MIT CSAIL Technical Report No 985

Abstract

We present a technique that enables the use of finite model finding to check the satisfiability of certain formulas whose intended models are infinite. Such formulas arise when using the language of sets and relations to reason about structured values such as algebraic datatypes. The key idea of our technique is to identify a natural syntactic class of formulas in relational logic for which reasoning about infinite structures can be reduced to reasoning about finite structures. As a result, when a formula belongs to this class, we can use existing finite model finding tools to check whether the formula holds in the desired infinite model.

1 Introduction

A new kind of analysis has become popular in the last decade in which a system is examined by considering all small cases within some bound. The rationale is that flaws are revealed more readily by this method than by conventional testing: exhausting a large space of small cases works better than considering a much smaller suite of cases, even if it includes larger ones.

Model checking is the preeminent example of this approach, and bounds the set of reachable states and sometimes also the length of execution traces. The success of model checking in hardware verification has generated great interest in applying it to software. Most model checkers, though, offer only rudimentary support for data structures, so most applications of model checking to software until now have focused on control properties, and data has either been ignored or abstracted away.

To handle data structures effectively within this context, a reduction to small cases is needed. With such a reduction, no special abstractions for data would be needed, and the same bounding mechanism used for trace length, for example, could be applied to the size of data structures.

How should data structures be represented in such an analysis? A relational representation is very attractive, because it fits both the analyses that are widely used at the low level, and the object-oriented view of a program at the high level. Symbolic model checkers such as SMV [18] already represent the state as a bit vector; the adjacency matrix representation of a relation is therefore easily integrated. In the object-oriented view of program state, the heap is a graph, with objects as nodes and fields of objects as edges between objects—in other words, a collection of relations, one per field. This view now predominates, because it’s simple and easily accounts for sharing (a shared object simply being in the range of two relations).

An important question to ask, therefore, is whether this relational viewpoint can accommodate a general theory of data structures. Can arbitrary structural properties be naturally expressed and analyzed by the small case approach? This question is not only of theoretical interest. It has arisen repeatedly amongst advanced users of one tool, the Alloy language and its associated analyzer [1], as they have discovered scenarios in which Alloy’s relational encoding does not seem to capture their intuitions about data structures.

This paper’s aim is to resolve this issue, not only for Alloy, but more generally for any tool that relies on small case analysis of a relational encoding. This includes not only model checkers (such as SMV [18] and NuSMV [5]), but also specification analysis tools based on constraints (such as ProB [23] and the Bremen USE tool [10]), and indeed potentially to any tool that encodes data relationally.

To frame the problem rigorously, a characterization of data structures independent of the relational viewpoint is needed. For this purpose, we use the theory of algebraic datatypes, which corresponds to the way most programmers think about structured values in datastructures, and is the basis for their implementation in many current programming languages.

We start by explaining the standard encoding of algebraic datatypes using relations in first order logic. This encoding is faithful, but it suffers from a major drawback: it requires all models of a formula to be infinite. Consequently, an analysis based on finite cases cannot be applied. To remedy this, we remove the logical axiom that is responsible for making models infinite. Surprisingly, most analyses performed in the absence of this axiom are still sound. There are however, analyses that will produce spurious counterexamples. The principal contribution of this paper is a simple syntactic criterion that guarantees that a formula being analyzed will not suffer from this problem. The criterion is easy to understand, and could be applied automatically by a tool, warning the user when an analysis on the relational encoding might produce results that do not correspond to the full theory of algebraic datatypes.

The contributions of the paper are:

- A recognition of the problem of handling data structures in relational encodings, with positive and nega-
tive illustrations;

- A rigorous formulation of the problem, in terms of encoding algebraic datatype axioms in first order logic, and invariance of formula semantics under the exclusion of the "generator" axiom that generates infinite models;

- A simple and effective syntactic criterion characterizing the class of formulas for which an analysis involving only finite tests is sound and complete.

2 An Example

In this section, we motivate the problem with an example of a relational encoding of a simple algebraic datatype. We show how the omission of a generator axiom can cause spurious counterexamples, but its inclusion results in inconsistency, making the encoding useless. The challenge is to determine under what conditions the axiom can be omitted while remaining faithful to the theory of algebraic datatypes.

The example will be given in Alloy [17], a modeling language based on a simple first-order logic with relational operators. Although our work was motivated by Alloy, our results apply more broadly, and the rest of the paper presents our theory in a standard logic that has no Alloy-specific features.

A datatype for lists would be declared in a language such as ML [31] like this:

datatype List = Nil | Cons of Element * List

where List is the datatype being declared, Element is the type corresponding to the elements, and Nil and Cons are constructors, with no arguments and two arguments respectively.

In Alloy, List and Element are represented as top-level sets (called signatures in Alloy). Nil is a singleton set — the set containing the empty list.

sig Element {
}
sig List {
}
one sig Nil extends List {

Cons is represented by a set Cons and two selectors, elt and rest:

sig Cons extends List {
  elt: Element,
  rest: List
}

The extends syntax makes Cons a subset of List, disjoint from Nil. The selectors are semantically just relations from the set Cons to the sets Element and List respectively.

The function cons can be written as an Alloy predicate

pred cons (e: Element, l: List, c: Cons) {
  c.elt = e and c.rest = l
}

which associates with an element e and a list l any object c in Cons such that e and l are the element and rest components of c.

Now let's consider checking some putative theorems. This assertion says that the element of a list just created with an application of cons is the element used in the application:

assert A {
  all e: Element, l: List, c: Cons |
  cons (e, l, c) => e = c.elt
}

This holds trivially—the consequent being contained in the hypothesis—and so, when when checked by the Alloy Analyzer, it yields no counterexamples. In contrast, suppose we check the assertion

assert B {
  all e: Element, l: List, c, c': Cons |
  (cons (e, l, c) and cons (e, l, c')) => c = c'
}

which claims that cons is deterministic. The Alloy Analyzer will give a counterexample such as this:

List = {L0, L1, L2}
Cons = {L1, L2}
Nil = {L0}
Element = {E0}
elt = {L1, E0, L2, E0}
rest = {L1, L0, L2, L0}
e = {E0}
l = {L0}
c = {L1}
c' = {L2}

in which cons produces the two lists L1 and L2 which are structurally identical but nevertheless distinct list objects.

This might be acceptable for some applications, but if we wanted to model the kind of list used in languages such as ML, in which equality is structural (and identity of cells therefore cannot be observed), we could add an axiom

fact {
  all l, l': List |
  l.elt = l'.elt and l.rest = l'.rest => l = l'
}

requiring that structurally identical lists have the same identity, ensuring that the assertion B is now valid.

Continuing with model exploration, we notice that in some cases Alloy generates cyclic lists as counterexamples of our properties. Because cyclic lists are not algebraic datatypes, we introduce the fact

fact {
  no l : List || l in l.^rest
}

ensuring that elt is an acyclic relation.

So far so good. Consider, however, an assertion claiming that cons is total:

assert C {
  all e: Element, l: List | some c: Cons |
  cons (e, l, c)
}

Given our intuition about algebraic datatypes, we expect this assertion to be valid. But in the relational setting, given the facts stated so far, the assertion C is actually invalid. The Alloy Analyzer will generate a counterexample such as
List = {L0}
Cons = {}
Nil = {L0}
Element = {EO}
e1 = {}
rest = {}
e = {EO}
l = {L0}

The problem, roughly speaking, is that the Analyzer is free to construct a counterexample in which there aren't enough lists.

Suppose, following our previous strategy, we attempt to add an axiom to rule out counterexamples of this form:

\[
\text{fact}\{ \\
\hspace{1cm} \text{all } l:\text{List}, e:\text{Element} \mid \text{some } c:\text{Cons} \mid e.\text{elt} = e \text{ and } c.\text{rest} = l \\
\} 
\]

This 'generator' axiom ensures that the selector relations are complete; for any combination of list and element, it requires the existence of list for which they are components. This will indeed rule out the counterexample above. Unfortunately, however, it rules out all (nonempty) counterexamples, even to a manifestly false assertion (for example that 0 equals 1). The problem is that this axiom has no finite models, and is therefore \textit{inconsistent} in a setting in which only finite models are considered.

The key idea of this paper is that a finite checker cannot incorporate this axiom, but must nevertheless be able to handle algebraic datatypes. The question then is what class of formulas have the same models whether or not this axiom is included. The contribution of this paper is a characterization of a class of such formulas that is both expressive and easily checked syntactically.

Assertion C, it turns, will not be in this class. The culprit is the innermost quantification. The nesting of quantifiers is not in itself problematic; rather, the problem is that the quantification is not bounded. If instead, it were bounded by an expression in terms of variables bound in an outer quantifier, no spurious counterexample would be generated, even in the absence of the generator axiom. For example, the assertion

\[
\text{assert D}\{ \\
\hspace{1cm} \text{all } c:\text{Cons} \mid \text{some } l:\text{Cons}(e, l, c) \\
\} 
\]

saying that each list is the result of an application of cons to some sublist, is valid, as expected (the expression \text{c.}\text{rest} is the application of the reflexive transitive closure of rest to c, giving the set of c's sublists).

3 Logic and Algebraic Datatypes

This section introduces our two formalisms: term algebras, a theory of algebraic datatypes, and a first-order logic with transitive closure. We show how a term algebra can be straightforwardly translated into first-order logic, using four axioms. One of these is a generator axiom that causes all models to be infinite. In the following section, we establish our main result about when this axiom can be omitted.

Throughout the paper, we use binary trees as the canonical example of algebraic datatypes. Being simple and familiar, trees serve well as a pedagogical example. In addition, because trees can represent all other algebraic datatypes, there is no loss of generality.

\textbf{Algebraic datatypes and term algebras.} We consider structures that contain two kinds of values, or \textit{sorts}: 1) a \textit{Tree} sort, corresponding to algebraic datatypes, and 2) an \textit{Object} sort, corresponding to all remaining values. In a programming language such as ML [31], we would define this algebraic datatype using a declaration such as:

\texttt{datatype Tree = Nil | Node of Tree * Object * Tree}
\texttt{datatype Object = Obj1 | Obj2 | \ldots | Obj38}

Note that the datatype \texttt{Tree} has an infinite set of values, because there is no bound on the size of a tree. On the other hand, we assume that we have already finitized the set \texttt{Object} corresponding to the remaining values. If our structure had only values of sort \texttt{Object}, we could use existing techniques to search for models of formulas (such as [16]); our goal, however, is to reason about the structures that also contain values of the sort \texttt{Tree}. One view of the results of this paper is that we show how to effectively finitize algebraic datatypes, without making the conclusions derived in the finitization meaningless with respect to the intended world of arbitrarily large datatypes.

Algebraic datatypes have proven to be useful not only in programming languages, but also in model theory, where they correspond to term algebras [26, Chapter 23], [13, Section 1.3]. Term algebras are algebras in which values are interpreted syntactically: given a term \( t \) without free variables (a \textit{ground term}), the interpretation of \( t \) is \( t \) itself. The term algebras corresponding to the \texttt{Tree} datatype are generated by:

1) a constant \texttt{Nil} of sort \texttt{Tree}, and
2) a binary constructor \texttt{Node} of type

\[
\texttt{Tree} \times \texttt{Object} \times \texttt{Tree} \rightarrow \texttt{Tree}
\]

We next present the logic we use to express the properties of structures containing terms and objects; we use this logic to write the formulas that we wish to analyze.

\textbf{A logic with transitive closure.} We consider a fragment of first-order logic with transitive closure. The syntax of our logic is in Figure 1: the nonterminal \( S \) denotes set-valued expressions, \( R \) denotes relation-valued expressions,
\[ M = (T, O, \iota), \quad \alpha : \text{Vars} \rightarrow T \cup O \]

\[ [s_1 \text{ setOp } s_2]^{M_a} = [s_1]^{M_a} \text{ setOp } [s_2]^{M_a} \]

\[ [s]^{M_a} = \{ y \mid \exists x \in [s]^{M_a}, \ (x, y) \in [R]^{M_a} \} \]

\[ [(x_1, \ldots, x_n)]^{M_a} = \{ \alpha(x_1), \ldots, \alpha(x_n) \} \]

\[ [r_1 \text{ setOp } r_2]^{M_a} = [r_1]^{M_a} \text{ setOp } [r_2]^{M_a} \]

\[ [r_1 \circ r_2]^{M_a} = [r_1]^{M_a} \circ [r_2]^{M_a} = \{ (x, z) \mid \exists y, (x, y) \in [r_1]^{M_a} \land (y, z) \in [r_2]^{M_a} \} \]

\[ \Delta^{M_a} = \{ (x, x) \mid x \in T \} \]

\[ [s_1 = s_2]^{M_a} = ([s_1]^{M_a} = [s_2]^{M_a}) \]

\[ [r_1 = r_2]^{M_a} = ([r_1]^{M_a} = [r_2]^{M_a}) \]

\[ [x_1 = x_2]^{M_a} = (\alpha(x_1) = \alpha(x_2)) \]

\[ [(x_1, x_2) \in R]^{M_a} = (\alpha(x_1), \alpha(x_2)) \in [R]^{M_a} \]

\[ [x \in R]^{M_a} = \alpha(x) \in [S]^{M_a} \]

\[ \neg [R]^{M_a} = \{ (x_0, x_n) \mid \exists n \geq 1, \exists x_1, \ldots, x_{n-1} \in T, \]

\[ \land_{i=1}^{n}(x_{i-1}, x_i) \in [R]^{M_a} \} \]

\[ [\forall \exists \text{ Tree}. F]^{M_a} = \forall t \in T, [F]^{M_{a'}}^{M_a}, \quad \alpha' = \alpha[x := t] \]

\[ [\forall x : \text{ Object}. F]^{M_a} = \forall o \in O, [F]^{M_{a'}}^{M_a}, \quad \alpha' = \alpha[x := o] \]

\[ [\exists x : \text{ Tree}. F]^{M_a} = \exists t \in T, [F]^{M_{a'}}^{M_a}, \quad \alpha' = \alpha[x := t] \]

\[ [\exists x : \text{ Object}. F]^{M_a} = \exists o \in O, [F]^{M_{a'}}^{M_a}, \quad \alpha' = \alpha[x := o] \]

Figure 2: Semantics for Logic of Figure 1

\[ \exists x : F(x) \land (\forall x, y, F(x) \land F(y)) \Rightarrow x = y \]

We interpret formulas in our logic over two-sorted structures \( M = (T, O, \iota) \) where \( T \) is the domain of the sort Tree, \( O \) is the domain of the sort Object, and \( \iota \) with domain \( S_{T} \cup S_{O} \) interprets the built-in sets and relations of the structure \( M \), so that \( \iota(s) \subseteq T \) or \( \iota(s) \subseteq O \) if \( s \) is a built-in set, and \( \iota(r) \subseteq T^2 \) or \( \iota(r) \subseteq O^2 \) or \( \iota(r) \subseteq T \times O \) or \( \iota(r) \subseteq O \times T \) if \( r \) is a built-in relation. The standard model-theoretic semantics of our logic is in Figure 2. The function \( \alpha : \text{Vars} \rightarrow T \cup O \) is a valuation that maps each variable to its value. If \( \varphi \) is a sentence (a formula with no free variables) then \([\varphi]^{M_a} = \text{true}\) does not depend on \( \alpha \), so when \( \varphi \) is a sentence and \([\varphi]^{M_a} = \text{true}\), we say that \( M \) is a model of the sentence \( \varphi \). A structure \( M \) is a model of a set of sentences if \( M \) is a model of each of the sentences in the set.

Note that, although we use set-theoretic notation such as \( x \in S \) and \( (x, y) \in R \), our logic does not allow quantification over sets, and is no stronger than first-order logic with transitive closure. Recall, however, that first-order logic is very expressive. Indeed, first-order logic has been used as a foundation for set theory and all of mathematics [30]. Note also that the axioms and definitions used to represent many mathematical problems in first-order logic are often made under the assumption that the logic is interpreted over finite structures. We view the results of this paper as a contribution towards reasoning about infinite structures using techniques that have proven to be effective for finite structures.

A language for term algebras. The language in Figure 1 presents a general logic over arbitrary sorts and relations. We next turn to the question of choosing the sets and relations that are appropriate for describing term algebras.

Term algebras can be described using constructor relations, such as Node, or using selector relations, which are the inverse of the constructors [13, Section 2.6]. For our purpose, it is more convenient to use selectors. Because we consider a binary tree, we use the selectors left, content, and right, where left and right denote the children of a node in the tree, and content denotes the Object value associated with a tree node. We represent selectors as binary relations that are partial functions defined on non-nil terms. We define the relation node as the following shorthand:

\[ (t_1, t_2, \alpha) \in \text{node} \iff (t_1, t_2) \in \text{left} \land (t_1, t_2) \in \text{content} \land (t_2, t_2) \in \text{right} \land t \neq \text{Nil} \]

We also use the subterm relation, defined using transitive closure:

\[ \text{subterm} \triangleq (\text{left} \cup \text{right}) \]
The term model. We are interested in checking the satisfiability of formulas over the term algebra structure \( M_T = (T_T, O, \cdot_T) \) given as follows:

- \( T_T \) is the set of ground terms generated by constants \( \text{Nil} \) and \( \text{Node} \); in other words, \( T \) is the least set such that
  1. \( \text{Nil} \in T_T \), and
  2. if \( t_1, t_2 \in T_T \) and \( o \in O \), then \( \text{Node}(t_1, o, t_2) \in T_T \).
- \( O \) is a finite set;
- \( \cdot_T \) is defined as follows:
  \( \cdot_T(\text{Nil}) = \text{Nil} \)
  \( \cdot_T(\text{left}) = \{ (\text{Node}(t_1, o, t_2), t_1) \mid t_1, t_2 \in T_T, o \in O \} \)
  \( \cdot_T(\text{content}) = \{ (\text{Node}(t_1, o, t_2), o) \mid t_1, t_2 \in T_T, o \in O \} \)
  \( \cdot_T(\text{right}) = \{ (\text{Node}(t_1, o, t_2), t_2) \mid t_1, t_2 \in T_T, o \in O \} \).

Figure 3 sketches one part of the structure \( M_T \).

Axioms for term algebras. We adopt the following axioms to describe the properties of term algebras:

- **Selectors**: The binary relations \( \text{left}, \text{content}, \) and \( \text{right} \) are total functions on the non-\( \text{Nil} \) elements of the sort \( \text{Tree} \), and are undefined on \( \text{Nil} \):
  1. \( \forall t :: \text{Tree}. t \neq \text{Nil} \implies (\exists t_1 :: \text{Tree}. (t, t_1) \in \text{left}) \wedge (\exists o :: \text{Object}. (t, o) \in \text{content}) \wedge (\exists t_2 :: \text{Tree}. (t, t_2) \in \text{right}) \)
  2. \( \forall t_1 :: \text{Tree}. \forall o :: \text{Object}. (\text{Nil}, t_1) \notin \text{left} \wedge (\text{Nil}, o) \notin \text{content} \wedge (\text{Nil}, t_2) \notin \text{right} \)

We assume that a simple type system of our two-sorted language rules out the application of relations to elements of inappropriate sort; for example, if \( t :: \text{Tree} \) and \( o :: \text{Object} \), then \((t, o) \in \text{left}\) is not a well-formed formula.

- **Uniqueness**: The defined relation \( \text{node} \) has the properties of a partial function:

\( \forall t, t', t_1, t_2 :: \text{Tree}. \forall o :: \text{Object}. (t, t_1, o, t_2) \in \text{node} \wedge (t', t_1, o, t_2) \in \text{node} \implies t = t' \)

- **Generator**: The defined relation \( \text{node} \) has the properties of a partial function:

\( \forall t_1, t_2 :: \text{Tree}. \exists o :: \text{Object}. t \equiv \text{Tree}. (t, t_1, o, t_2) \in \text{node} \)

(This axiom holds in \( M_T \), but we will consider the consequences of omitting it from the axiomatization.)

- **Acyclicity**: A term is never a proper subtree of itself; that is, the subterm relation is acyclic:

\( \forall t :: \text{Tree}. (t, t) \notin \text{subterm} \)

We denote by \( \text{SUGA} \) the conjunction of the axioms above (taking the first letter of the name of each axiom).

Note that the \( \text{SUGA} \) axioms have no finite models. Namely, although not all models of \( \text{SUGA} \) are isomorphic, they all contain an infinite chain of elements \( t_0, t_1, t_2, \ldots \) where \( t_0 = \text{Nil} \) and \((t_{i+1}, t_i, o, \text{Nil}) \in \text{node} \). These elements exist by the **Generator** axiom; the **Acyclicity** axiom guarantees that they are all distinct because they are ordered by the **subterm** relation.

In first-order logic without transitive closure, term algebras have a complete axiomatization [26, Chapter 23], [25]: there is a set of first-order sentences whose consequences are precisely the sentences that are true in the structure \( M_T \) (this set of sentences is infinite and requires some axiom schemas). However, even a complete axiomatization does not characterize the models up to isomorphism. For example, our \( \text{SUGA} \) axioms allow countable models with countably infinite paths of \( \text{left} \) and \( \text{right} \) that never terminate at \( \text{Nil} \). The completeness of the axiomatization of term algebras is not of direct interest to us in any case, because a complete axiomatization forces the model to be infinite. Instead, we look for subclasses of formulas that can be checked on finite structures, and we show the soundness of our technique using a model-theoretic approach: we look at the truth value of the formulas in the desired term model \( M_T \) (as opposed to checking whether the formulas are a consequence of an axiomatization of \( M_T \) as in a proof-theoretic approach).

4 Finite Satisfiability Result

This section presents the main results of our paper, which enable the checking of properties of algebraic datatypes using finite models. The basic idea of our approach is the following: to prevent all models from being infinite, we drop the **Generator** axiom. Denote by \( \text{SUA} \) the conjunction of the remaining axioms (**Selectors**, **Uniqueness**, **Acyclicity**). It turns out that, among the finite structures, \( \text{SUA} \) characterizes precisely the substructures of the term model that are subterm-closed (if \( t \) is in the structure, then so is each sub-term of \( t \)). Having proved this characterization, we identify a class of sentences whose validity in a finite model implies the validity in the full infinite model \( M_T \).

We next define the notion of a subterm-closed finite substructure of \( M_T \), illustrated in Figure 3. Intuitively, a finite substructure \( M_0 = (T_0, O, \cdot) \) of \( M_T \) is a structure obtained from \( M_T \) by selecting a finite set \( T_0 \) of terms and preserving all the relations between the terms in \( T_0 \). A structure is subterm-closed if a subtree of each tree in \( T_0 \) is also in \( T_0 \). More precisely, we have the following:

Consider a term model \( M_T = (T_T, O, \cdot_T) \). A substructure of \( M_T \) is a structure \( M_0 = (T_0, O, \cdot_0) \) where \( T_0 \subseteq T_T \) and the relations given by \( \cdot_0 \) are restrictions of the corresponding relations given by \( \cdot_T \), that is, \( \cdot_0(\text{left}) = \cdot_T(\text{left}) \wedge T_0^2 \), \( \cdot_0(\text{right}) = \cdot_T(\text{right}) \wedge T_0^2 \), and \( \cdot_0(\text{content}) = \cdot_T(\text{content}) \wedge T_0 \times O \). (We have for simplicity assumed that substructures have the same domain \( O \) of values of the sort \( \text{Object} \).) A subterm-closed finite substructure of \( M_T \) is a finite substructure \( M_0 \) of \( M_T \) whose domain of terms \( T_0 \) satisfies the property \( t \in T_0 \wedge (t, t_1) \in T_T \wedge \forall t_1, t_2 :: T_T. (t, t_1, o, t_2) \in \text{node} \).

We then have the following completeness theorem that explains why the \( \text{SUA} \) axioms are adequate. This theorem allows us to ensure that any model of \( \text{SUA} \) axioms has precisely the properties of a subterm-closed finite substructure.
\( \varphi \) holds in some subterm-closed finite substructure \( M_0 \) of \( M_T \), so \( \varphi \) holds in the full term model \( M_T \). We thus obtain a method to check whether a formula \( \varphi \) holds in \( M_T \). In the rest of this section, we generalize this result by allowing arbitrary quantification in \( \varphi \), as long as it is bounded by previously introduced values. The intuitive reason why this generalization is possible is that we are checking formulas on subterm-closed structures, which means that the bounded quantification has the same semantics in the substructure \( M_0 \) and in the full infinite structure \( M_T \).

Let \( S \) be a set-valued term, denoted \( S \) in Figure 1, and suppose that \( S \) does not contain variable \( t \). A bounded universal term quantifier

\[
\forall_S t :: \text{Tree}, F
\]

is a shorthand for the formula

\[
\forall t :: \text{Tree}, t \in S \Rightarrow F
\]

Dually, a bounded existential term quantifier

\[
\exists_S t :: \text{Tree}, F
\]

is a shorthand for the formula

\[
\exists t :: \text{Tree}, t \in S \land F
\]

Hence, bounded quantifiers are expressible in terms of the ordinary quantifiers, but are more restrictive. An existential—bounded-universal sentence requires each universal quantifier to be bounded by some set expression \( S \). More precisely, we have the following definition:

**Definition 1** An existential—bounded-universal sentence (an EBU sentence) is a formula of the form

\[
Q_1 v_1 :: s_1, \ldots, Q_n v_n :: s_n, \psi
\]

where \( \psi \) is a quantifier-free formula (denoted \( B \) in Figure 1) and each \( Q_i v_i :: s_i \) is a quantifier or a bounded quantifier of one of the following forms:

- An existential term quantifier \( \exists v_k :: \text{Tree}; \)
- A bounded universal term quantifier \( \forall_S v_k :: \text{Tree} \) where the free variables of the set-valued term \( S \) are among the previously quantified variables \( v_1, \ldots, v_{k-1} \);
- A bounded existential term quantifier \( \exists_S v_k :: \text{Tree} \) where the free variables of the set-valued term \( S \) are among the previously quantified variables \( v_1, \ldots, v_{k-1} \) (this quantifier is a special case of the existential term quantifier);
- A universal object quantifier \( \forall v_k :: \text{Object}; \)
- An existential object quantifier \( \exists v_k :: \text{Object}. \)

We write \( \varphi \in \text{EBU} \) to denote that \( \varphi \) is an EBU sentence.

Note the ways in which EBU sentences generalize purely existential sentences: not only is it possible to have arbitrary bounded quantifiers, it is also possible to introduce new unrestricted existential quantifiers, even after bounded universal quantifiers.

We are now ready to state our main theorem:
procedure TermSat
input: φ an EBU sentence
output: if φ is true in some term model $M_T$: a finite substructure $M_0$ of $M_T$ where φ holds
 if φ is false in all term models $M_T$: no result (infinite loop)
begin
    k := 1;

Figure 4: A semidecision procedure for checking satisfiability of EBU sentences in the term model $M_T$.

Theorem 2 (Finite Satisfiability Theorem) Let φ be an EBU sentence and $M_T$ a term model. Then φ holds in $M_T$ if and only if it holds in some subterm-closed finite substructure $M_0$ of $M_T$.

The proof of Theorem 2 is in Section 8.

The identification of EBU sentences and the proof that they can be verified on finite models is the main contribution of this paper. In the sequel, we explore some of the consequences of this result.

5 Consequences

Given the results of the previous section, we can now answer the question we posed in Section 2. An analysis of an Alloy model in which algebraic datatypes are encoded relationally will yield sound counterexamples so long as the formula being checked is in EBU. A syntactic check for membership in EBU based on Definition 1 is easy to implement. The result extends to bounded model checkers (such as NuSMV [6]) whose analysis consists of finding a model of a formula. The language of formulas for such model checkers could be soundly extended to EBU sentences over algebraic datatypes.

Analysis procedure. The analysis procedure suggested by our result is shown in Figure 4: to check whether an EBU sentence φ holds in $M_T$, search for increasingly large finite models of SUA $\land$ φ. The procedure captures the spirit of analyses such as that performed by the Alloy Analyzer [16, 17]; in practice, the search for models would employ some heuristics and would not require an exhaustive enumeration. The correctness and completeness of the procedure follows from the results of this section and is the main result of this paper:

- we can check the condition that a structure is a subterm-closed submodel of $M_T$ by simply conjuring axioms SUA to φ, thanks to Theorem 1;
- we know that the existence of the returned finite model $M_k$ implies that φ holds in $M_T$, thanks to the ($\iff$) (soundness) direction of Theorem 2;
- we know that if φ holds in model $M_T$, then the algorithm will find a finite model $M_k$ which proves this fact, thanks to the ($\Rightarrow$) (completeness) direction of Theorem 2.

Closure under boolean operations. Having identified EBU sentences as a useful class of formulas for which the algorithm in Figure 4 is applicable, we next examine the following question. If φ$_1$, φ$_2$ $\in$ EBU, is there an effectively constructible sentence $\phi$ $\in$ EBU such that the following equivalences hold in $M_T$:

- $\phi \iff (\phi_1 \land \phi_2)$
- $\phi \iff (\phi_1 \lor \phi_2)$
- $\phi \iff \neg \phi_1$
- $\phi \iff (\phi_1 \Rightarrow \phi_2)$

It turns out that the answer to first two questions is “yes”, whereas the answer to the last two questions is “no”. In other words, EBU sentences are closed only under positive boolean combinations, but not closed under negation or implication. We make this claim precise using the following two propositions.

Proposition 1. Let φ$_1$ $\equiv$ BQ$_1$, F$_1$ and φ$_2$ $\equiv$ BQ$_2$, F$_2$ be EBU sentences where BQ$_1$ and BQ$_2$ denote sequences of quantifiers and bounded quantifiers and where F$_1$, F$_2$ are quantifier-free formulas. Let BQ$_1$ $\cdot$ F$_1$ be the result of renaming the variables in φ$_2$ so that they are all distinct from the variables in φ$_1$. Then

$$
\begin{align*}
\phi_1 \land \phi_2 & \iff BQ_1 \cdot BQ_2 \cdot F_1 \land F_2 \\
\phi_1 \lor \phi_2 & \iff BQ_1 \cdot BQ_2 \cdot F_1 \lor F_2
\end{align*}
$$

Moreover, BQ$_1$, BQ$_2$, F$_1$ $\land$ F$_2$ and BQ$_1$, BQ$_2$, F$_1$ $\lor$ F$_2$ are EBU sentences.

The condition (1) follows from the basic monotonocity property of quantifiers and operations $\land$, $\lor$. The fact that the concatenation of disjoint EBU sequences of quantifiers is again an EBU sequence of quantifiers follows from the definition of EBU sentences.

We next turn to the absence of the closure under negation and implication. We first note that the entire class of EBU sentences is undecidable.

Fact 2. The problem of determining, given an EBU sentence φ, whether φ holds in $M_T$, is undecidable.

Fact 2 follows from the fact that the subterm relation is definable in our logic, and from the undecidability result in [30, Section 4], which shows a reduction from the Post correspondence problem to the satisfiability of sentences with existential quantifiers and bounded universal quantifiers.

Fact 2 has two main consequences for this paper. The first consequence is that, from the viewpoint of computability, the semidecision procedure in Figure 4 is as good as we can hope for. The second consequence is the absence of closure under negation and implication, as given by the following proposition.

Proposition 2. There is no effective algorithm that, given a sentence $\phi \in$ EBU, constructs a sentence in EBU equivalent to $\neg \phi$. Consequently, there is no such algorithm that constructs a sentence equivalent to $\phi \Rightarrow \text{false}$. 

The following is an indirect argument for Proposition 2: suppose that there is such an algorithm. Consider any EBU sentence \( \varphi \). Let \( \mathcal{S} \) be the sentence computed by the algorithm, so that \( \mathcal{S} \) is equivalent to \( \varphi \). Then either \( \varphi \) or \( \mathcal{S} \) holds in \( M_T \), so if we run two copies of the procedure in Figure 4 in parallel, one with the input \( \varphi \) and the other with the input \( \mathcal{S} \), then one of the algorithms will eventually terminate and we will conclude that \( \varphi \) is either true or false. This implies that the class of EBU formulas is decidable, contradicting Fact 2.

**Arbitrary algebraic datatypes.** We have presented our result for binary trees, but it applies to all algebraic datatypes, and more generally, to any structured data. Indeed, it is easy in relational logic to reason about records and tuples that have an \emph{a priori} bounded number of components; just introduce a new variable for each component. What the results of this paper imply is that we can also reason about structures such as binary trees; that do not have an \emph{a priori} bound on their size. It is not difficult to generalize the proofs of Theorem 1 and Theorem 2 to the case of any finite number of mutably recursive algebraic datatypes. Alternatively, we can encode any number of datatypes using binary trees. Indeed, the experience with programming languages such as LISP [28] is convincing evidence that data structures can be represented using LISP-like lists, which are binary trees.) The idea of representing algebraic datatypes with trees is to replace each constructor application \( C_k(t_1, \ldots, t_n, o_1, \ldots, o_m) \) with an expression

\[
\text{Node}(f_{t_1, o_1}, \text{Node}(t_2, o_2, \ldots, \text{Node}(t_n, o_n, \text{Nil}, \ldots)))
\]

where \( f_{t_i} \) is a finite tree (of size \( O(\log k) \)) that encodes the name of the constructor \( C_k \), where \( P = \max(n, m) \), \( t_i = \text{Nil} \) if \( i > n \) and \( o_i = \text{Nil} \) if \( i > m \). Here \( o_0 \in O \) is some arbitrary fixed object from the set of uninterpreted objects. The corresponding selector relations are similarly definable using quantifier-free formulas in terms of selectors \emph{left} and \emph{right}, and so is the subterm relation. Note that, when reasoning about arbitrary algebraic datatypes we are interested not in all possible trees, but only in the substructure of \( M_T \) which is the image of the embedding. In other words, we would like to ensure that the binary trees that represent the values of variables in formulas are consistent with the type system of the original algebraic datatypes. Luckily, this condition is expressible using our logic with transitive closure. Therefore, it suffices to restrict all quantified variables to the terms that satisfy this condition, and the resulting formula can be checked using the algorithm in Figure 4.

The scope of our result. After realizing that our technique applies to algebraic datatypes, a natural question to ask is: does the technique fundamentally depend on the properties of the structure of algebraic datatypes, such as the uniqueness of \emph{left} and \emph{right} relations (as given by the Selectors axiom), the uniqueness of the parent relation \emph{node} (as given by the Uniqueness axiom), or even the acyclicity (given by the Acyclicity axiom)? When examining this question it is worthwhile to consider two separate questions:

- How do we generalize the notion of subterm-bounded substructures of \( M_T \) to the case of substructures of some other infinite structure \( M_T \) of interest? (The generalization of Theorem 2.)

Suppose that we are interested in checking constraints over an infinite structure \( M_T \) with relation symbols \( r_1, \ldots, r_n \). It turns out that the only essential requirement on the structure \( M_T \) is that, for some term variables \( t \), the set \( \{ t \}. s(r_1 \cup \ldots \cup r_n)^M_{ \infty} = \) finite for each valuation \( \alpha \). In other words, as long as the set of elements "below" each element of \( M_T \) is finite, we can use bounded quantification to reduce the truth value of EBU sentences in \( M_T \) to the satisfiability in finite substructures below the "below" relation. In particular, the technique applies to structures that contain shared elements and cycles.

- How do we axiomatize a class of finite structures of interest? (The generalization of Theorem 1.)

From an algorithmic point of view, this question admits a wider spectrum of solutions than just the use of axioms in first-order logic with transitive closure (although the use of axioms may have an advantage in the context of constraint-solving tools). Indeed, given a family of finite structures of interest (in particular, given a family of finite subterm-closed substructures of \( M_T \)) we can use any language of computable functions to define an executable test predicate that determines whether a finite structure is isomorphic to one of the finite structures of interest. In other words, we can use an algorithm specialized for a given problem to filter the finite structures of interest. This idea of using "executable predicates" appears in the form of run-time assertions in many programming languages and has found applications in software testing [5, 27].

Because of these generalizations, we expect our result to be applicable to a range of infinite structures.

6 Related Work

**Constraint-checking tools.** Because of its full automation, model checking approaches based on finitization of the problem space are very attractive. These approaches have had great success for control-intensive problems [6, 48] such as those arising in hardware verification. The complexity of software systems often comes from the data structures that they manipulate, and notations such as UML [35] have been used to describe such constraints. The Alloy notation [16, 17] can also be used to describe such constraints; the Alloy Analyzer tool [1] can then search for the structures that satisfy these constraints. Our experience in using the Alloy notation and the analyzer to reason about structured values was the immediate inspiration for this paper. Because it establishes a general correspondence between satisfiability in finite and infinite models, our result is potentially applicable not only to Alloy, but also to tools such as MACE [29], Paradox [7], USE [10], ProB [23], RACER [40], and FaCT [14].

**Algebraic datatypes.** Our paper uses algebraic datatypes as a well-studied example of unbounded structured values. Algebraic datatypes are the basis of the algebraic approach to formal specification and verification [2, 4, 11, 12]. The use of the list algebraic datatype was pioneered by LISP [28]. User-defined algebraic datatypes go back to ML [31] and are used in variants such as Haskell [9] and Objective Caml [22].
Term algebras without transitive closure. The first-order theory of term algebras is decidable [25, 26, 37]. Because the interpretation of Object is a finite set, omitting the transitive closure from our logic makes formulas decidable even with arbitrary (not only bounded) quantifiers. The complexity of the resulting decision problem is non-elementary [8, 9] with the height of the tower of exponentials linear in the number of quantifier alternations in the formula [42]. More tractable classes of term algebras include the class of quantifier-free formulas [33]. Several decidable extensions of term algebras have been proved decidable [20, 21, 36, 38, 41], mostly using quantifier elimination techniques.

Term algebras with a subterm relation. Adding a subterm relation to the first-order language of term algebras makes the problem substantially more difficult. Indeed, [30] shows that even the satisfiability of formulas with bounded universal quantifiers is undecidable (although the satisfiability of the purely existential fragment with a subterm relation is still decidable). As we noted in Section 5, the undecidability result for algebras with subterms applies to our logic as well, because the subterm relation is expressible using transitive closure. A search for counterexamples is useful even for an undecidable logic (and is, in fact, at least as important as the search for counterexamples in decidable logics), and the results of this paper show how to perform such search for a useful class of formulas.

First-order logic with transitive closure. First-order logic with transitive closure is useful for reasoning about program data structures and has been used not only in Alloy [17], but also in shape analysis tools such as TVLA [24] and FAM [32]. Among the decidable fragments with transitive closure are monadic second-order logic [19, 34] and some subclasses of the existential monadic second-order logic of graphs [15].

Complexity and bounded quantification. In their study of lower and upper bounds on the complexity of logical theories, Ferrante and Rackoff [9, Page 30] describe the notion of H-bounded structures for some function H, which enables a reduction of general quantifiers to bounded quantifiers. The existence of appropriate such function implies the decidability of the structure, so such H does not exists for term algebras with subterm relation. Our use of bounded quantification is different: we have syntactically imposed boundedness of universal quantifiers and showed that it implies the ability to use finite structures to reason about certain classes of formulas in infinite structures.

7 Conclusions

The language of sets and relations has proven to be a very powerful notation for modeling a range of structures existing in software design and analysis. Model finding tools have made this approach accessible and practical. So far, model finding tools have been restricted to arbitrarily large, but finite models. However, some useful structures are inherently infinite, in particular the algebraic datatypes such as lists and trees. Such structures are widely used in implementations and models of software, but when we try to apply existing tools to these structures, we are faced, in general, with either ruling out all models (which is sound, but entirely useless), or allowing the possibility that the tool returns unsound, meaningless models that do not apply to the desired infinite structures.

In this paper we have presented a useful and natural class of formulas for which the existence of a finite model reveals the satisfiability of the formula in the infinite structure. For this class of properties, we have proved that it is possible to partially axiomatize the desired structure in such a way that finite models are simply substructures of the desired infinite structure. In this way, concrete feedback from model finding tools can be brought to a range of ubiquitous data structures that would otherwise remain out of their scope.

8 Proofs of Theorems

Theorem 1. A two-sorted structure M is a model of SUA if M is isomorphic to some subterm-closed finite substructure M₀ of M₁₁.

Proof. We prove both directions of the equivalence.

(⇒): Suppose that a structure M is isomorphic to a subterm-closed model M₀ of M₁₁. Then M satisfies some formulas as M₀. Therefore, it suffices to verify that M₀ satisfies the SUA axioms Selectors, Uniqueness, Acyclicity, Axioms Uniqueness and Acyclicity hold in M₁₁, so they hold in M₀ as well: indeed, a relation that has two values in
a substructure $M_0$ also has two values in the larger structure $M_T$, and a cycle in $M_0$ is also a cycle in $M_T$. Axiom Selectors holds because $M_0$ is subterm-closed: the components of every non-nil term $t$ in $T_0$ are also in $T_0$.

$$\Rightarrow$$: Suppose that a finite two-structure $T = (T, O, \alpha)$ satisfies SUA axioms. We identify a subterm-closed finite structure $M_0 = (T_0, O, \alpha_0)$ isomorphic to $M$ by establishing a relation $\mathcal{F} \subseteq T \times T_T$ and showing that $g$ is an isomorphism where $g = f \cup \Delta_0$ and $\Delta_0$ is the identity relation on $T$. We define $f$ using the following least fixpoint construction. Let $f_0 = (\iota(Nil), Nil)$ and let

$$f_{i + 1} = f_i \cup \{(t', \text{Node}(t_0, \alpha_0)), t \in T\}$$

$$\left(\begin{array}{l}
(t', t_0) \in (\iota, left), \\
(t', t_1) \in \iota(right), \\
(t', o) \in \iota(\text{content}), \\
(t_0, t_1), (t_0, t_2) \in f_i
\end{array}\right)$$

Then define $f = \bigcup_{i \geq 0} f_i$. In other words, we map $\iota(Nil)$ to Nil and we extend the relation by following parent relation in both $M$ and $M_0$. We now define a measure on the elements of structures $M$ and $M_0$. Consider an element $t \in T$ of structure $M$ and consider any sequence of elements $t_0, t_1, \ldots$, such that $t_0 = t$ and $(t_0, t_1) \in \iota(left) \cup \iota(right)$. Because $M$ satisfies Acyclicity and $T$ is finite, the sequence is finite. Moreover, because of the axiom Selectors, the sequence terminates at the element $\iota(Nil)$. For each element $t$, let $d(t)$ be the maximum of the lengths of all such sequences. We correspondingly define $d(t)$ for $t \in T_T$ of the structure $M_0$.

We then prove by induction on $i$ the conjunction of the following properties:

P1) $\text{dom}(f_i) = \{t' \in T \mid d(t') \leq i\}$

P2) each relation $g_i = f_i \cup \Delta_0$ is an partial isomorphism, that is, that $g_i$ is an isomorphism between structures induced by the domain of $g_i$ (denoted $\text{dom}(g_i)$) and the range of $g_i$ (denoted $\text{ran}(g_i)$).

Base case. $g_0$ is trivially a partial isomorphism because $\text{dom}(\iota) = (\iota(Nil))$ and $\text{ran}(\iota) = \iota(Nil) = \omega_0(\iota(Nil))$, so P1 holds. Moreover, from Selectors it follows that if $d(t) = 0$ then $\iota(t) = \iota(Nil)$, so P1 and P2 also hold.

Inductive step. Suppose that $g_i$ satisfies P1 and P2; we show that $g_{i+1}$ satisfies these properties as well.

• P1. Let $t' \in \text{dom}(f_{i+1})$. By definition of $f_{i+1}$, there exist $t_1, t_2 \in \text{dom}(f_i)$ such that $(t', t_1) \in (\iota, left)$ and $(t', t_2) \in \iota(right)$. By induction hypothesis, $d(t_1') \leq i$ and $d(t_2') \leq i$. By axiom Selectors, there are no elements $o \in T$ other than $t_0, t_2$ such that $(t_0, o) \in (\iota, left) \cup \iota(right)$, Therefore, $d(t') \leq 1 + \max(d(t_1'), d(t_2')) \leq i + 1$. Conversely, let $t' \in T$ be such that $d(t') \leq i + 1$. If $d(t') \leq i$ then $t' \in \text{dom}(f_i) \subseteq \text{dom}(f_{i+1})$, so let $d(t') = i + 1$. Then $t' \notin \text{dom}(f_i)$ so by Selectors there exist unique elements $t_1, t_2 \in T$ and $o \in O$ such that $(t', t_1) \in (\iota, left)$, $(t', t_2) \in \iota(right)$ and $(t', o) \in \iota(\text{content})$. Because $1 + \max(d(t_1'), d(t_2')) = d(t') \leq i + 1$, we have that $d(t_1) \leq i$ and that $d(t_2) \leq i$. By induction hypothesis $t_1, t_2 \in \text{dom}(f_i)$. Again by induction hypothesis, $f_i$ is a partial isomorphism, so there exist terms $t_1, t_2 \in T_T$ such that $(t_1, t_2) \in f_i$ and $(t_1, t_2) \in f_i$. By definition of $f_{i+1}$ we have $(t', \text{Node}(t_1, o, t_2)) \in f_{i+1}$, so $t' \in \text{dom}(f_{i+1})$.

• P2, function. For $t' \in \text{dom}(f_i)$, the property follows by inductive hypothesis, because $f_{i+1}$ does not add new values to elements that are already in $f_i$. So let $(t', t_1, t_2) \in f_{i+1}$. Then for both $(t', t_1)$ and $(t', t_2)$ there are elements $t_1, t_2 \in T$ such that $(t', t_1) \in (\iota, left)$ and $(t', t_2) \in \iota(right)$, and by Selectors these elements are unique. Moreover, by induction hypothesis, $f_i$ is functional, so $t_1, t_2$ are related via $f_i$ to unique elements $t_1, t_2 \in T_T$. Therefore, Node(t, o, t) is the unique element $t$ such that $(t, t) \in f_{i+1}$.

• P2, injectivity. By definition of $f_i$, there is exactly one element $t$ with the property $(t, t) \in f_i$, namely $\iota(Nil)$. Hence, injectivity can be violated only on non-nil terms. Consider $t = \text{Node}(t_1, o, t_2) \in \iota(right)$, a tuple $(t', t)$ is in $f_{i+1}$ only if there are some $t_1, t_2 \in T$ such that $(t', t_1), (t', t_2) \in f_i$, $(t', t') \in (\iota, left)$, and $(t', t_2) \in \iota(right)$. By induction hypothesis, such $t_1, t_2$ are unique because $f_i$ is a partial isomorphism. Finally, by Uniqueness, there is at most one such $t$ such that $(t', t') \in (\iota, left)$ and $(t', t_2) \in \iota(right)$, so $t'$ is unique.

• P2, Nil preservation. Clearly $(\iota(Nil), Nil) \in f_0 \subseteq f_{i+1}$, so interpretation of Nil is mapped to the interpretation of Nil.

• P2, left preservation. Let $(t', t_1, t_2) \in f_{i+1}$. We show that $(t', t_1) \in (\iota, left)$ if $(t_1, t_2) \in (\iota, left)$. If $(t_1, t_2) \in \text{dom}(f_i)$, the property holds by induction hypothesis, so suppose that $t' \in (\iota, left) \cup \iota(right)$. Suppose first $(t', t_1) \in (\iota, left)$. Then $(t', t_1, t_2) \in \text{dom}(f_{i+1})$ so by definition of $f_{i+1}$ there exists $t \in O$, $t_1 \in T$ and $t_2 \in T_T$ such that $(t', t) \in (\iota, left)$, $(t, t_1) \in f_i$, and $(t, \text{Node}(t_1, o, t_2)) \in f_{i+1}$. By axiom Selectors, $t_1 = t_2$, so $(t_1, t_2) \in f_i$. We have shown above that $f_{i+1}$ is functional, so $t_1 = t_2$. Furthermore, $t = \text{Node}(t_1, o, t_2)$. By definition of $\iota$, $(t_1, t_2) \in (\iota, left)$. Conversely, suppose that $(t_1, t_2) \in (\iota, left)$. By definition of $\iota$, this means there are $o \in O$ and $t_2 \in T_T$ such that $t = \text{Node}(t_1, o, t_2)$. By definition of $f_{i+1}$, there are $t, t_1, t_2 \in T$ such that $(t', t) \in f_{i+1}$, $(t, t_1) \in f_i$, and $(t, \text{Node}(t_1, o, t_2)) \in (\iota, left)$. We have shown that $f_{i+1}$ is injective, so $t = t' \in f_i$. Hence, we have $(t', t') \in (\iota, left)$, as desired.

Theorem 2. Let $\varphi$ be an EBU sentence and $M_T$ a term model. Then $\varphi$ holds in $M_T$ iff $\varphi$ holds in some subterm-closed finite substructure $M_0$ of $M_T$.

Proof. We prove both directions of the equivalence.

$(\Leftarrow)$: Suppose that $\varphi$ holds in a subterm-closed finite substructure $M_0 = (T_0, O, \alpha_0)$ where $T_0 \subseteq T_T$. Then $\varphi$ is a bijection $T_0 \to T_T$; it preserves left and right because $f_0$ does, and it preserves content by construction. Therefore, $M_0$ is the desired model and $g$ is the desired isomorphism.
in $M_0$ or $M_T$, the universal quantifiers range only over elements of $T_0$, so they still hold in $M_0$. We next make this argument more precise.

Observe the following properties of set-valued and relation-valued terms in our language, for every structure $M$ and every valuation $\alpha$:

- if $R$ is a relation-valued expression, then
  \[
  [R]^{M_0} \subseteq \{ \text{left} \cup \text{right} \}^{M_0} \tag{2}
  \]
- if $S$ is a set-valued term with free variables $x_1, \ldots, x_n$ on which $\alpha$ is defined, then
  \[
  [S]^{M_0} \subseteq \{ \{x_1, \ldots, x_n\}, \text{left} \cup \text{right} \}^{M_0} \tag{3}
  \]

These properties follow by induction on the size of the expressions $R$ and $S$.

Note also that $M_0$ is a substructure of $M_T$, so by induction on size of $R$ and $S$ we have

\[
[R]^{M_0} = [R]^{M_T} \cap T_0^n
\]

\[
[S]^{M_0} = [S]^{M_T} \cap T_0^n
\tag{4}
\]

In this inductive proof the interesting case is showing (applied the induction hypothesis)

\[
([R_1]^{M_T} \cap T_0^n) \cup ([R_2]^{M_T} \cap T_0^n) = ([R_1]^{M_T} \cup [R_2]^{M_T}) \cap T_0^n
\]

The $\subseteq$ inclusion holds by definition of the relation composition $\alpha$, whereas the $\supseteq$ inclusion follows from (2) and the fact that $M_0$ is substructure closed.

We next show that the truth value of a quantifier-free formula $F$ is the same in $M_0$ and $M_T$ when the variables of $F$ are interpreted in $T_0$. We show by induction on the structure of formula $F$ the following claim:

For all $\alpha : \text{Vars} \to T_0 \cup O$,

\[
[F]^{M_0,\alpha} = [F]^{M_T,\alpha}. \tag{5}
\]

Indeed, (5) holds for atomic formulas by condition (4) and the assumption that $\alpha(x) \in T_0 \cup O$. Moreover, this property is preserved by propositional combinations, so it holds for all boolean combinations.

Finally, given an EBU sentence $\varphi$, we prove the following relationship for all quantified subformulas $F$ of $\varphi$ for all $\alpha : \text{Vars} \to T_0 \cup O$, $[F]^{M_0,\alpha}$ implies $[F]^{M_T,\alpha} = \text{true}$.

The base case corresponds to the previously proved case of quantifier-free formulas. We show that the condition is preserved under existential quantifiers, bounded universal quantifiers, and quantifiers over the finite set $O$. So suppose that $[F]^{M_0,\alpha}$ implies $[F]^{M_T,\alpha}$ for all $\alpha : \text{Vars} \to T_0 \cup O$ and suppose that $\alpha : \text{Vars} \to T_0 \cup O$ and $[F_1]^{M_0,\alpha}$.

- Let $F_1 \equiv \exists y : \text{Tree}. F$. Then there exists $t \in T_0$ such that $[F]^{M_0,\alpha}$ where $\alpha = \alpha[\forall y = t]$. By induction hypothesis $[F]^{M_T,\alpha} = \text{true}$, so $[F_1]^{M_T,\alpha} = \text{true}$.

- Let $F_1 \equiv \forall y : \text{Tree}. F$ for some set expression $S$. Then $[F]^{M_0,\alpha} = \text{true}$ for each $t \in [S]^{M_0,\alpha}$. From (3), (4), $\alpha : \text{Vars} \to T_0 \cup O$ and the fact that $M_0$ is substructure closed, we conclude $[S]^{M_T,\alpha} = [S]^{M_0,\alpha} \subseteq T_0$. Consider arbitrary $t \in [S]^{M_T,\alpha}$, so $[F]^{M_0,\alpha}[\forall y = t] = \text{true}$. Because $t \in T_0$, by induction hypothesis $[F]^{M_T,\alpha}[\forall y = t] = \text{true}$. This proves $[F_1]^{M_T,\alpha} = \text{true}$.

- The cases $F_1 = \exists y : \text{Object}. F$ and $F_1 = \forall y : \text{Object}. F$ are straightforward because the quantifiers are monotonic and the structures $M_T$ and $M_0$ have the same domain of uninterpreted objects $O$.

This completes the proof of one direction of our statement. Note that we have not relied on the fact that $M_T$ is full term model. In fact, this direction still holds for $M_0$ and $M_T$ where $M_0$ is a substructure of $M_T$ and $M_T$ is a substructure of $M_0$ if the EBU sentence holds in $M_0$, then it also holds in the larger substructure $M_0$. We will use this generalization in the proof of the converse direction.

\[\Rightarrow : \text{Let } \varphi \text{ be EBU sentence. We prove by induction that for all subformulas } F \text{ of } \varphi \text{ the following holds: for each } \alpha : \text{Vars} \to T_T, \text{ if } [F]^{M_T,\alpha} = \text{true} \text{, then there exists a finite subterm-closed model } M_0 \text{ and a valuation } \alpha_0 \text{ such that } \alpha_0(x_i) = \alpha(x_i) \text{ for each variable } x_i \text{ free in } F, \text{ such that } [F]^{M_0,\alpha_0} = \text{true}. \text{ The proof of this claim is by induction on the number of quantifiers in } F. \]

For the base case, assume that $F$ is quantifier-free, and let $x_1, \ldots, x_n$ be the variables of $F$. Then let $T_0 = \{ \{x_1, \ldots, x_n\}, \text{left} \cup \text{right} \}^{M_T,\alpha}$ and let $M_0$ be the substructure of $M_T$ induced by $T_0$. Let $\alpha_0(x_i) = \alpha(x_i)$ for $1 \leq i \leq n$ and let $\alpha_0(o) = \alpha(x_i)$ for $n+1 \leq \alpha(x_i) \in O$. Then $\alpha_0 : \text{Vars} \to T_0 \cup O$, so by (5) we have $[F]^{M_0,\alpha_0} = \text{true}$; we have thus identified the desired $M_0$ and $\alpha_0$.

For the inductive step, assume that claim holds for formula $F$, we prove that it holds for $F_1$ which is the result of quantifying $F$. Suppose that $[F]^{M_T,\alpha}$. We consider several cases.

- Let $F_1 \equiv \exists y : \text{Tree}. F$. Then there exists $t \in T_T$ such that $[F]^{M_T,\alpha}$ where $\alpha = \alpha[\forall y = t]$. By induction hypothesis, there exists $\alpha_0$ that agrees with $\alpha$ on free variables of $F$ and a finite subterm-closed model $M_0$ such that $[F]^{M_0,\alpha_0}$. This means that $[F]^{M_0,\alpha_0}$ and $\alpha_0$ certainly agrees with $\alpha$ on the variables free in $F_1$.

- Let $F_1 \equiv \forall y : \text{Tree}. F$. Let $\overline{S} = [S]^{M_T,\alpha}$. Assume first $\overline{S} \neq \emptyset$. Then for each $t \in \overline{S}$, if $\alpha(t) = \alpha[t_i = t]$, then $[F]^{M_T,\alpha}$. By induction hypothesis there exists a model $M_0(t) = (T_0(t), O, \alpha(t))$ and a valuation $\alpha(t)$ such that $[F]^{M_0(t),\alpha(t)}$ and $\alpha(t)$ agrees with $\alpha(t)$ on the free variables of $F$. Then let

\[T_0 = \overline{S} \cup \bigcup_{t \in \overline{S}} T_0(t)\]

Let $T_0$ be the subterm closure of $T_0$, given by $T_0 = T_0 \cup \{ t \in \overline{S}, t \in \text{subterm}^{M_T,\alpha} \}$. The union $T_0$ is finite because $S$ is finite, and each $T_0(t)$ is finite. Therefore, the subterm closure $T_0$ is finite, so there exists a finite subterm-closed structure $M_0 = (T_0, O, \alpha(t))$. By the generalized version of ($\Rightarrow$), we have

\[M_0(t) \subseteq M_0 \]

where $t \in \overline{S}$ is arbitrary. Next, consider the special case $\overline{S} = \emptyset$. Let

\[T_0 = \{ x_1, \ldots, x_n \}, \text{left} \cup \text{right} \]
• \( F_1 \equiv \exists v_0 :: \text{Object, } F \). This case is analogous to the case \( F_1 \equiv \exists v_2 :: \text{Tree, } F \).

• \( F_1 \equiv \forall v_0 :: \text{Object, } F \). This case is similar to the case \( F_1 \equiv \forall v_0 :: \text{Tree, } F \), but slightly simpler. For each \( o \in O \), if \( \alpha(o) = \alpha[v_0 \leftarrow o] \), then \( [F]^{M_\mathcal{T} - \alpha(\mathcal{O})} \), so by induction hypothesis there exists a model \( M_0(o) = (T_0(o), O, \iota_0(o)) \) and a valuation \( \alpha_0(o) \) such that \( [F]^{M_0(o) - \alpha_0(o)} \), and \( \alpha_0(o) \) agrees with \( \alpha(o) \) on free variables of \( F \). Then let

\[
T_0 = \bigcup_{o \in O} T_0(o)
\]

The union \( T_0 \) is finite because \( \mathcal{S} \) is finite, and each \( T_0(t) \) is finite. \( T_0 \) is also subterm closed because each \( T_0(o) \) is subterm closed. Therefore, there exists a finite subterm-closed structure \( M_0 = (T_0, O, \iota_0) \). By the generalized version of the \( (\Rightarrow) \) direction, because \( M_0(o) \) is a substructure of \( M_0 \), we have that \( [F]^{M_0 - \alpha_0(\mathcal{O})} \) for each \( \alpha \in O \). We conclude \( [F_1]^{M_0 - \alpha_0(\mathcal{O})} \) where \( \alpha_1 \in O \) is arbitrary.
