 2007, McGuire et al. 2010). The model explicitly couples biogeochemical processes with soil thermal dynamics of permafrost and non-permafrost soils (figure S1(a)), and is able to simulate the soil temperature profile and the seasonal freeze-thaw depth to define the active layer (Zhuang et al. 2001, 2002, 2003). The freeze-thaw depth determines the lower boundary of microbial activity in the soil. The density of soil carbon decays exponentially through the soil profile. The biogeochemistry has also been coupled with a sophisticated Hydrological Module (HM, figure S1(a)), which is able to simulate the soil moisture profile and water table depth for both upland and wetland ecosystems. TEM also couples carbon/nitrogen dynamics to the production of methane (figure S1(a)). The Methane Dynamics Module explicitly simulates the processes of CH4 production (methanogenesis) and CH4 oxidation (methanotrophy), as well as the transport of the gas between the soil and the atmosphere (figure S1(b), Zhuang et al. 2004). Various versions of TEM have been applied for quantifying carbon dynamics in boreal regions (e.g., He et al. 2014, Zhu et al. 2014). However, these previous model simulations have not explicitly treated the carbon stoichiometry associated with both aerobic and anaerobic decomposition occurring in dynamically changing extent of upland and wetland areas of boreal ecosystems.

In this study, we define net ecosystem exchange (NEE) as the net exchange of CO2 with the

(Moore et al. 1998).
atmosphere, which is consistent with the definition of NEE by Chapin et al. (2006). For upland ecosystems, NEE is calculated as the difference between heterotrophic respiration ($R_H$) and net primary production (NPP). For wetland ecosystems, we extend this definition of NEE to also consider CO$_2$ emissions due to wetland methane oxidation ($R_{MW}$) and CO$_2$ release accompanied with the production of CH$_4$ under anaerobic condition ($R_{CM}$):

$$\text{NEE} = R_H + R_{MW} + R_{CM} - \text{NPP}. \quad (1)$$

A negative NEE represents a land sink of atmospheric CO$_2$ whereas a positive value represents a land source.

2.3. Representation of Wetland inundation extent

To make spatially and temporally explicit estimates of net CO$_2$ and CH$_4$ exchanges between the land surface and the atmosphere due to changes in wetland inundation extent in northern high latitudes (north of 45°N), we apply TEM to two datasets of static wetland inundation extent and one time-series dataset where the maximum wetland inundation extent changes annually from 1993 to 2004. The first static wetland inundation extent dataset is extracted from the NASA/GLASS global natural wetland dataset at a spatial resolution of 1° × 1° (Matthews and Fung 1987). This dataset is resampled to a spatial resolution of 0.5° × 0.5° (referred to as Wet1). The second static wetland inundation extent dataset is from the Global Lakes and Wetlands Database (GLWD, Lehner and Döll 2004) where we resample a 30 s raster wetland distribution map to a spatial resolution of 0.5° × 0.5° (referred to as Wet2). The time-series dataset of dynamic inundation extent (Papa et al. 2010) contains the monthly distribution of surface water extent at a ∼25 km sampling resolution and we resampled to 0.5° × 0.5° raster maps, which are geographically consistent with Wet1 and Wet2. To associate the inundation data with our model parameterizations for wetland ecosystems, we overlay the monthly changes of inundation extent from 1993 to 2004 to the Wet1 dataset to create 144 monthly maps. The new wetland inundation extent data set (hereafter referred to as Wet3) contains the wetland types defined in Matthews and Fung (1987), but with annual maximum inundation extents (figure S2). Permanent inland water bodies are excluded in the original satellite data (Prigent et al. 2007). Specifically, for any particular year within the period 1993–2004, an annual map of maximum inundation extent is developed. The annual map consists of the maximum inundation extent for every pixel, which is determined based on its monthly inundation data. These annual maximum inundation extent maps with a mean annual inundation area of 3.15 Mkm$^2$ are used in Wet3 simulations (figure 1(b)). Note that inundation area for some months could be larger than the static wetland area in Wet1 for some pixels. The extra inundated-area for a particular pixel in the Wet3 data is assumed to be covered with the same wetland types as in the Wet1 data for that pixel.

2.4. Other input datasets

To drive TEM, we also use spatially-explicit data of monthly climate, land cover, soil texture, soil-water pH, elevation, and leaf area index (LAI). The static data sets include potential natural vegetation (Melillo et al. 1993), soil texture (Zhuang et al. 2003), and soil-water pH (Carter and Scholes 2000). The historical monthly air temperature, precipitation, vapor pressure, and cloudiness data sets are from the National Centers for Environmental Prediction (http://www.ncep.noaa.gov). LAI is internally estimated as a function of vegetation carbon within TEM for each 0.5° latitude × 0.5° longitude grid cell. More details about the input data can be found in supplementary material.

2.5. Model parameterization and regional simulations

To conduct the study for the region, which is spatially heterogeneous with respect to land ecosystem types, soils, and climate, we apply the parameterizations for both tundra and boreal forest ecosystems described in previous studies (Zhuang et al. 2003, 2004) to simulate CH$_4$ consumption as well as net CO$_2$ exchanges in upland ecosystems for the corresponding classes in each wetland map. To simulate methane emissions from wetland ecosystems, we use the parameterization of methane dynamics from Zhuang et al. (2004), in which the simulation of CH$_4$ emissions was optimized to field measurements at several sites (table S1). To simulate net CO$_2$ exchanges in wetland ecosystems, we calibrated the revised TEM for three wetland ecosystem types (table S1) including wet tundra wetlands, alpine tundra wetlands, and forested wetlands using a Bayesian inference technique (Tang and Zhuang 2009). Field-based estimates of NEE (table S1) are used to compare with model simulations to optimize TEM parameters.

To examine the effect of inter-annual changes in wetland inundation extent on carbon fluxes, we conduct a ‘core’ regional simulation with the organized wetland (Wet3) and upland data for the period of 1993–2004. In this simulation, the annual maximum inundation area detected with satellite is treated as wetlands, i.e., the wetland distribution and area change from year to year. To illustrate the effect of the interannual changes of wetland inundation extent, we conduct two other simulations with the ‘static’ inundation extent datasets Wet1 and Wet2. Each simulation was spun-up for 100 years. For each simulation, the model is run twice for each pixel, once for the upland parameterization and once for the wetland parameterization. In the cases where a grid cell goes
from wetland to upland or from upland to wetland, we multiply the fluxes for each land cover type by the new fraction of wetland and upland.

With the ‘core’ simulation, we first examine the carbon balance in the region with an explicit consideration of both wetland and upland ecosystems. We then analyze how CO₂ and CH₄ fluxes are related to changes of climate and wetland area extent at an annual time step. In addition, we examine the effects of soil moisture, soil temperature, water table depth, and active layer depth on CO₂ and CH₄ dynamics in the region.

To quantify the sensitivity of both CO₂ and CH₄ fluxes to the uncertain wetland inundation extent in the region, we conduct two additional simulations with slight modifications of the Wet3 dataset. One simulation assumes a 10% increase of the wetland inundation extent for those pixels having wetland distribution in Wet3 whereas the other assumes a 10% decrease in wetland inundation extent. We chose 10% because this value was the approximate percentage change of inundation area between 1993 and 2004.

3. Results

3.1. Inter-annual variation of regional CO₂ and CH₄ dynamics

Driven with the dynamic wetland inundation data, our simulation indicates that inter-annual variations of CH₄ emissions from the land ecosystems in the region range from 56.9 Tg CH₄ yr⁻¹ in 2004 to 81.3 Tg CH₄ yr⁻¹ in 1994 (table 1). The region acts as a sink of $-1.28 \pm 0.03$ Pg C yr⁻¹ for the period of 1993–2004. Wetland ecosystems are persistently a net sink for CO₂ that ranges from $-0.38$ to $-0.41$ Pg C yr⁻¹ during the period of 1993–2004 for the total area ranging from 2.93 to 3.46 million km². The upland ecosystems are also a sink from $-0.6$ to $-1.1$ Pg C yr⁻¹ for the total area ranging from 37.18 to 37.71 million km² over the region (figure 2).

---

**Figure 1.** Dynamics of monthly and annual net CH₄ emissions (a), annual maximum wetland inundation areas (b), air temperature (c), and precipitation (d) in the region from 1993 to 2004. Wet1 and Wet2 represent the monthly CH₄ emissions and constant wetland areas for two static wetland datasets. Wet3 represents the monthly CH₄ emissions or maximum dynamic inundation area.

Note: Global warming potential (GWP, Pg CO\textsubscript{2} equivalents year\textsuperscript{−1}) is calculated on a 100-year time horizon, i.e., 1 g of CH\textsubscript{4} is equivalent to 25 g of CO\textsubscript{2} (IPCC 2007). Negative NEE/GWP indicates a sink of greenhouse gases from the atmosphere and positive NEE/GWP indicates a source of greenhouse gases to the atmosphere.
inter-annual variation in net CH4 emissions of the entire region is significantly correlated with annual maximum wetland inundation extent and inversely correlated with annual precipitation, but there is no significant correlation with the annual air temperature (table 2). It is not clear why annual precipitation and annual inundation extent are not correlated. It is possible that the variability in annual inundation extent is determined by seasonal patterns in precipitation (e.g., rain in late summer or high snow pack in winter), which may not necessarily correlate with annual precipitation. There are also no significant correlations of annual CH4 emissions with the mean annual soil temperature at depth 20 cm, active layer depth, and water table depth. Inter-annual variation in NEE is not significantly correlated with these environmental variables except wetlands area at the annual temporal resolution.

The spatial patterns of exchanges of CO2 and CH4 (figure S3) vary depending on the wetland inundation extent, which fluctuates in the region (figure S2). Both CO2 and net CH4 emissions exhibit a significant spatial variability as demonstrated with two inundation extent extreme years 1994 (the highest) and 2004 (the lowest). During 1994, a larger wetland inundation area estimates a higher methane production and emissions (81.3 Tg CH4 yr⁻¹). For CO2 dynamics, the region acts as a carbon sink of −1.26 Tg C yr⁻¹ as a balance of a wetland sink of −0.41 Pg C yr⁻¹ and an upland sink of −0.85 Pg C yr⁻¹ (figure 2). In contrast, the smallest wetland inundation extent in 2004 estimates the regional net methane emissions as small as 56.9 Tg CH4 yr⁻¹ (figure 1, table 1). The NEE is a sink of −1.29 Pg C yr⁻¹ as a result of both uplands and wetlands sinks (figure 2).

There are large differences in net methane emissions and net carbon exchanges under static and dynamical wetland inundation conditions (table 1). Under the ‘static’ wetland inundation extent conditions Wet1 and Wet2, the regional methane emissions range from 51.3 ± 2.6 to 73.0 ± 3.6 Tg CH4 yr⁻¹ during the period of 1993–2004 (figure S4(a)). For NEE, the region acts as a persistent sink ranging from −1.29 ± 0.04 to −1.40 ± 0.05 Pg C yr⁻¹ under static wetland inundation conditions (table 1).

3.2. Seasonal dynamics of CO2 and CH4 in the region
All three ‘core’ simulations show a similar seasonal CH4 emission pattern, peaking in July (figure S4(b)). In wetland areas, the carbon sink corresponds to the size of wetlands in three simulations in summer months (figure S5(a)). The sink estimates range from
Table 2. Pearson correlations ($R$) of simulated annual ($n = 12$) net methane emissions, NEE, and GWP with environmental variables based on satellite-detected annual maximum inundation extent data for the study region from 1993 to 2004.

Nine inversion studies estimated that net \( \text{CH}_4 \) emissions of boreal region wetlands are \( 34 \pm 13 \) Tg CH\(_4\) yr\(^{-1}\) (Chen and Prinn 2006). Another inversion constrained by atmospheric observations of methane and its \(^{13}\text{C}/^{12}\text{C}\) isotopic ratio data indicates that the boreal region releases 30–64 Tg CH\(_4\) yr\(^{-1}\), presumably mainly from wetlands (Mikaloff Fletcher et al 2004, McGuire et al 2012). A more recent study using satellite data estimated that mean summer emissions are 53 Tg CH\(_4\) yr\(^{-1}\) from boreal-Arctic wetlands (Watts et al 2014). The ‘static’ wetland inundation dataset Wet1 estimates CH\(_4\) emissions that are comparable with the various inversions, while both Wet2 and dynamic wetland inundation extent dataset Wet3 estimates much higher emissions due to the larger wetland or inundated area in the latter two datasets (table 1). Annual emissions correlate well with annual wetland inundation area. In particular, the highest emissions occur in 1994, which is primarily explained by the largest inundation area in the period. Both static and dynamic wetland simulations estimate higher emissions in 1998 than in 1999, which is consistent with the inversion results (e.g., Mikaloff Fletcher et al 2004, Chen and Prinn 2006). While annual maximum wetland inundation area is larger in 1998 than in 1999, so are the annual precipitation and air temperature (figures 1(c) and (d)), suggesting that climatic conditions in 1998 also favor the methane emissions. A number of studies have suggested that the difference in CH\(_4\) emissions between 1998 and 1999 is the responses to temperature changes associated with the warm conditions in 1998 due to the strong El Niño phenomena (e.g., Dlugokencky et al 2001, Cunnold et al 2002). Indeed, 1998 was marked with elevated temperatures in the region from June to August (Bell et al 1999), and its annual temperature was higher than the 12-year average annual temperature over the region and the annual temperature of 1999. In addition, some high northern latitudes regions experienced elevated precipitation from April to September, which might have also led to the elevated wetland emissions for the year 1998 (Curtis et al 2001, Dlugokencky et al 2001). Our analysis indicates that precipitation in 1998 is indeed higher than in year 1999 while air temperature and inundated land area is also above the average of the study period (figure 1(d)). The temperature and wetland inundation responses together dominate the positive anomaly of net methane emissions for the year 1998 in the region.

Our simulations further indicate that the three wetland datasets estimate similar seasonal dynamics of methane emissions with different magnitudes over the region (figure S4(b)). The peak emissions occur in July. These seasonal dynamics are dominated by climatic factors, rather than wetland inundation extent. To consider the seasonal rather than annual wetland inundation extent in a future analysis will improve the estimates of seasonal dynamics. To date, most atmospheric transport chemistry and inversion models have primarily based their analyses on methane fluxes estimated without considering changes of wetland inundation extent (e.g., Houweling et al 1999, Cunnold et al 2002, Dentener et al 2003, Wang et al 2004, Chen and Prinn 2005, 2006). Coupling estimates of methane emissions considering both seasonal and interannual wetland inundation extent dynamics with these atmospheric models should improve modeling atmospheric methane concentrations.

3.3. Sensitivity of net exchanges of \( \text{CO}_2 \) and CH\(_4\)

For a 10% change in annual maximum wetland inundation extent, our simulations indicate that the regional net exchanges of \( \text{CO}_2 \) and CH\(_4\) are affected by subsequent changes of wetland and upland areas (table 1). Net exchanges of CH\(_4\) are more sensitive to wetland inundation extent changes than NEE. Specifically, if wetland inundation extent increases or decreases by 10% in each wetland grid cell, the regional source of methane increases 13% or decreases 12%, respectively. In contrast, the regional NEE responds with only 7–9% changes to the changes in wetland inundation extent (table 1). The response of net CH\(_4\) emissions is mainly due to the stronger effect of the changes in inundated areas on methane production than on methane consumption as methane consumption in uplands is an order of magnitude less than wetland methane production (see figure 3). The response of regional NEE to changes in wetland inundation area is dominated by the response of aerobic decomposition to changing wetland area. Upland area changes due to changing inundation area are relatively small given that the upland area is much larger than wetland area, the upland NEE thus does not change significantly.

4. Discussion and summary

4.1. Regional wetland emissions and atmospheric concentrations of CH\(_4\)

Nine inversion studies estimated that net CH\(_4\) emissions of boreal region wetlands are 34 ± 13 Tg CH\(_4\) yr\(^{-1}\) (Chen and Prinn 2006). Another inversion constrained by atmospheric observations of methane and its \(^{13}\text{C}/^{12}\text{C}\) isotopic ratio data indicates that the boreal region releases 30–64 Tg CH\(_4\) yr\(^{-1}\), presumably mainly from wetlands (Mikaloff Fletcher et al 2004, McGuire et al 2012). A more recent study using satellite data estimated that mean summer emissions are 53 Tg CH\(_4\) yr\(^{-1}\) from boreal-Arctic wetlands (Watts et al 2014). The ‘static’ wetland inundation dataset Wet1 estimates CH\(_4\) emissions that are comparable with the various inversions, while both Wet2 and dynamic wetland inundation extent dataset Wet3
decomposition of the soils (see equation (1)). Based on the static wetland inundation extent of the Wet1 and Wet2 datasets, the region is estimated to be a consistent sink (table 1). The annual NEE ranges from $-1.23$ to $-1.50$ Pg C yr$^{-1}$ for the period 1993–2004. The dynamic wetland inundation extent estimates the region to be a similar sink at $-1.28 \pm 0.03$ Pg C yr$^{-1}$. The larger regional sink under static wetland inundation conditions is due to the larger wetland area prescribed by the Wet2 dataset that enhances the carbon sink. The smaller regional sink is mainly due to the decrease of the regional wetland carbon sink as wetlands area decreases under the dynamic wetland inundation condition. Although the wetland area is much smaller than the upland area in this region and both NPP and $R_{H}$ of upland are much higher than that of wetlands, the strength of the carbon sink of the wetlands account for about one-third of the total regional sink. For instance, the sink of wetlands ($-0.42$ Pg C yr$^{-1}$ or 126.4 g C m$^{-2}$ yr$^{-1}$) of 2002 is about half of the upland sink (figure 2(c)). This suggests that the wetland ecosystems play a disproportional role in affecting regional NEEs. Breakdown of the wetland emissions of CO$_2$ shows that the majority of emissions are from the unsaturated zone of the wetland soils, which is created with the fluctuation of water table depth (figure 3). This aerobic decomposition accounts for 80% of the total wetland CO$_2$ emissions while the release of carbon associated with the methane oxidation and production varies between 40 and 60 Tg C yr$^{-1}$ with wetland inundation extents.

In comparison with an earlier estimate of a sink of 51.1 Tg C yr$^{-1}$ over the 1997–2006 time period (McGuire et al 2010), our estimated regional NEE magnitudes based on the satellite-detected dynamic wetland extent dataset are much larger. If we account for fire emissions (246.5 Tg C yr$^{-1}$) and the decomposition of agricultural and forestry products (13.5 Tg C yr$^{-1}$) estimated by McGuire et al (2010) for the same region in our analysis, our estimates of NEE will be a large sink of $-1.0$ Pg C yr$^{-1}$ under the dynamic wetland conditions. A recent inter-model comparison shows that the multi-model mean annual NEE for Alaska is largely carbon neutral (Fisher et al 2014) while some observations suggest that portions of the region have been a source of CO$_2$ to the atmosphere (Oechel et al 2000, 2014). The differences of carbon budget estimates between various models and our estimates are at least due to: (1) different processes being considered by the models; (2) different models parameterizations; (3) different sensitivity of the models to the same forcing data; and (4) different

![Figure 3. Inter-annual variations of wetland emissions of carbon dioxide ($R_{EMIT}$) partitioned to aerobic emissions ($R_{A}$) from the unsaturated zone of the wetland soil profile due to fluctuations of water table depth, the emissions accompanied with methane oxidation ($R_{CWM}$), and the emissions accompanied with the methane production ($R_{CM}$) from 1993 to 2004 for (a) Wet1, (b) Wet2, and (c) Wet3.](image-url)
treatment of land ecosystems (e.g., the inundated area changing) among the models (Melton et al 2012, Bohn et al 2015). The TransCom model means for the period of 1995–2006 for the region range from a source of $0.03 \text{ Pg C yr}^{-1}$ to a sink of $-0.89 \text{ Pg C yr}^{-1}$ with a large uncertainty (Gurney et al 2004, 2008). Using the estimates of NEE that consider the effects of wetland inundation extent changes and both aerobic and anaerobic decomposition as priors for atmospheric inversion modeling may reduce the current discrepancy between process-based biogeochemical modeling and inversion estimates.

4.3. Regional GWPs of CO$_2$ and CH$_4$

Previous evaluation of regional radiative forcing estimated as GWPs was based on regional methane emissions and NEEs that have not considered changes in wetland inundation extent (e.g., Zhuang et al 2007). Consideration of wetland inundation dynamics reduced the estimated regional negative climate forcing (figure 4, table 1). Overall, the estimated regional GWP sink using either static or dynamic inundated area data increases during the study period (figure 4). The increase estimated using dynamic inundation data is mainly due to the decrease of CH$_4$ emissions resulting from the declining inundated area (figure 1). The slight increase estimated using two static wetland datasets is due to the slight increase of the carbon sink (table 1). Our sensitivity analysis indicates that the regional GWP under the conditions of either a 10% increase or a 10% decrease in inundation area of the Wet3 dataset differs little (less than 6%) from the estimates with Wet3 (table 1). Thus, changes in CH$_4$ fluxes associated with a 10% change in wetland inundation extent appear to compensate for changes in CO$_2$ fluxes. This suggests that rather large changes in wetland inundation extent would be required to significantly alter the balance of NEE and methane emissions and to influence the GWP in the region. The heterogeneity of NEE and methane emissions as wetland and upland fractions change inter-annually across the landscape as well as climatic changes results in a large spatial variability in GWP across the pan-Arctic (figure S3).

The regional annual GWP is significantly correlated with interannual wetland inundation extent (table 2). Net methane emissions correlate with wetland inundation extent more significantly than NEE, which suggests that future changes of wetland inundation extent will greatly affect regional net ecosystem carbon and CH$_4$ exchanges at annual scales. If wetland inundation extent increases, there will be more regional CH$_4$ emissions, but less regional CO$_2$ emissions from a relatively smaller upland area and a stronger carbon sink in a relatively larger wetland area. As a result, the regional GWP source will be weaker (figure 4). Future climate predictions with general circulation models therefore should consider the feedback that is induced by these CO$_2$ and CH$_4$ dynamics under changing wetland areas in addition to the physical feedbacks of wetland distribution (e.g., Gutowski et al 2007, Prigent et al 2011).

It is important to note that the greatest limitation of this analysis is the use of relatively coarse resolution (i.e., $0.5^\circ \times 0.5^\circ$) wetland inundation datasets, which do not capture small features within wetlands that create CH$_4$ hotspots. An average wetness across these large pixels is also likely to underestimate actual CH$_4$ fluxes (e.g. Becker et al 2008, Baird et al 2009).
Additional studies are needed to analyze how these small-scale features of wetlands affect our analysis. This study considers the influence of water table depth and the stoichiometry of CO₂ and CH₄ during soil anaerobic and aerobic decomposition processes in developing regional estimates of CO₂ and CH₄ fluxes. The study shows that the use of satellite-detected wetland inundation extent essentially reduces the regional GWP sink estimated using static wetland inundation extent data sets and the regional dynamics of CO₂ and CH₄ respond differently to changes of wetland inundation extent with CH₄ fluxes being more sensitive than CO₂ fluxes. Future studies should thus consider the dynamics of wetland inundation extent in quantifying both net CO₂ and CH₄ fluxes and their feedbacks to the atmospheric climate and chemistry at regional and global scales. Inundation area data developed from satellite sensors such as NASA Soil Moisture Active Passive will be valuable for making additional progress on understanding how inundation area influences greenhouse gas exchange in the study region.
