ABSTRACT

A \textit{data-graph computation} — popularized by such programming systems as Galois, Pregel, GraphLab, PowerGraph, and GraphChi — is an algorithm that performs local updates on the vertices of a graph. During each round of a data-graph computation, an \textit{update function} atomically modifies the data associated with a vertex as a function of the vertex’s prior data and that of adjacent vertices. A \textit{dynamic} data-graph computation updates only an active subset of the vertices during a round, and these updates determine the set of active vertices for the next round.

This paper introduces \textit{PRISM}, a chromatic-scheduling algorithm for executing dynamic data-graph computations. \textit{PRISM} uses a vertex-coloring of the graph to coordinate updates performed in a round, precluding the need for mutual-exclusion locks or other nondeterministic data synchronization. A \textit{multibag} data structure is used by \textit{PRISM} to maintain a dynamic set of active vertices as an unordered set partitioned by color. We analyze \textit{PRISM} using work-span analysis. Let \( G = (V, E) \) be a degree-\( \Delta \) graph colored with \( \chi \) colors, and suppose that \( Q \subseteq V \) is the set of active vertices in a round. Define \( \text{size}(Q) = |Q| + \sum_{v \in Q} \deg(v) \), which is proportional to the space required to store the vertices of \( Q \) using a sparse-graph layout. We show that a \( P \)-processor execution of \textit{PRISM} performs updates in \( Q \) using \( O(\chi (\log(Q/\chi) + \log \Delta) + \log P) \) span and \( \Theta(\text{size}(Q) + \chi + P) \) work. These theoretical guarantees are matched by good empirical performance. We modified GraphLab to incorporate \textit{PRISM} and studied seven application benchmarks on a 12-core multicore machine. \textit{PRISM} executes the benchmarks 1.2–2.1 times faster than GraphLab’s nondeterministic lock-based scheduler while providing deterministic behavior.

This paper also presents \textit{PRISM-R}, a variation of \textit{PRISM} that executes dynamic data-graph computations deterministically even when updates modify global variables with associative operations. \textit{PRISM-R} satisfies the same theoretical bounds as \textit{PRISM}, but its implementation is more involved, incorporating a \textit{multivector} data structure to maintain an ordered set of vertices partitioned by color.

1. INTRODUCTION

Many systems from physics, artificial intelligence, and scientific computing can be represented naturally as a \textit{data graph} — a graph with data associated with its vertices and edges. For example, some physical systems can be decomposed into a finite number of elements whose interactions induce a graph. Probabilistic graphical models in artificial intelligence can be used to represent the dependency structure of a set of random variables. Sparse matrices can be interpreted as graphs for scientific computing.

Intuitively, a data-graph computation is an algorithm that performs local updates on the vertices of a data graph. Several software systems have been implemented to support parallel data-graph computations, including Galois [63], Pregel [78], GraphLab [75, 76], PowerGraph [48], and GraphChi [64]. These systems often support “complex” data-graph computations, in which data can be associated with edges as well as vertices and updating a vertex \( v \) can modify any data associated with \( v \), \( v \)’s incident edges, and the vertices adjacent to \( v \). For ease in discussing chromatic scheduling, however, we shall principally restrict ourselves to “simple” data-graph computations (which correspond to “edge-consistent” computations in GraphLab), although most of our results straightforwardly extend to more complex models. Indeed, six out of the seven GraphLab applications described in [74, 75] are simple data-graph computations.

Updates to vertices proceed in \textit{rounds}, where each vertex can be updated at most once per round. In a \textit{static} data-graph computation, the \textit{activation set} \( Q_r \) of vertices updated in a round \( r \) — the set of \textit{active} vertices — is determined \textit{a priori}. Often, a static data-graph computation updates every vertex in each round. Static data-graph computations include Gibbs sampling [41, 42], iterative graph coloring [30], and \textit{n}-body problems such as the fluidanimate PARSEC benchmark [10].

We shall be interested in \textit{dynamic} data-graph computations, where the activation set changes round by round. Dynamic data-graph computations include the Google PageRank algorithm [21].
loopy belief propagation [82, 87], coordinate descent [32], coEM [84], alternating least-squares [54], singular-value decom-
sition [47], and matrix factorization [95].

We formalize the computational model as follows. Let $G = (V, E)$ be a data graph. Denote the neighbors, or adjacent vertices, of a vertex $v \in V$ by $\text{Adj}[v] = \{ u \in V : (u, v) \in E \}$. The degree of $v$ is thus $\deg(v) = |\text{Adj}[v]|$, and the degree of $G$ is $\deg(G) = \max(\deg(v) : v \in V)$. A (simple) dynamic data-graph computation is a triple $(G, f, Q_0)$, where

- $G = (V, E)$ is a graph with data associated with each vertex $v \in V$;
- $f : V \to 2^{\text{Adj}[v]}$ is an update function; and
- $Q_0 \subseteq V$ is the initial activation set.

The update $S = f(v)$ implicitly computes as a side effect a new value for the data associated with $v$ as a function of the old data associated with $v$ and $v$’s neighbors. The update returns a set $S \subseteq \text{Adj}[v]$ of vertices that must be updated later in the computation. During a round $r$ of the dynamic data-graph computation, each vertex $v \in Q_r$ is updated at most once, that is, $Q_r$ is a set, not a multiset. For example, an update $f(v)$ might activate a neighbor $u$ only if the value of $v$ changes significantly.

The advantage of dynamic over static data-graph computations is that they avoid performing many unnecessary updates. Studies in the literature [75, 76] show that dynamic execution can enhance the practical performance of many applications. We confirmed these findings by implementing static and dynamic versions of several data-graph computations. The results for a PageRank algorithm on a power-law graph of 1 million vertices and 10 million edges were typical. The static computation performed approximately 15 million updates, whereas the dynamic version performed less than half that number of updates.

A serial reference implementation

Before we address the issues involved in scheduling and executing dynamic data-graph computations in parallel, let us first hone our intuition with a serial algorithm for the problem. Figure 1 gives the pseudocode for SERIAL-DDGC. This algorithm schedules the updates of a data-graph computation by maintaining a FIFO queue $Q$ of activated vertices that have yet to be updated. Sentinel values enqueued in $Q$ on lines 4 and 9 demarcate the rounds of the computation such that the set of vertices in $Q$ after the rth sentinel has been enqueued is the activation set $Q_r$ for round $r$.

Given a data-graph $G = (V, E)$, an update function $f$, and an initial activation set $Q_0$, SERIAL-DDGC executes the data-graph computation $(G, f, Q_0)$ as follows. Lines 1–2 initialize $Q$ to contain all vertices in $Q_0$. The while loop on lines 3–14 then repeatedly dequeues the next scheduled vertex $v \in Q$ on line 5 and executes the update $f(v)$ on line 11. Executing $f(v)$ produces a set $S$ of activated vertices, and lines 12–14 check each vertex in $S$ for membership in $Q_r$, enqueuing all vertices in $S$ that are not already in $Q_r$.

We can analyze the time SERIAL-DDGC takes to execute one round $r$ of the data-graph computation $(G, f, Q_0)$. Define the size of an activation set $Q_r$ as

$$\text{size}(Q_r) = |Q_r| + \sum_{v \in Q_r} \deg(v).$$

The size of $Q_r$ is asymptotically the space needed to store all the vertices in $Q_r$, and their incident edges using a standard sparse-graph representation, such as compressed-sparse-rows (CSR) format [93]. For example, if $Q_0 = V$, we have $\text{size}(Q_0) = |V| + 2|E|$ by the handshaking lemma [29, p. 1172–3]. Let us make the reasonable assumption that the time to execute $f(v)$ serially is proportional to $\deg(v)$. If we implement the queue as a dynamic (resiz-

**Figure 1:** Pseudocode for a serial algorithm to execute a data-graph computation $(G, f, Q_0)$. SERIAL-DDGC takes as input a data graph $G$ and an update function $f$. The computation maintains a FIFO queue $Q$ of activated vertices that have yet to be updated and sentinel values NIL, each of which demarcates the end of a round. An update $S = f(v)$ returns the set $S \subseteq \text{Adj}[v]$ of vertices activated by that update. Each vertex $u \in S$ is added to $Q$ if it is not currently scheduled for a future update.

The salient challenge in parallelizing data-graph computations is to deal effectively with races between updates, that is, logically parallel updates that read and write common data. A determinacy race [36] (also called a general race [83]) occurs when two logically parallel instructions access the same memory location and at least one of them writes to that location. Two updates in a data-graph computation conflict if executing them in parallel produces a determinacy race. A parallel scheduler must manage or avoid conflicting updates to execute a data-graph computation correctly and deterministically.

The standard approach to preventing races associates a mutual-exclusion lock with each vertex of the data graph to ensure that an update on a vertex $v$ does not proceed until all locks on $v$ and $v$’s neighbors have been acquired. Although this locking strategy prevents races, it can incur substantial overhead from lock acquisition and contention, hurting application performance, especially when update functions are simple. Moreover, because runtime happen-
stance can determine the order in which two logically parallel updates acquire locks, the data-graph computation can act nondeter-
ministically; different runs on the same inputs can produce different results. Without repeatability, parallel programming is arguably much harder [19, 67]. Nondeterminism confounds debugging.

A known alternative to using locks is chromatic scheduling [1, 9], which schedules a data-graph computation based on a coloring of the data-graph computation’s conflict graph — a graph with an edge between two vertices if updating them in parallel would produce a race. For a simple data-graph computation, the conflict graph is simply the data graph itself. The idea behind chromatic scheduling is fairly simple. Chromatic scheduling begins by computing a (vertex) coloring of the conflict graph — an assignment of colors to the vertices such that no two adjacent vertices share the same color. Since no edge in the conflict graph connects two

-able) table [29, Section 17.4], then line 14 executes in $\Theta(1)$ amortized time. All other operations in the for loop on lines 12–14 take $\Theta(1)$ time, and thus all vertices activated by executing $f(v)$ are examined in $\Theta(\deg(v))$ time. The total time spent updating the vertices in $Q_r$ is therefore $\Theta(Q_r \cdot \sum_{v \in Q_r} \deg(v)) = \Theta(\text{size}(Q_r))$, which is linear time: time proportional to the storage requirements for the vertices in $Q_r$ and their incident edges.
vertices of the same color, updates on all vertices of a given color can execute in parallel without producing races. To execute a round of a data-graph computation, the set of activated vertices \( Q \) is partitioned into \( \chi \) color sets — subsets of \( Q \) containing vertices of a single color. Updates are applied to vertices in \( Q \) by serially stepping through each color set and updating all vertices within a color set in parallel. The result of a data-graph computation executed using chromatic scheduling is equivalent to that of a slightly modified version of SERIAL-DDGC that starts each round (immediately before line 9 of Figure 1) by sorting the vertices within its queue by color.

Chromatic scheduling avoids both of the pitfalls of the locking strategy. First, since only nonadjacent vertices in the conflict graph are updated in parallel, no races can occur, and the necessity for locks and their associated performance overheads are precluded. Second, by establishing a fixed order for processing different colors, any two adjacent vertices are always processed in the same order, and the data-graph computation is executed deterministically. Although chromatic scheduling potentially loses parallelism because colors are processed serially, we shall see that this concern does not appear to be an issue in practice.

To date, chromatic scheduling has been applied to static data-graph computations, but not to dynamic data-graph computations. This paper addresses the question of how to perform chromatic scheduling efficiently when the activation set changes on the fly, necessitating a data structure for maintaining dynamic sets of vertices in parallel.

**Contributions**

This paper introduces PRISM, a chromatic-scheduling algorithm that executes dynamic data-graph computations in parallel efficiently in a deterministic fashion. PRISM employs a “multibag” data structure to manage an activation set as a list of color sets. The multibag achieves efficiency using “worker-local storage,” which is memory locally associated with each “worker” thread executing the computation.

We analyze the performance of PRISM using work-span analysis [29, Ch. 27]. The work of a computation is intuitively the total number of instructions executed, and the span corresponds to the longest path of dependencies in the parallel program. We shall make the reasonable assumption that a single update \( f(v) \) executes in \( \Theta(\deg(v)) \) work and \( \Theta(\lg(\deg(v))) \) span.\(^1\) Under this assumption, on a degree-\( \Delta \) data graph \( G \) colored using \( \chi \) colors, PRISM executes the updates on the vertices in the activation set \( Q_r \) of a round \( r \) on \( P \) processors in \( O(\text{size}(Q_r) + \chi + P) \) work and \( O(\chi(\lg(Q_r/\chi) + \lg \Delta) + \lg P) \) span.

Surprisingly, the “price of determinism” incurred by using chromatic scheduling instead of the more common locking strategy appears to be negative for real-world applications. As Figure 2 indicates, on seven application benchmarks, PRISM executes 1.2–2.1 times faster than GraphLab’s comparable, but nondeterministic, locking strategy. This performance gap is not due solely to superior engineering or load balancing. A similar performance overhead is observed in a comparably engineered lock-based scheduling algorithm, Cilk+Locks. PRISM outperforms Cilk+Locks on all but one benchmark and is on average (geometric mean) 1.18 times faster.

PRISM behaves deterministically as long as every update is pure: it modifies no data except for that associated with its target vertex. This assumption precludes the update function from modifying global variables to aggregate or collect values. To support this common use pattern, we describe an extension to PRISM, called PRISM-R, which executes dynamic data-graph computations deterministically even when updates modify global variables using associative operations. PRISM-R replaces each multibag PRISM uses with a “multivector,” maintaining color sets whose contents are ordered deterministically. PRISM-R executes in the same theoretical bounds as PRISM, but its implementation is more involved.

**Outline**

The remainder of this paper is organized as follows. Section 2 reviews dynamic multitreading, the parallel programming model in which we describe and analyze our algorithms. Section 3 describes PRISM, the chromatic-scheduling algorithm for dynamic data-graph computations. Section 4 describes the multibag data structure PRISM uses to represent its color sets. Section 5 presents our theoretical analysis of PRISM. Section 6 describes a Cilk Plus [56] implementation of PRISM and presents empirical results measuring this implementation’s performance on seven application benchmarks. Section 7 describes PRISM-R and its multivector data structure. Section 8 offers some concluding remarks.

## 2. BACKGROUND

We implemented the PRISM algorithm in Cilk Plus [56], a dynamic multitreading concurrency platform. This section provides background on the dag model of multitreading that embodies this and other similar concurrency platforms, including MIT Cilk [39], Cilk++ [70], Fortress [2], Habenero [6, 24], Hood [18], Java Fork/Join Framework [66], Task Parallel Library (TPL) [69], Threading Building Blocks (TBB) [88], and X10 [26]. We review

Figure 2: Comparison of dynamic data-graph schedulers on seven application benchmarks. All runtimes are in seconds and were calculated by taking the median 12-core execution time of 5 runs on an Intel Xeon X5650 with hyperthreading disabled. The runtime of PRISM includes the time used to color the input graph. PR/G and PR/L run a PageRank algorithm on the web-Google [72] and soc-LiveJournal [4] graphs, respectively. ID/250 and ID/1000 run an image denoise algorithm to remove Gaussian noise from 2D grayscale images of dimension 250 by 250 and 1000 by 1000. FBP/C1 and FBP/C3 perform belief propagation on a factor graph provided by the cora-1 and cora-3 datasets [79, 91]. ALS/N runs an alternating least squares algorithm on the NPIC-500 dataset [81].

---

\(^1\) Other assumptions about the work and span of an update can easily be made at the potential expense of complicating the analysis.
the Cilk model of multithreading, the notions of work and span, and the basic properties of the work-stealing runtime systems underlying these concurrency platforms. We briefly discuss worker-local storage, which PRISM’s multibag data structure uses to achieve efficiency.

### The Cilk model of multithreading

The Cilk model of multithreading [16, 17] is described in tutorial fashion in [29, Ch. 27]. The model views the executed computation resulting from running a parallel program as a computation dag in which each vertex denotes an instruction, and edges denote parallel control dependencies between instructions. To analyze the theoretical performance of a multithreaded program, such as PRISM, we assume that the program executes on an ideal parallel computer, where each instruction executes in unit time, the computer has ample bandwidth to shared memory, and concurrent reads and writes incur no overheads due to contention.

We shall assume that algorithms for the dag model are expressed using the Cilk-like primitives [29, Ch. 27] spawn, sync, and parallel for. The keyword spawn when preceding a function call F allows F to execute in parallel with its continuation — the statement immediately after the spawn of F. The complement of spawn is the keyword sync, which acts as a local barrier and prevents statements after the sync from executing until all earlier spawned functions return. These keywords can be used to implement other convenient parallel control constructs, such as the parallel for loop, which allows all of its iterations to operate logically in parallel. The work of a parallel for loop with n iterations is the total number of instructions in all executed iterations. The span is \( \Theta(n) \) plus the maximum span of any loop iteration. The \( \Theta(n^2) \) term comes from the fact that the runtime system executes the loop iterations using parallel divide-and-conquer, and thus fans out the iterations as a balanced binary tree in the dag.

### Work-span analysis

Given a multithreaded program whose execution is modeled as a dag A, we can bound the P-processor running time of the program using work-span analysis [29, Ch. 27]. Recall that the work \( T_A(A) \) is the number of instructions in A, and the span \( T_s(A) \) is the length of a longest path in A. Greedy schedulers [20, 35, 49] can execute a deterministic program with work \( T_A \) and span \( T_s \) on P processors in time \( T_P \) satisfying

\[
\max\{T_A/P, T_s\} \leq T_P \leq T_A + T_s,
\]

and a similar bound can be achieved by more practical “work-stealing” schedulers [16, 17]. The speedup of an algorithm on P processors is \( T_1/T_P \), which Inequality (1) shows to be at most \( P \) in theory. The parallelism \( T_1/T_s \) is the greatest theoretical speedup possible for any number of processors.

### Work-stealing runtime systems

Runtime systems underlying concurrency platforms that support the dag model of multithreading usually implement a work stealing scheduler [17, 23, 50], which operates as follows. When the runtime system starts up, it allocates as many operating-system threads, called workers, as there are processors. Each worker keeps a ready queue of tasks that can operate in parallel with the task it is currently executing. Whenever the execution of code generates parallel work, the worker puts the excess work into the queue. Whenever it needs work, it fetches work from its queue. When a worker’s ready queue runs out of tasks, however, the worker becomes a thief and “steals” work from another victim worker’s queue. If an application exhibits sufficient parallelism compared to the actual number of workers/processors, one can prove mathematically that the computation executes with linear speedup.

### Worker-local storage

Worker-local storage refers to memory that is private to a particular worker thread in a parallel computation. In this paper, in a P-processor execution of a parallel program, a variable \( x \) implemented using worker-local storage is stored as an array of \( P \) copies of \( x \). A worker accesses its local copy of \( x \) using a runtime-provided worker identifier to index the array of worker-local copies of \( x \). The Cilk Plus runtime system, for example, provides the 

```c
__cilk_get_worker_number()
```

API call, which returns an integer identifying the current worker. PRISM assumes the existence of a runtime-provided GET-WORKER-ID function that executes in \( \Theta(1) \) time and returns an integer from 0 to \( P - 1 \).

### 3. The PRISM Algorithm

This section presents PRISM, a chromatic-scheduling algorithm for executing dynamic data-graph computations deterministically. We describe how PRISM differs from the serial algorithm in Section 1, including how it maintains activation sets that are partitioned by color using a multibag data structure.

Figure 3 shows the pseudocode for PRISM, which differs from the SERIAL-DDGC routine from Figure 1 in two main ways: the use of a multibag data structure to implement \( Q \), and the call to COLOR-GRAPH on line 1 to color the data graph.

A multibag \( Q \) represents a list \( \langle C_0, C_1, \ldots, C_{k-1} \rangle \) of \( \chi \) bags (unordered multisets) and supports two operations:

- \( \text{MB-INSERT}(Q, v, k) \) inserts an element \( v \) into bag \( C_k \) in \( Q \). A multibag supports parallel MB-INSERT operations.
- \( \text{MB-COLLECT}(Q) \) produces a collection \( \mathcal{E} \) that represents a list of the nonempty bags in \( Q \), emptying \( Q \) in the process.

PRISM stores a distinct color set in each bag of a multibag \( Q \). Section 4 describes and analyzes the implementation of the multibag data structure.

PRISM calls COLOR-GRAPH on line 1 to color the given data graph \( G = (V, E) \) and obtain the number \( \chi \) of colors used. Although it is NP-complete to find either an optimal coloring of a graph [40] — a coloring that uses the smallest possible number of colors — or a \( O(\mathcal{V}^\epsilon) \)-approximation of the optimal col-

---

**Figure 3:** Pseudocode for PRISM. The algorithm takes as input a data graph \( G \), an update function \( f \), and an initial activation set \( Q_0 \). COLOR-GRAPH colors a given graph and returns the number of colors it used. The procedures MB-COLLECT and MB-INSERT operate the multibag \( Q \) to maintain activation sets for PRISM. PRISM updates the value of \( r \) after each round of the data-graph computation.
Figure 4: A multibag data structure. (a) A multibag containing 19 elements distributed across 4 distinct bags. The contents of each bag are partitioned across the corresponding subbags in 3 nonempty worker-local SPA's. (b) The output of MB-COLLECT when executed on the multibag in (a). Sets of subbags in collected-subbags are labeled with the bag $C_k$ that their union represents.

4. THE MULTIBAG DATA STRUCTURE

This section presents the multibag data structure employed by PRISM. The multibag uses worker-local sparse accumulators [44] and an efficient parallel collection operation. We describe how the MB-INSERT and MB-COLLECT operations are implemented, and we analyze them using work-span analysis [29, Ch. 27]. When used in a $P$-processor execution of a parallel program, a multibag $Q$ of $\chi$ bags storing $n$ elements supports MB-INSERT in $\Theta(1)$ worst-case time and MB-COLLECT in $O(n + \chi + P)$ work and $O(|\log n + \chi + \log P|)$ span.

A sparse accumulator (SPA) [44] implements an array that supports lazy initialization of its elements. A SPA $T$ contains a sparsely populated array $T.array$ of elements and a log $T.log$, which is a list of indices of initialized elements in $T.array$. To implement multibags, we shall only need the ability to create a SPA, access an arbitrary SPA element, or delete all elements from a SPA. For simplicity, we shall assume that an uninitialized array element in a SPA has a value of NIL. When an array element $T.array[i]$ is modified for the first time, the index $i$ is appended to $T.log$. An appropriately designed SPA $T$ storing $n = |T.log|$ elements admits the following performance properties:

- Creating $T$ takes $\Theta(1)$ work.
- Each element of $T$ can be accessed in $\Theta(1)$ work.
- Reading all initialized elements of $T$ takes $\Theta(n)$ work and $\Theta(|\log n|)$ span.
- Emptying $T$ takes $\Theta(1)$ work.

A multibag $Q$ is an array of $P$ worker-local SPA's, where $P$ is the number of workers executing the program. We shall use $p$ interchangeably to denote either a worker or that worker’s unique identifier. Worker $p$’s local SPA in $Q$ is thus denoted by $Q[p]$. For a multibag $Q$ of $\chi$ bags, each SPA $Q[p]$ contains an array $Q[p].array$ of size $\chi$ and a log $Q[p].log$. Figure 4(a) illustrates a multibag with $\chi = 7$ bags, 4 of which are nonempty. As Figure 4(a) shows, the worker-local SPAs’s in $Q$ partition each bag $C_k \in Q$ into subbags $\{C_{k,0}, C_{k,1}, \ldots, C_{k,p-1}\}$, where $Q[p].array[k]$ stores subbag $C_{k,p}$.

Implementation of MB-INSERT and MB-COLLECT

The worker-local SPAs’s enable a multibag $Q$ to support parallel MB-INSERT operations without creating races. Figure 5 shows
MB-INSERT($Q, v, k$)
1. $p = \text{GET-WORKER-ID}()$
2. if $[p, array[k]] == \text{NIL}$
3. Append($Q[p], log, k$)
4. $Q[p], array[k] = \text{new subbag}$
5. Append($Q[p], array[k], v$)

Figure 5: Pseudocode for the MB-INSERT multibag operation to insert an element $v$ into bag $C_k$ in multibag $Q$.

Figure 6: Pseudocode for the MB-COLLECT multibag operation. Calling MB-COLLECT on a multibag $Q$ produces a pair of arrays $\text{collected-subbags}$, which contains all nonempty subbags in $Q$ sorted by their associated bag’s index, and $\text{bag-offsets}$, which associates sets of subbags in $Q$ with their corresponding bag.

### Analysis of multibags

We now analyze the work and span of the multibag’s MB-INSERT and MB-COLLECT operations, starting with MB-INSERT.

**Lemma 1.** Executing MB-INSERT takes $\Theta(1)$ time in the worst case.

**Proof.** Consider each step of a call to MB-INSERT($Q, v, k$). The GET-WORKER-ID procedure on line 1 obtains the executing worker’s identifier $p$ from the runtime system in $\Theta(1)$ time, and line 2 checks if the entry $Q[p], array[k]$ is empty in $\Theta(1)$ time. Suppose that $Q[p], log$ and each subbag in $Q[p], array$ are implemented as dynamic arrays that use a deamortized table-doubling scheme [22]. Lines 3–5 then take $\Theta(1)$ time each to append $k$ to $Q[p], log$, create a new subbag in $Q[p], array[k]$, and append $v$ to $Q[p], array[k]$. □

The next lemma analyzes the work and span of MB-COLLECT.

**Lemma 2.** In a $P$-processor parallel program execution, a call to MB-COLLECT($Q$) on a multibag $Q$ of $\chi$ bags whose contents are distributed across $m$ distinct subbags executes in $O(m + \chi + P)$ work and $O(\log m + \chi + 1g P)$ span.

**Proof.** We analyze each step of MB-COLLECT in turn. We shall use a helper procedure PREFIX-SUM($A$), which computes the all-prefix sums of an array $A$ of $n$ integers in $\Theta(n)$ work and $\Theta(\log n)$ span. (Blelloch [11] describes an appropriate implementation of PREFIX-SUM.) Step 1 replaces each entry in $Q[p], log$ in each worker-local SPA $Q[p]$ with the appropriate index-subbag pair $(k, C_{k,p})$ in parallel, which requires $\Theta(m + P)$ work and $O(\log m + 1g P)$ span. Step 2 gathers all index-subbag pairs into a single array. Suppose that each worker-local SPA $Q[p]$ is augmented with the size of $Q[p], log$ as Figure 4(a) illustrates. Executing PREFIX-SUM on these sizes and then copying the entries of $Q[p], log$ into $\text{collected-subbags}$ in parallel therefore completes Step 2 in $\Theta(m + P)$ work and $O(\log m + 1g P)$ span. Step 3 can sort the $\text{collected-subbags}$ array in $\Theta(m + \chi)$ work and $O(\log m + \chi)$ span using a variant of a parallel radix sort [15, 27, 98] as follows:

1. Divide $\text{collected-subbags}$ into $m/\chi$ groups of size $\chi$, and create an $m/\chi \times \chi$ matrix $A$, where entry $A_{ij}$ stores the number of subbags with index $j$ in group $i$. Constructing $A$ can be done with $\Theta(m + \chi)$ work and $O(\log m + \chi)$ span by evaluating the groups in parallel and the subbags in each group serially.

2. Evaluate PREFIX-SUM on $A^T$ (or, more precisely, the array formed by concatenating the columns of $A$ in order) to produce a matrix $B$ such that $B_{ij}$ identifies which entries in the sorted version of $\text{collected-subbags}$ will store the subbags with index $j$ in group $i$. This PREFIX-SUM call takes $\Theta(m + \chi)$ work and $O(\log m + 1g \chi)$ span.

3. Create a temporary array $T$ of size $m$, and in parallel over the groups of $\text{collected-subbags}$, serially move each subbag in the group to an appropriate index in $T$, as identified by $B$. Copying these subbags executes in $\Theta(m + \chi)$ work and $\Theta(\log m + \chi)$ span.

4. Rename the temporary array $T$ as $\text{collected-subbags}$ in $\Theta(1)$ work and span.

Finally, Step 4 can scan $\text{collected-subbags}$ for adjacent pairs of entries with different bag indices to compute $\text{bag-offsets}$ in $\Theta(m)$ work and $\Theta(\log m)$ span, and Step 5 can reset every SPA in $Q$ in parallel using $\Theta(P)$ work and $\Theta(1g P)$ span. Totaling the work and span of each step completes the proof. □

Although different executions of a program can store the elements of $Q$ in different numbers $m$ of distinct subbags, notice that $m$ is never more than the total number of elements in $Q$.

### 5. ANALYSIS OF PRISM

This section analyzes the performance of PRISM using work-span analysis [29, Ch. 27]. We derive bounds on the work and span of PRISM for any simple data-graph computation $(G, f, Q_0)$. Recall that we make the reasonable assumptions that a single update $f(v)$
executes in $\Theta(\deg(v))$ work and $\Theta(\log(\deg(v)))$ span, and that the update only activates vertices in $\text{Adj}[v]$.

**Theorem 3.** Suppose that PRISM colors a degree-$\Delta$ data graph $G = (V,E)$ using $\chi$ colors, and then executes the data-graph computation $(G,f,Q_r)$. Then, on $P$ processors, PRISM executes updates on all vertices in the activation set $Q_r$ for a round $r$ using $O(\text{size}(Q_r) + \chi + P)$ work and $O(\chi(\log(Q_r/\chi) + \log \Delta) + \log P)$ span.

**Proof.** Let us first analyze the work and span of one iteration of lines 6–15 in PRISM, which performs the updates on the vertices belonging to one color set $C \subseteq Q_r$. Consider a vertex $v \in C$. Lines 8 and 9 execute in $\Theta(\deg(v))$ work and $\Theta(\log(\deg(v)))$ span. For each vertex $u$ in the set $S$ of vertices activated by the update $f(v)$, Lemma 1 implies that lines 11–15 execute in $\Theta(1)$ total work. The parallel for loop on lines 10–15 therefore executes in $\Theta(S)$ work and $\Theta(\log S)$ span. Because $|S| \leq \deg(v)$, the parallel for loop on lines 7–15 thus executes in $\Theta(\text{size}(C))$ work and $\Theta(\log C + \max_{v \in C} \log(\deg(v))) = O(\log C + \log \Delta)$ span.

By processing each of the $\chi$ color sets belonging to $Q_r$, lines 6–15 therefore execute in $\Theta(\text{size}(Q_r) + \chi)$ work and $O(\chi(\log(Q_r/\chi) + \log \Delta))$ span. Lemma 2 implies that line 5 executes MB-COLLECT in $O(Q_r + \chi + P)$ work and $O(\log Q_r + \chi + \log P)$ span. The theorem follows, because $|Q_r| \leq \text{size}(Q_r)$.

## 6. EMPIRICAL EVALUATION

This section describes our empirical evaluation of PRISM. We implemented PRISM in Cilk Plus [56] and compared its performance to that of three other schedulers for executing data-graph computations. This section presents three studies of PRISM’s performance. The first study, which compared PRISM to a non-deterministic locking strategy, indicates that the overhead of managing multibags is less than the cost of a locking protocol. The second study, which compared PRISM to a chromatic scheduler for static data-graph computations, shows that the overhead of maintaining activation sets dynamically is only about 20% more than using static activation sets. This study suggests that it is worthwhile to use dynamic data-graph computations instead of static ones even if only modest amounts of work can be saved by avoiding unnecessary updates. The third study shows the performance of PRISM is relatively insensitive to the number of colors used to color the data graph, as long as there is sufficient parallelism.

| Graph          | $|V|$       | $|E|$       | $\chi$ | CILK+LOCKS | PRISM | Coloring |
|----------------|------------|------------|--------|------------|-------|----------|

| web-NotreDame  | 325,729    | 1,469,680  | 154    | 1.1        | 0.8   | 12%      |

**Figure 7:** Performance of PRISM versus CILK+LOCKS when executing 10 $|V|$ updates of the PageRank [21] data-graph computation on a suite of six real-world graphs and six synthetic graphs. Column “Graph,” identifies the input graph, and columns $|V|$ and $|E|$ specify the number of vertices and edges in the graph, respectively. Column $\chi$ gives the number of colors PRISM used to color the graph. Columns “CILK+LOCKS” and “PRISM” present 12-core running times in seconds for the respective schedulers. Each running time is the median of 5 runs. Column “Coloring” gives the percentage of PRISM’s running time spent coloring the graph.

**Experimental setup**

We implemented PRISM and the multibag data structure in Cilk Plus [56], compiling with the Intel C++ compiler, version 13.1.1. Our source code and data are available from http://supertech.csail.mit.edu. To implement the GET-COLOR procedure, the PRISM implementation used a deterministic multicore coloring algorithm [52], which was also coded in Cilk Plus. For comparison, we engineered three other schedulers for executing dynamic data-graph computations in parallel:

- **CILK+LOCKS** uses a locking scheme to avoid executing conflicting updates in parallel. The locking scheme associates a shared-exclusive lock with each vertex in the graph. Prior to executing an update $f(v)$, vertex $v$’s lock is acquired exclusively, and a shared lock is acquired for each $u \in \text{Adj}[v]$. A global ordering of locks is used to avoid deadlock.
- **CHROMATIC** treats the dynamic data-graph computation as a static one — it updates every vertex in every round — and it uses chromatic scheduling to avoid executing conflicting updates in parallel.
- **ROUND-ROBIN** treats the dynamic data-graph computation as a static one and uses the locking strategy to coordinate updates that conflict.

These schedulers were implemented within a modified multicore version of GraphLab. Specifically, we modified GraphLab’s engine to replace GraphLab’s explicit management of threads with the Cilk Plus runtime. Using the GraphLab framework, we tested these schedulers on existing GraphLab applications with little to no alteration of the application code. The benchmarks were run on Intel Xeon X5650 machines, each with 12 2.67-GHz processing cores (hyperthreading disabled), 49 GB of DRAM; two 12-MB L3-caches, each shared among 6 cores; and private L2- and L1-caches of sizes 128 KB and 32 KB, respectively.

**Overheads for locking and for chromatic scheduling**

We compared the overheads associated with coordinating conflicting updates of a dynamic data-graph computation using locks versus using chromatic scheduling. We evaluated these overheads by comparing the 12-core execution times for PRISM and CILK+LOCKS to execute the PageRank [21] data-graph computation on a suite of graphs. We used PageRank for this study because of its relatively cheap update function, which updates a vertex $v$ by first scanning $v$’s incoming edges to aggregate the data from among...
The page contains a detailed discussion on the performance of a system named PRISM, focusing on its scalability and efficiency. The text describes how PRISM maintains activation sets using a multibag, which incurs relatively little overhead compared to other methods. It also discusses the parallelism of PRISM, with results from experiments showing that PRISM outperforms other schedulers in most cases.

**Figure 8:** Performance of three schedulers on the seven application benchmarks from Figure 2, modified so that all vertices are activated in every round. Column “# Updates” specifies the number of updates performed in the data-graph computation. Columns “ROUND-ROBIN,” “CHROMATIC,” and “PRISM,” list the 12-core running times in seconds for the respective schedulers to execute each benchmark. Each running time is the median of 5 runs.

**Figure 9:** Scalability of PRISM on the image-denoise application as a function of χ, the number of colors used to color the data graph. The parallelism T1/Tm is plotted together with the actual speedup T1/T12 achieved on a 12-core execution. Parallelism values were measured using the Cilkview scalability analyzer [53], which measures the work and span of a Cilk program by counting instructions. Speedup on 12 cores was computed as the ratio of the 1-core and 12-core running times.

**Dynamic-scheduling overhead**

To investigate the overhead of using multibags to maintain activation sets, we compared the 12-core running times of PRISM, CHROMATIC, and ROUND-ROBIN on the seven benchmark applications from Figure 2. For this study, we modified the benchmarks slightly for each scheduler in order to provide a fair comparison. First, because PRISM typically executes fewer updates than a scheduler for static data-graph computations does, we modified the update functions used in PRISM for each application so that every update on a vertex v always activates all vertices u ∈ Adj[v]. This modification guarantees that PRISM executes the same set of updates each round as ROUND-ROBIN and CHROMATIC. Additionally, we modified the update functions used by ROUND-ROBIN and CHROMATIC to remove any work that would be unnecessary in a statically scheduled computation.

Figure 8 presents the results of these tests, which reveal the overhead PRISM incurs to maintain activation sets using a multibag. As Figure 8 shows, PRISM executed 1.0 to 2.0 times slower than CHROMATIC on the benchmarks with a geometric-mean slowdown of 1.2. PRISM nevertheless outperformed ROUND-ROBIN on all but the ID/250 and ID/1000 benchmarks due to ROUND-ROBIN’s lock overhead. These results indicate that PRISM incurs relatively little overhead to maintain activation sets with multibags.

**Scalability of PRISM**

To study the parallel scalability of PRISM, we measured the parallelism T1/Tm and the 12-core speedup T1/T12 of PRISM executing the image-denoise application as we varied the number of colors used to color the application’s data-graph. The image-denoise application performs belief propagation to remove Gaussian noise added to a gray-scale image. The data graph for the image-denoise application is a 2D grid in which each vertex represents a pixel, and there is an edge between any two adjacent pixels. PRISM typically colors this data-graph with just 4 colors. To perform this study, we artificially increased χ by repeatedly taking a random nonempty subset of the largest set of vertices with the same color and assigning those vertices a new color. Using this technique, we ran the image-denoise application on a 500-by-500 pixel input image for values of χ between 4 and 250,000 — the last data point corresponding to a coloring that assigns all pixels distinct colors.

Figure 9 plots the results of these tests. As Figure 9 shows, although the parallelism of PRISM is inversely proportional to χ, PRISM’s speedup on 12 cores is relatively insensitive to χ as long as the parallelism is greater than 120. This result harmonizes with the rule of thumb that a program with parallelism above 100 times the number of workers ought to achieve near perfect linear speedup [28].

7. **THE PRISM-R ALGORITHM**

This section introduces PRISM-R, a chromatic-scheduling algorithm that executes a dynamic data-graph computation determinis-
tically even when updates modify global variables using associative operations. The multivector data structure, which is a theoretical improvement to the multibag, is used by PRISM-R to maintain activation sets that are partitioned by color and ordered deterministically. We describe an extension of the model of simple data-graph computations that permits an update function to perform associative operations on global variables using a parallel reduction mechanism. In this extended model, PRISM-R executes dynamic data-graph computations deterministically while achieving the same work and span bounds as PRISM.

Data-graph computations that modify global variables

Several frameworks for executing data-graph computations allow updates to modify global variables in limited ways. Pregel aggregators [78], and GraphLab’s sync mechanism [75], for example, both support data-graph computations in which an update can modify a global variable using parallel modifications to a global variable using parallel reductions [12,25,57,58,60,65,80,88], that is, they coordinate these modifications by applying them to local views (copies) of the variable and then reducing (combining) those copies together using a binary reduction operator.

A reducer (hyperobject) [38,68] is a general parallel reduction mechanism provided by Cilk Plus and other dialects of Cilk. A reducer is defined on an arbitrary data type $T$, called a view type, by defining an IDENTITY operator and a binary REDUCE operator for views of type $T$. The IDENTITY operator creates a new view of the reducer. The binary REDUCE operator defines the reducer’s reduction operator. A reducer is a particularly general reduction mechanism because it guarantees that, if its REDUCE operator is associative, then the final result in the global variable is deterministic: every parallel execution of the program produces the same result. Other parallel reduction mechanisms, including Pregel aggregators and GraphLab’s sync mechanism, provide this guarantee only if the reduction operator is also commutative.

Although PRISM is implemented in Cilk Plus, PRISM does not produce a deterministic result if the updates modify global variables using a noncommutative reducer. The reason is that the order in which a multibag stores the vertices of an activation set depends on how the computation is scheduled. As a result, the order in which lines 7–15 of PRISM evaluate the vertices in a color set $C$ can differ depending on scheduling. Therefore, if two updates on vertices in $C$ modify the same reducer, then the relative order of these modifications can differ between runs of PRISM, even if a single worker happens to execute both updates.

PRISM-R extends PRISM to support data-graph computations that use reducers. Before presenting PRISM-R, we first describe the multivector data structure that is used by PRISM-R to maintain deterministically ordered color sets.

```

---

The multivector data structure

A multivector represents a list of $\chi$ vectors (ordered multisets). It supports two operations — MV-INSERT and MV-COLLECT — which are analogous to the multibag operations MB-INSERT and MB-COLLECT, respectively. We now sketch the design of the multivector data structure.

The multivector relies on properties of a work-stealing runtime system. Consider a parallel program modeled by a computation dag $A$ in the Cilk model of multithreading. The serial execution order $R(A)$ of the program lists the vertices of $A$ according to a depth-first traversal of $A$. A work-stealing scheduler partitions $R(A)$ into a sequence $R(A) = \langle t_0, t_1, \ldots, t_{M-1}\rangle$, where each trace $t_i \in R(A)$ is a contiguous subsequence of $R(A)$ executed by exactly one worker. A multivector represents each vector as a sequence of trace-local subvectors — subvectors that are modified within exactly one trace. The ordering properties of traces imply that concatenating a vector’s trace-local subvectors in order produces a vector whose elements appear in the serial execution order. The multivector data structure assumes that a worker can query the runtime system to determine when it starts executing a new trace.

A multivector stores its nonempty trace-local subvectors in a log tree, which represents an ordered multiset of elements and supports $\Theta(1)$-work append operations. A log tree is a binary tree in which each node $L$ stores a dynamic array $L$.sublog. The ordered multiset that a log tree represents corresponds to a concatenation of the tree’s dynamic arrays in a post-order tree traversal. Each log-tree node $L$ is augmented with the size of its subtree $L$.size counting the number of log-tree nodes in the subtree rooted at $L$. Using this augmentation, the operation FLATTEN($L$,$A$,$L$.size − 1) described in Figure 10 flattens a log tree rooted at $L$ of $n$ nodes and height $h$ into a contiguous array $A$ using $\Theta(n)$ work and $\Theta(h)$ span.

To handle parallel MV-INSERT operations, a multivector employs a log-tree reducer, that is, a Cilk Plus reducer whose view type is a log tree. Figure 11 presents the pseudocode for the IDENTITY and REDUCE operations for the log-tree reducer. Notice that the log-tree reducer’s REDUCE operation is logically associative, that is, for any three log-tree reducer views $a$, $b$, and $c$, the views produced by REDUCE(REDUCE($a$, $b$), $c$) and REDUCE($a$, REDUCE($b$, $c$)) represent the same ordered multiset.

To maintain trace-local subvectors, a multivector $Q$ consists of an array of $P$ worker-local SPA’s, where $P$ is the number of processors executing the computation, and a log-tree reducer. The SPA $Q[p]$ for worker $p$ stores the trace-local subvectors that worker $p$ appended since the start of its current trace. The log-tree reducer $Q$-log-reducer stores all nonempty subvectors created.

Figure 12 sketches the MV-INSERT($Q$, $v$, $k$) operation to insert element $v$ into the vector $C_k \in Q$. MV-INSERT differs from MB-INSERT in two ways. First, when a new subvector is created and added to a SPA, lines 6–7 additionally append that subvector to $Q$-log-reducer, thereby maintaining the log-tree reducer. Second, lines 2–3 reset the contents of the SPA $Q[p]$ after worker $p$ begins...
executing a new trace, thereby ensuring that \( Q[p] \) stores only trace-local subvectors.

Figure 13 sketches the MV-COLLECT operation, which returns a pair \((\text{vector-offsets}, \text{collected-subvectors})\) analogous to the return value of MB-COLLECT. MV-COLLECT differs from MB-COLLECT primarily in that Step 1, which replaces Steps 1 and 2 in MB-COLLECT, flattens the log tree underlying \( Q \), \text{log-reducer} to produce the unsorted array \text{collected-subvectors}. MV-COLLECT also requires that \text{collected-subvectors} be sorted using a stable sort on Step 2. The integer sort described in the proof of Lemma 2 for MB-COLLECT is a stable sort suitable for this purpose.

**Analysis of multivector operations**

We now analyze the work and span of the MV-INSERT and MV-COLLECT operations, starting with MV-INSERT.

**Lemma 4.** Executing MV-INSERT takes \( \Theta(1) \) time in the worst case.

**Proof.** Resetting the SPA \( Q[p] \) on line 3 can be done in \( \Theta(1) \) worst-case time with an appropriate SPA implementation, and appending a new subvector to a log tree takes \( \Theta(1) \) time. The theorem thus follows from the analysis of MB-INSERT in Lemma 1.

Lemma 5 bounds the work and span of MV-COLLECT.

**Lemma 5.** Consider a computation \( A \) with span \( T_w(A) \), and suppose that the contents of a multivector \( Q \) of \( \chi \) vectors are distributed across \( m \) subvectors. Then a call to MV-COLLECT\((Q)\) incurs \( \Theta(m + \chi) \) work and \( \Theta(\log m + \chi + T_w(A)) \) span.

**Proof.** Flattening the log-tree reducer in Step 1 is accomplished in two steps. First, the FLATTEN operation writes the nodes of the log-tree to a contiguous array. FLATTEN has span proportional to the depth of the log tree, which is bounded by \( O(T_w(A)) \), since at most \( O(T_w(A)) \) reduction operations can occur along any path in \( A \) and \text{REDUCE} for log trees executes in \( \Theta(1) \) work [38]. Second, using a parallel-prefix sum computation, the log entries associated with each node in the log tree can be packed into a contiguous array, incurring \( \Theta(m) \) work and \( \Theta(\log m) \) span. Step 1 thus incurs \( \Theta(m) \) work and \( \Theta(\log m + T_w(A)) \) span. The remaining steps of MV-COLLECT, which are analogous to those of MB-COLLECT and analyzed in Lemma 2, execute in \( \Theta(\chi + \log m) \) span.

**8. CONCLUSION**

Researchers over multiple decades have advocated that the difficulty of parallel programming can be greatly reduced by using some form of deterministic parallelism [7, 8, 13, 19, 33, 34, 36, 37, 43, 51, 55, 85, 86, 92, 97]. With a deterministic parallel program, the programmer observes no logical concurrency, that is, no nondeterminism in the behavior of the program due to the relative and nondeterministic timing of communicating processes such as occurs when one process arrives at a lock before another. The semantics of a deterministic parallel program are therefore serial, and reasoning about such a program’s correctness, at least in theory, is no harder than reasoning about the correctness of a serial program. Testing, debugging, and formal verification is simplified, because there is no need to consider all possible relative timings (interleavings) of operations on shared mutable state.

The behavior of PRISM corresponds to a variant of SERIAL-DGDC that sorts the activated vertices in its queue by color at the start of each round. Whether PRISM executes a given data
graph on 1 processor or many, it always behaves the same. With PRISM-R, this property holds even when the update function can perform reductions. Lock-based schedulers do not produce such a strong guarantee of deterministicism. Although updates in a round executed by a lock-based scheduler appear to execute according to some linear order, this order is nondeterministic due to races on the acquisition of locks.

Blelloch, Fineman, Gibbons, and Shun [14] argue that deterministic programs can be fast compared with nondeterministic programs, and they document many examples where the overhead for converting a nondeterministic program into a deterministic one is small. They even document a few cases where this “price of deterministicism” is slightly negative. To their list, we add the execution of dynamic data-graph computations as having a price of determinism. They even document a few cases where this “price of determinism” is significantly negative. We conjecture that research will uncover many more parallel applications that admit to efficient deterministic solutions.
