Measurement of the $b$-Quark Production Cross Section in 7 and 13 TeV $pp$ Collisions

R. Aaij et al.*
(LHCb Collaboration)

(Received 15 December 2016; revised manuscript received 9 January 2017; published 3 February 2017)

Measurements of the cross section for producing $b$ quarks in the reaction $pp \to b\bar{b}X$ are reported in 7 and 13 TeV collisions at the LHC as a function of the pseudorapidity $\eta$ in the range $2 < \eta < 5$ covered by the acceptance of the LHCb experiment. The measurements are done using semileptonic decays of $b$-flavored hadrons decaying into a ground-state charmed hadron in association with a muon. The cross sections in the covered $\eta$ range are $72.0 \pm 0.3 \pm 6.8$ and $154.3 \pm 1.5 \pm 14.3 \, \mu$b for 7 and 13 TeV. The ratio is $2.14 \pm 0.02 \pm 0.13$, where the quoted uncertainties are statistical and systematic, respectively. The agreement with theoretical expectation is good at 7 TeV, but differs somewhat at 13 TeV. The measured ratio of cross sections is larger at lower $\eta$ than the model prediction.

DOI: 10.1103/PhysRevLett.118.052002

Production of $b$ quarks in high energy $pp$ collisions at the LHC provides a sensitive test of models based on quantum chromodynamics [1]. Searches for physics beyond the standard model (SM) often rely on the ability to accurately predict the production rates of $b$ quarks that can form backgrounds in combination with other high energy processes [2]. In addition, knowledge of the $b$-quark yield is essential for calculating the sensitivity of experiments testing the SM by measuring $CP$-violating and rare decay processes [3].

We present here measurements of production cross sections for the average of $b$-flavored and $\bar{b}$-flavored hadrons, denoted $pp \to H_bX$, where $X$ indicates additional particles, in $pp$ collisions recorded by LHCb at both 7 and 13 TeV center-of-mass energies, and their ratio. These measurements are made as a function of the $H_b$ pseudorapidity $\eta$ in the interval $2 < \eta < 5$, where $\eta = - \ln \left[ \tan \left( \theta / 2 \right) \right]$, and $\theta$ is the angle of the weakly decaying $b$ or $\bar{b}$ hadron with respect to the proton direction. We report results over the full range of $b$-hadron transverse momentum, $p_T$. The $H_b$ cross section has been previously measured at LHCb in 7 TeV collisions using semileptonic decays to $D^0 \mu^- X$ [4] and $b \to J/\psi X$ decays [5]. Previous determinations were made at the Tevatron collider in $p\bar{p}$ collisions near 2 TeV center-of-mass energy [6]. Other LHC experiments have also measured $b$-quark production characteristics at 7 [7], and 13 TeV [8].

The method presented in this Letter is more accurate because the normalization is based on well-measured semileptonic $D^0$ and $B^-$ branching fractions, and the equality of semileptonic widths for all $b$ hadrons, in contrast to inclusive $J/\psi$ production which relies on the assumption that the $b$-hadron particle species are produced in the same proportions as at LEP [9], or those that just use one specific $b$ hadron, which needs the $b$-hadron fractions to extrapolate to the total.

The production cross section for a hadron $H_b$ that contains either a $b$ or $\bar{b}$ quark, but not both, is given by

$$\sigma(pp \to H_bX) = \frac{1}{2} \left[ \sigma(B^0) + \sigma(B^\pm) \right] + \frac{1}{2} \left[ \sigma(B^0) + \sigma(B^-) \right] + \frac{1}{2} \left[ \sigma(B^0) + \sigma(B^+) \right] + \frac{1}{2} \left[ \sigma(B^0) + \sigma(B^-) \right] + \frac{1}{2} \left[ \sigma(\Lambda_b^0) + \sigma(\bar{\Lambda}_b^0) \right],$$

(1)

where $\delta$ is a correction that accounts for $\Xi_b$ and $\Omega_b^-$ baryons; we ignore $B_c$ mesons since their production level is estimated to be only 0.1% of $b$ hadrons [10].

Our estimate of $\delta$ is based on a paper by Voloshin [11], in which two useful relations are given:

$$\Gamma(\Xi_b^0 \to \Xi^- \mu^+ \nu) = \Gamma(\Lambda_b^0 \to \Lambda \mu^+ \nu),$$

and

$$\frac{\Gamma(\Xi_b^0)}{\Gamma(\Lambda_b^0)} = 0.11 \pm 0.03 \pm 0.03,$$

(2)

where the latter is determined from Tevatron data, and the second uncertainty is assigned from the allowable SU(3) symmetry breaking. The $b$-hadron fractions determined there [9] agree with the ones measured by LHCb for other $b$-flavored hadrons [12]. Since the lifetimes of the $\Lambda_b^0$ and $\Xi_b^0$ are equal within their uncertainties [9], assuming that the two branching fractions are equal gives us an estimate of 0.11 for the $\Xi_b^0/\Lambda_b^0$ semileptonic decay ratio. However, this must be doubled, using isospin invariance, to account for the $\Xi_b^-$. To this we must add the $\Lambda_b^-$ contribution, taken as 15% of the $\Xi_b^0$, thus arriving at an estimate of $\delta$ of $0.25 \pm 0.10$, where the uncertainty is the one in Eq. (2).
added in quadrature to our estimate of the uncertainties from assuming isospin and lifetime equalities.

To measure these cross sections we determine the signal yields of $b$ decays into a charm hadron plus a muon for a given integrated luminosity $L$ and correct for various efficiencies described below. Explicitly,

$$
\sigma(pp \to H_b \nu) = \frac{1}{2L} \left[ \left( \frac{n(D^0 \mu)}{\epsilon_{D^0} \times B_{D^0}} + \frac{n(D^+ \mu)}{\epsilon_{D^+} \times B_{D^+}} \right) \frac{1}{B(B \to DX\mu)} \right. \\
\left. + \left( \frac{n(D^{*+} \mu)}{\epsilon_{D^{*+}} \times B_{D^{*+}}} \right) \frac{1}{B(B \to DX\mu)} \right]_{\epsilon_{X\mu}}
$$

(3)

where $n(X,\mu)$ means the number of detected charm hadron plus muon events and their charge conjugates, with corresponding efficiencies denoted by $\epsilon_{X\mu}$. The charm branching fractions, $B_{X\mu}$, used in this analysis, along with their sources, are listed in the Supplemental Material [13]. The PDG average is used for the $D^0$ and $D^+$ modes [9]. For the $D^+$ mode there is only one measurement by CLEO III, so that is used [14]. For the $\Lambda^+_c$ we average measurements by BES III [15] and Belle [16]. The expression $B(B \to DX\mu)$ denotes the average branching fraction for $B^0$ and $B^-$ semileptonic decays.

The $B^0$ and $B^-$ semileptonic branching fractions are obtained with a somewhat different procedure than that adopted by the PDG, whose actual estimate is difficult to derive from the posted information. We take three measurements that are mostly model independent and average them. The first one was made by CLEO using inclusive leptons at the $\Upsilon(4S)$ resonance without distinguishing whether they are from $\overline{B}^0$ or $B^-$ meson decays [17]. The $\Upsilon(4S)$, however, does not have an equal branching fraction into $\overline{B}^0 B^0$ and $B^- B^+$ mesons. In fact the fraction into neutral $B$ pairs is $\alpha = 0.486 \pm 0.006$ [9], with the remainder going into charged $B$ pairs. Therefore, to compute the $B^0$ and $B^-$ semileptonic branching fractions we need to use the following coupled equations

$$
\alpha B^0_{SL} + (1 - \alpha)B^-_{SL} = (10.91 \pm 0.09 \pm 0.24)\% , \\
B^0_{SL}/B^-_{SL} = \tau^0/\tau^- = 0.927 \pm 0.004 ,
$$

(4)

where $\tau^0$ and $\tau^-$ are the lifetimes [9]. The numbers extracted from the solution are listed in Table I, along with direct measurements from CLEO [17], BABAR [18], and Belle [19]. These latter two analyses measure the semileptonic decays of $\overline{B}^0$ and $B^-$ mesons separately. They do not cover the full momentum range so a correction has to be applied; this was done by the PDG [9]. Since $D^0$ and $D^+$ mesons are produced in both $\overline{B}^0$ and $B^-$ decays, we sum their yields and use the average semileptonic branching fraction for $\overline{B}^0$ and $B^-$ decays, $(\overline{B}^0 + B^-)$.

The semileptonic $B$ branching fractions we use are listed in Table II. Since we are detecting only $b \to c\mu\nu$ modes, we have to correct later for the fact that there is a small $1\%$ $b \to u\mu\nu$ component [9].

The semileptonic widths $\Gamma_{SL}$ are equal for all $H_b$ species used in this analysis except for a small correction for $\Lambda^0_b$ decays ($B_{SL} = \Gamma_{SL}/\Gamma = \Gamma_{SL} \times \tau$). This has proven to be true in the case of charm hadron decays even though the lifetimes of $D^0$ and $D^+$ differ by a factor of 2.5. The decays of the $\Lambda^0_b$ are slightly different due to the absence of the chromomagnetic correction that affects $B$-meson decays but is absent in $b$ baryons [20–22]. Thus $\Gamma_{SL}$, and also $B_{SL}$, are increased for the $\Lambda^0_b$ by $(4.2\%$) [12].

The input for the $\overline{B}^0$ lifetime listed in Table II uses only measurements in the flavor-specific decay $\overline{B}^0 \to D_s^- \pi^-$ from CDF [23] and LHCb [24]. Other measurements can in principle be used, e.g., in $J/\psi \phi$ or $J/\psi f_0(980)$ final states, but they then involve also determining $\Delta \Gamma_b$. Older measurements involving semileptonic decays are

Table I. Measured semileptonic decay branching fractions for $\overline{B}^0$ and $B^-$ mesons. The correlation of the errors in the underlying measurements in the average is taken into account. The CLEO numbers result from solving Eq. (4).

suspected of having larger uncontrolled systematic uncertainties [25]. Finally, the $\Lambda^0_b$ lifetime is taken from the HFAG average [26].

Corrections due to cross feeds among the modes, for example, from $\bar{B} \rightarrow D K \mu^- \pi^+$ events or $\Lambda^0_b \rightarrow D N \mu^- X$ decays are well below our sensitivity, and thus we do not include them.

The data used here correspond to integrated luminosities of $284.10 \pm 4.86 \text{pb}^{-1}$ collected at 7 TeV and $4.60 \pm 0.18 \text{pb}^{-1}$ at 13 TeV [27], where special triggers were implemented to minimize uncertainties. The LHCb detector [28,29] is a single-arm forward spectrometer covering the pseudorapidity range $2 < \eta < 5$. Components include a high-precision tracking system consisting of a silicon-strip vertex detector surrounding the dipole magnet with a bending power of about 4 Tm, and three stations of silicon-strip detectors and straw drift tubes placed downstream of the magnet. Different types of charged hadrons are distinguished using information from two ring-imaging Cherenkov detectors (RICH). Muons are identified by a system composed of alternating layers of iron and multiwire proportional chambers.

Events of potential interest are triggered by the identification of a muon in real time with a minimum $p_T$ of 1.48 GeV in the 7 TeV data [30], and 0.9 GeV in the 13 TeV data (further restricted in the higher level trigger to $p_T > 1.3$ GeV) [31]. In addition, to test for inconsistency with production at the primary vertex (PV), the $\chi^2$ for the muon is computed as the difference between the vertex fit $\chi^2$ of the PV reconstructed with and without the considered track. We require that $\chi^2_{\text{IP}}$ be larger than 200 at 7 TeV (16 at 13 TeV), and in the 7 TeV data only, the impact parameter of the muon must be greater than 0.5 mm. There is a prescale by a factor of 2 for both energies and an additional prescale of a factor of 2 for the $D^0 \mu^-$ channel in the 7 TeV data.

These events are subjected to further requirements in order to select those with a charmed hadron decay which forms a vertex with the identified muon that is detached from the PV. The charmed hadron must not be consistent with originating from the PV. We use the decays $D^0 \rightarrow K^- \pi^+$, $D^+ \rightarrow K^- \pi^+ \pi^0$, $D^+_s \rightarrow K^- K^+ \pi^+$, and $\Lambda^+_c \rightarrow p K^- \pi^+$. (The related branching fractions are given in the Supplemental Material [13].) The RICH system is used to determine a likelihood for each particle hypothesis. We use selections on the differences of log-likelihoods ($L$) to separate protons from kaons and pions, $L(p) - L(K) > 0$ and $L(p) - L(\pi) > 10$, kaons from pions $L(K) - L(\pi) > 4$, and pions from kaons $L(K) - L(\pi) < 3$ for 7 and < 10 for 13 TeV. In addition, in order to suppress background, the average $p_T$ of the charmed hadron daughters must be larger than 700 MeV for three-body and 600 MeV for two-body decays, and the invariant mass of the charmed hadron plus muon must range from approximately 3 to 5 GeV. Furthermore, the charm plus $\mu$ vertex must be within a radius less than 4.8 mm from the beam line to remove contributions of secondary interactions in the detector material due to long-lived particles, and the charm hadron must decay downstream of this vertex.

Since detection efficiencies vary over the available phase space, we divide the data into two-dimensional intervals in $p_T$ of the charm plus $\mu$ system, and $\eta$, where the latter is determined from the relative positions of the charm plus $\mu$ vertex and the PV. We fit the data for each charm plus $\mu$ combination in each interval simultaneously in invariant mass of the charm hadron and $\ln(IP/mm)$ variables, where $IP$ is the measured impact parameter of the charmed hadron with respect to the PV in units of mm.

As an example of the fitting technique consider $D^+_s \mu^-$ candidates integrated over $p_T$ and $\eta$ for the 7 TeV data. Figure 1(a) shows the $K^+ K^- \pi^+$ invariant mass spectrum, while (b) shows the $\ln(IP/mm)$ distribution. The invariant mass signal is fit for the $D^+_s$ yield with a double-Gaussian function where the means of the two Gaussians are constrained to be the same. The common mean and the widths are determined in the fit. (A second double-Gaussian shape is used to fit the higher mass decay of $D^{*-} \rightarrow \pi^+ D^0$, $D^0 \rightarrow K^- K^-$, an additional consideration only in this mode.) The $\ln(IP/mm)$ shape of the signal component, determined by simulation, is a bifurcated Gaussian where the peak position and width parameters are determined by the fit. The combinatorial background is modeled with a linear shape. (The other modes at both energies are shown in the Supplemental Material [13].) The signal yields for charm hadron plus muon candidates integrated over $\eta$ are also given in the Supplemental Material [13].

The major components of the total efficiency are the off-line and trigger efficiencies. The latter is measured with respect to the off-line, which has several components from tracking, particle identification, event selection, and overall event size cuts. These have been evaluated in a data-driven manner whenever possible. Only the event selection efficiencies have been simulated. Samples of simulated events, produced with the software described in Refs. [32–34], are used to characterize signal and background contributions. The particle identification efficiencies are determined from calibration samples of $D^{*-} \rightarrow \pi^+ D^0$, $D^0 \rightarrow K^- \pi^+$ decays for kaons and pions, and $\Lambda \rightarrow p \pi^- \pi^-$ for protons. The trigger efficiencies including the muon identification efficiency are determined using samples of $b \rightarrow J/\psi X$, $J/\psi \rightarrow \mu^+ \mu^-$ decays, where one muon is identified and the other used to measure the efficiencies. For the overall sample they are typically 20% for the 7 TeV data and 70% for the 13 TeV data, only weakly dependent on $\eta$. The difference is caused primarily by the impact parameter cut on the muon of 0.5 mm in the 7 TeV data. The efficiency for the overall event size requirement is determined using $B^- \rightarrow J/\psi K^-$ decays where much looser criteria were applied. These efficiencies are all above 95% and are determined with
negligible uncertainties. The total efficiencies given as a function of $\eta$ and $p_T$ for both energies are shown in the Supplemental Material [13].

There is dwindling efficiency toward small $p_T$ values of the charmed hadron plus muon. Data in the regions with negligible efficiency are excluded, and a correction is made using simulation to calculate the fraction of events that fall within inefficient regions. These numbers are calculated for each bin of $\eta$ within inefficient regions. These numbers are calculated for each bin of $\eta$ within inefficient regions, and the overall fits as solid lines (blue). The dot-dashed (green) curve shows the $D_s^+$ signal from $b$ decay, while the dashed (purple) curve $D_s^+$ from prompt production. The dotted curve (orange) shows the $D^{*+}$ component. The dashed line (red) shows the combinatorial background. The same fits using a logarithmic scale are shown in (c) and (d).

The inclusive $b$-hadron cross sections as functions of $\eta$ are given in Fig. 2, along with a theoretical prediction called FONLL [35]. These results are consistent with and supersede our previous results at 7 TeV [4]. The ratio of cross sections is predicted with less uncertainty, and indeed most of the experimental uncertainties (discussed below) also cancel, with the largest exception being the luminosity error. In Fig. 2(c), we compare the $\eta$-dependent cross-section ratio for 13 TeV divided by 7 TeV with the FONLL prediction. We see higher ratios at lower values of $\eta$ than given by the prediction, which indicates that the cross section at $\eta$ values near 2 is growing faster than at larger values.

The results as a function of $\eta$ are listed in Table III. The total cross sections at 7 and 13 TeV integrated over $2 < \eta < 5$ are $72.0 \pm 0.3 \pm 6.8$ and $154.3 \pm 1.5 \pm 14.3 \mu b$ for 7 and 13 TeV. The ratio is $2.14 \pm 0.02 \pm 0.13$. This agrees with the theoretical prediction at 7 TeV of $62^{+28}_{-22} \mu b$, and is a bit larger than the 13 TeV prediction of $111^{+51}_{-44} \mu b$. While the measured ratio is consistent with the prediction of $1.79^{+0.21}_{-0.15}$, it disagrees with the combination of shape and normalization.

Systematic uncertainties are considerably larger than the statistical errors. The ones that are independent of $\eta$ are listed in Table IV. The luminosity and muon trigger efficiency uncertainties in the ratio are each obtained by assuming a $-50\%$ correlated error [36]. The uncertainty in the tracking efficiency is given by taking 0.5% per muon track and 1.5% per hadron track [37]. The various final states used to simulate the efficiencies can contribute to an overall efficiency change. This is estimated by taking the
When added in quadrature with the uncertainties on the measured branching fractions. These are then added in quadrature and taking into account the uncertainties on the measured branching fractions. These are then added in quadrature and referred to as the $b$ decay cocktail in Table IV.

The fraction of higher mass $b$-baryon states with respect to the $\Lambda_b^0$ is given by $\delta = 0.25 \pm 0.10$, which represents a 40% relative uncertainty that affects only the baryon contribution to Eq. (3).

There are also $\eta$-dependent systematic uncertainties in the cross section that arise from the trigger efficiency, the event selection, the hadron identification, and the corrections for the low $p_T$ region with low efficiencies. When added in quadrature with the $\eta$-independent uncertainties, the total errors range from (8.5–11.0)% at 7 TeV to (8.7–9.7)% at 13 TeV. There is some cancellation in the ratio giving a range of (5.6–7.3)%.

In conclusion, new results for the $b\overline{b}$ production cross section at 7 TeV are in good agreement with the original $\eta$-dependent cross-section measurement previously reported [4], and are in agreement with the theoretical prediction (FONLL) [35]. The 13 TeV results are somewhat higher in magnitude than the theory, and generally agree with the shape and magnitude measured using inclusive $b \to J/\psi X$ decays [36]. The cross-section ratio of 13 to 7 TeV as a function of $\eta$ differs from the FONLL model by 5 standard deviations, including the systematic uncertainties. This discrepancy is mainly the difference in the low $\eta$ bins.

To get an idea of the cross section in the full $\eta$ range we use

**TABLE IV.** Systematic uncertainties independent of $\eta$ on the $pp \to H_bX$ cross sections at 7 and 13 TeV and their ratio.

[13] See Supplemental Material at http://link.aps.org/supplemental/10.1103/PhysRevLett.118.052002 for the decay modes and charm hadronic branching fractions used in this analysis; The signal yields in the different $b$ decay modes, fitted to the different invariant mass spectra and $ln(\Gamma_p/\Gamma_m)$ distributions for charm hadron plus muon events, and efficiencies for different $\eta$ and $p_T$ intervals.
