Investigating the Pathway of Asparagine-Linked Glycoprotein Biosynthesis

by
Mary O'Reilly

Submitted to the Department of Chemistry

Requirements for the Degree of Doctor of Philosophy

ABSTRACT

The biosynthesis of asparagine-linked glycoproteins, highly conserved throughout all eukaryotes, requires a dolichylpyrophosphate-linked tetradecasaccharide precursor (Dol-PP-GlcNAc₂Man₆Glc₃), from which the tetradecasaccharide is transferred co-translationally to nascent polypeptides in the lumen of the ER by the multimeric membrane-bound enzyme, oligosaccharyl transferase (OT). The saccharide donor is assembled by a series of membrane-bound enzymes, which together comprise the dolichol pathway.

Despite over two decades of genetic and bioinformatics approaches that have identified the vast majority of dolichol pathway genes in yeast, the roles of two mannosyltransferases in the pathway, Alg2 and Alg11, remained ambiguous. This thesis describes the biochemical studies that were carried out to clarify these roles. The substrate specificity of Alg1, the first mannosyltransferase in the pathway, was studied, and this enzyme was also used as a tool to prepare Man β 1,4-GlcNAc₂-PP-Dol from synthetic GlcNAc₂-PP-Dol. Access to this trisaccharide intermediate facilitated the characterization of Alg2 function, proposed to be involved in addition of the second and/or third mannose. A cell membrane fraction isolated from *E. coli* overexpressing thioredoxin-tagged Alg2 was used to demonstrate that this enzyme carries out an α 1,3-mannosylation, followed by an α 1,6-mannosylation, to form the branched pentasaccharide intermediate of the dolichol pathway. Having the means to access this intermediate chemoenzymatically, it was thus possible to define the function of Alg11, which had similarly been proposed to catalyze addition of the fourth and/or fifth mannose. Using the same procedure, TRX-Alg11 was shown to catalyze two sequential α 1,2-mannosylations onto the α 1,3-branch of the pentasaccharide substrate to afford the heptasaccharide intermediate. The elucidation of the dual function of each of these enzymes thus completes the identification of the entire ensemble of glycosyltransferases that comprise the dolichol pathway.

Finally, peptidyl mimics based on the consensus site for glycosylation by OT on nascent polypeptides, Asn-Xaa-Thr/Ser, were designed and evaluated. Both substrate-based peptide isosteres and product-based neoglycoconjugates were used to investigate the conformational and stereoelectronic preferences of OT binding. Neoglycoconjugates also showed promise as inhibitors of the deglycosylating enzyme Peptide: *N*-glycanase (PNGase), which aids in the degradation of misfolded proteins in the secretory pathway.

Thesis Supervisor: Barbara Imperiali

Title: Class of 1922 Professor of Chemistry and Professor of Biology

Acknowledgements

My advisor, Professor Barbara Imperiali, and I began our journeys at MIT together, and it has been a great pleasure to share mine with her. Her enthusiasm and good humor set the tone for our open and exceedingly supportive working environment, which she very skillfully maintains. I am also grateful for her patience and her understanding. I would also like to thank my thesis committee, Professors JoAnne Stubbe, Cathy Drennan, and Sarah O'Connor, for the generosity with which they share their time, advice, and support.

For the fact that I am here at MIT to begin with, I am indebted to Professor Jean Chmielewski. Not only did she give me the opportunity to work in her lab as an undergraduate, her excitement and creativity inspired me to pursue graduate school. In the end it was her encouragement and her support that brought me here.

I have been fortunate to collaborate with a number of former and current members of the lab on a variety of endeavors. Vincent Tai taught me the secrets of working with dolichyl compounds, Stephane Peluso taught me peptide synthesis with the beloved hula shaker, Maria de L. Ufret set the bar high with the skill and speed that she demonstrated with the OT assay, and Sarah O'Connor and Carlos Bosques were so helpful to me that it is hard to believe now that we didn't actually work together. I have recently been extremely lucky to have Guofeng Zhang join forces with me, and thanks to him there is a story to tell about Alg11 in this thesis.

For showing great prowess at the MALDI, I have Langdon Martin and Matthieu Sainlos to thank. Very big thanks also go to Jebrell Glover, not only for sharing his expertise with me, especially in the cell membrane prep, but for selflessly assuming the role of Imperiali lab expert in all things biological. For the survival of my computer, I have Melissa Shults, and her patience, to thank.

I would like to thank everyone in the lab for cheering me on through the writing of this thesis, especially Eranthie Weerapana, Bianca Sculimbrenne, and Beth Vogel, for reading portions of it. Not only has Eranthie read nearly every chapter of this thesis, she has also been an incredible resource, as I was clever enough to wait for her to go through the process first.

So many of my labmates, former and current, have been much more than that to me, and I thank them for their friendship. Rob Dempski set a great example for critical thinking and at the same time was fun outside of the lab. I am also grateful to Mark Nitz, for challenging me and inspiring me, and for good advice both in and out of the lab, and to Kathy Franz, whose eagerness to solve problems outside of just her own created a stimulating environment. When Eranthie Weerapana joined the lab a year after me, I was asked to take her under my wing. The irony of that situation continues to astound me, considering how much I have come to look up to her. Not only has she been willing to let me "hurt her brain" in thinking through innumerable experimental details with me, she has also sustained me through some extraordinarily difficult decisions with wisdom and compassion, and for all these things I thank her. Many thanks also go to Seungjib Choi, for being a fountain of synthetic advice, and for his realism. To Elvedin Lukovic, for his enormous heart, his humor, and for selflessly defending against awkward silences in any situation. To Galen Loving, for making us all laugh at life, and especially

ourselves, with his poignant grasp of humanity. To Bianca Sculimbrene, for her infectious personality and her no-nonsense good advice, which has often been much appreciated. To Matthieu, for reminding me that enjoying life is not incompatible with working hard, and for the self-sacrifice he has shown in helping me in many ways to get through these last few months. To Dora Cidalia Almeida Carrico-Moniz, for having the longest name I've ever seen, and also for being the most genuine person I think I have ever known. Thank you for your encouragement at every turn. To Langdon Martin, for his eager willingness to take on any responsibility, from sushi coordinator to minimeeting entertainer. To Anne Reynolds for being a great cubby-mate. I'm glad that I have had the opportunity to get to know her. And to Beth, for her indefatigable good cheer, and for introducing me to the poet, Rumi, who said:

“Look as long as you can at the friend you love,
no matter whether that friend is moving away from you
or coming back toward you.”

Thanks to everyone else who has made this journey so much more rewarding, from beginning to end. To Kevin McDonnell, Adam Mezo, Jen Ottesen, Dierdre Pierce, Paula Eason, Peter Soderman, Mike Shogren-Knaak, Nathalie Jotterand, for welcoming me into the lab and making it feel like home. To those I have seen come and go, including Mayssam Ali, Soonsil Hyun, Harm Brummerhop, Eugenio Vasquez, Debbie Rothman, Christina Carrigan, Christian Hackenberger, and to those who remain, Debbie Pheasant, Nelson Olivier, Andreas Aemissegger, Ryu Yoshida, Mark Chen, Angelyn Larkin, Meredith Hartley, Brenda Goguen, and Wendy Iskenderian. I am glad to know that Mark, Angelyn, and Meredith will be here in the years to come to continue the pursuit of the challenging but rewarding adventure that is “glyco”.

I would also like to thank my family. My uncle Joe and his family have opened their home to me for the past several years. I will miss having Thanksgiving and Easter in Connecticut. I am grateful to my father for passing down to me his sense of wonder, and to my mother for helping me with my math homework, from grade school through college. Their unique blend of strengths has made them a fantastic team by which to be guided. My brother, Kevin, who inherited all of the common sense, is nevertheless always willing to share it with me, and I am grateful to him for that. I can also count on grounding from Shelby Johnson. Being inseparable in high school, and then going on to live together for the duration of college, meant that we would either end up despising each other or being friends for life. I am glad that it is the latter, though there were some close calls... as her friendship has been a constant source of strength. The support that I have had from my family and all of my friends has been overwhelming, and I appreciate them all immensely.

Und	undecaprenyl
UPR	Unfolded Protein Response
Xaa	used to denote any amino acid

Chapter I: Introduction

Asparagine-linked protein glycosylation is one of the most prevalent, and also most complicated, protein modifications known. Due to the wide variety of monosaccharide units, glycosyl linkages, branching of oligosaccharides, and diversity of processing by glycosyltransferases and hydrolases, glycans on mature glycoproteins represent a highly heterogeneous population.¹ Unlike DNA and protein biopolymers, such non-templated diversity allows for a fine-tuning of the functions of glycans.² The biological roles of *N*-linked glycans are numerous, and include facilitation of protein folding, oligomerization, and structural stability, control of intracellular trafficking, secretion, and catalytic activity of enzymes, protection from proteases, as well as regulation of the expression of receptors on the cell surface and cell-cell adhesion.³ In viral glycoproteins, such as GP120 in Human Immunodeficiency Virus (HIV) and hemagglutinin in the influenza virus, *N*-linked glycans serve to modulate antigenicity, evade the immune system, aid in fusion and infectivity, and to help support virion production.

In contrast to the vast heterogeneity of mature glycoproteins, the initial protein glycosylation occurs through the co-translational transfer of a homogeneous tetradecasaccharide donor containing *N*-acetylglucosamine (GlcNAc), mannose (Man), and glucose (Glc) units from the dolichylpyrophosphate-linked donor, Glc₃Man₉GlcNAc₂-PP-Dol, to an asparagine residue within the consensus sequon, Asn-Xaa-Thr/Ser.⁴ This transfer is mediated by the multimeric, membrane-bound enzyme, oligosaccharyltransferase (OT).⁵⁻⁷ It is the glycosidase-mediated trimming, first in the ER and then in the Golgi, and the Golgi glycosyltransferase-mediated elaboration that creates the eventual diversity.⁸ The rate of glycosylation must meet the demands of protein

synthesis, and therefore the machinery for the biosynthesis of the tetradecasaccharide donor (Glc₃Man₉GlcNAc₂-PP-Dol), as well as the glycosylation and protein synthesis machinery must be co-localized and intimately coordinated. This thesis will focus primarily on biochemical studies toward understanding the glycosylation steps carried out by the glycosyltransferases comprising the dolichol pathway (Chapters II-V). This thesis will also address the protein glycosylation and deglycosylation steps involved in glycoprotein biosynthesis and quality control, respectively.

Overview of *N*-linked glycoprotein biosynthesis

The secretory pathway of eukaryotes begins on the cytosolic face of the ribosome-docked rough ER. The events occurring from the initiation of protein synthesis to glycosylation involve the precise orchestration of the ER machinery depicted in Figure I-1.^{6,9,10} Ribosomes are targeted to the ER membrane upon translation of a hydrophobic N-terminal signal sequence, which is a feature of proteins expressed in the secretory pathway, including secreted, membrane-bound, and lysosomal proteins. The signal sequence is recognized by the membrane-bound signal recognition particle, thus recruiting the ribosome to the cytosolic face of the rough ER membrane. Here, the growing polypeptide chain is guided through a pore in the membrane created by the translocon. As the nascent polypeptide emerges from the membrane into the lumen of the ER, a signal peptidase (Sec11p in yeast) is present to cleave the signal sequence (though not all signal sequences are removed). OT, also present at the site of the translocon, glycosylates Asn-Xaa-Thr/Ser sequons once they have cleared the membrane surface by approximately fourteen residues, using the tetradecasaccharide donor provided

by the dolichol pathway.¹¹ Not all of these sequons are glycosylated, and it is generally believed that the neighboring sequences and local conformational preferences may play a role in transfer to a particular sequence. Details of sequon usage are still being examined.

Figure I-1. Protein synthesis and glycosylation machinery in the secretory pathway.

As the biosynthesis of the nascent glycoprotein is proceeding, protein folding ensues. The extent of folding that occurs prior to release from the ribosome is still unclear. To ensure that only correctly folded proteins are produced, eukaryotes have evolved an intricate quality control system, as depicted in Figure I-2.^{2, 12, 13} The first steps (in the center of the figure below the membrane) are sequential deglycosylation of the two terminal glucose residues by Glucosidase I and Glucosidase II. The monoglucosylated form of the oligosaccharide is then specifically recognized by the lectin (or carbohydrate-binding) domain in calnexin (CNX) or calreticulin (CRT). These chaperones, with seemingly overlapping functions, are highly homologous to each other, with the major difference being that CNX (not shown in the figure) is membrane-bound, while CRT is a soluble protein in the ER lumen. This lectin/oligosaccharide interaction is

believed to sequester the glycoproteins, affording them an opportunity to fold before aggregation can occur, and these chaperones also aid in the folding process by recruiting the protein disulfide isomerase-like protein, ERp57. By the action of Glucosidase II, the final glucose is removed, thus lowering the affinity of the lectin site for the saccharide and favoring glycoprotein release.

Figure I-2. Quality control pathway of nascent glycoprotein folding.

Upon release from CRT or CNX, proteins may complete the folding process and then be transported out of the ER in vesicles to undergo saccharide trimming and elaboration in the Golgi. However, misfolded proteins are recognized by the UDP-Glc:

glycoprotein glucosyltransferase (UGGT), and reglucosylated on the Man₉GlcNAc₂ core. Regeneration of the monoglucosylated species allows rebinding to CRT or CNX, thus prolonging the opportunity for glycoproteins to fold properly. Glycoproteins may go through several rounds of deglycosylation and glucosylation in what is known as the calnexin/calreticulin (CNX/CRT) cycle, during which time the UGGT effectively acts as a sensor for misfolded protein. This sensing behavior occurs with delicate specificity that favors neither fully folded nor fully misfolded proteins, presumably by recognizing hydrophobic patches on proteins.¹⁴ However, misfolded glycoproteins not associated with CRT/CNX can also be recognized by an α 1,2-mannosidase, ER Mannosidase I, which removes a single mannose from the middle branch of the triantennary oligosaccharide species. This species is recognized by the ER degradation-enhanced alpha mannosidase-like protein (EDEEM), and is then destined for ER-assisted degradation (ERAD). Thus, nascent proteins that are unable to fold properly do not remain CNX/CRT cycle *ad infinitum*. Upon retrotranslocation to the cytosol, misfolded glycoproteins are ubiquitinated by the action of ubiquitin-conjugating enzyme (E2) and ubiquitin ligase (E3), deglycosylated by the soluble enzyme Peptide: *N*-glycanase (PNGase), and finally degraded by the proteasome. PNGase acts by cleaving the asparagine amide to release the glycan in a manner similar to cysteine proteases. Through the chemical synthesis of the relevant oligosaccharide species, molecular-level details of the specificity and binding affinities of lectin-like domains in UGGT, CRT, and E3 have been elucidated.^{15, 16}

Overview of the dolichol pathway

To accomplish the biosynthesis of the dolichylpyrophosphate-linked tetradecasaccharide (Glc₃Man₅GlcNAc₂-PP-Dol) donor for *N*-linked protein glycosylation (Figure I-3), a series of membrane-bound glycosyltransferases that comprise the dolichol pathway catalyze the sequential transfer of monosaccharide units onto a membrane-bound dolichylpyrophosphate carrier.^{4, 17-19}

Figure I-3. A) Structure of the tetradecasaccharide product of the dolichol pathway. The gray background highlights the saccharides that are transferred on the cytosolic face of the ER membrane. B) Cartoon diagram of the tetradecasaccharide product indicates the configuration of the glycosidic linkages. (black squares, GlcNAc; gray circles, Man; black circles, Glc; P, phosphate).

As shown in Figure I-4, The first seven transferases, including one glycosylphosphate transferase and six glycosyltransferases, build up the intermediate $\text{Man}_5\text{GlcNAc}_2\text{-PP-Dol}$ on the cytoplasmic face of the ER membrane prior to translocation of the intermediate to the luminal face of the membrane. The topology of these events was established by testing the sensitivity or resistance of the glycosyltransferase activities in intact vesicles to proteases, and the recognition of dolichylpyrophosphate-linked saccharide intermediates to the mannose-specific lectin, Concanavalin A.^{20, 21}

Figure I-4. The sequence and topology of the glycosyltransferase steps, with the proposed enzyme associated with each step indicated. (black squares, GlcNAc; gray circles, Man; black circles, Glc; P, phosphate; wavy lines, dolichyl group).

The translocation, or “flipping”, of the heptasaccharide intermediate has long been suspected to be protein-dependent, but only recently was a candidate gene, *RFT1*, identified.²² The mechanism of this process is still unknown, and it does not appear to be

ATP-dependent. Some evidence exists for the dolichyl-induced modification of phospholipid packing of the membrane to induce a hexagonal phase.²³ This disruption of the bilayer may aid in the flipping of the heptasaccharide. Interestingly, NMR studies of dolichol reveal a coiled structure in membrane-mimicking environments that may contribute to membrane disruption.²⁴⁻²⁶ Structures solved with the addition of native peptides taken from transmembrane-spanning regions of dolichyl-binding proteins revealed altered conformations that may also be expected to affect the membrane packing in conjunction with dolichol.

Once translocation has occurred, the remaining glycosyltransferases act on the luminal side of the membrane to complete the assembly of the tetradecasaccharide. To ensure the proper assembly of *N*-linked glycoproteins, this assembly process follows a strict order of addition, and both Rft1 and OT are believed to demonstrate a strong preference for the heptasaccharide and tetradecasaccharide structures, respectively.^{22, 27} These features are important, as the proper assembly of the full oligosaccharide is crucial for the recognition of nascent glycoproteins by the lectins of the quality control pathway for the prevention of misfolded protein production.

Glycosyl donor substrates for oligosaccharide biosynthesis

The glycosyl donors that provide the monosaccharide units for the growing oligosaccharide differ in the activating group, depending on whether these substrates are being used in the cytosol or in the ER lumen (Figure I-5).¹⁸ In the cytosol, the nucleotide-activated sugars UDP-GlcNAc and GDP-Man, which are not

transported into the ER lumen, are used as substrates. Dolichylphosphate-linked monosaccharide donors, Man-P-Dol and Glc-P-Dol, are used as substrates in the lumen for the final seven glycosylation steps. These dolichylphosphate-linked substrates are biosynthesized on the cytoplasmic face of the ER membrane from Dol-P and the nucleotide-activated sugars, GDP-Man and UDP-Glc, by Dpm1 and Alg5 (*S. cerevisiae*), respectively, and then undergo a translocation to face the lumen. There are not yet any candidate proteins for these translocation processes, but studies in liposomes argue against passive transport.²⁸ While the absence of GDP-Man in the lumen makes Man-P-Dol transport necessary, it is not clear why Glc-P-Dol must be synthesized in the cytosol, since UDP-Glc does get transported into the lumen.

Figure I-5. Summary of the activated monosaccharide donor substrates for the glycosyltransferases in the dolichol pathway. (black squares, GlcNAc; gray circles, Man; black circles, Glc; P, phosphate; wavy lines, Dol; open arrows indicate translocation).

Biosynthesis and recycling of the carrier group, dolichyl phosphate (Dol-P)

Dolichyl phosphate (Dol-P) acts as the carrier for the growing oligosaccharide chain, anchoring it to the membrane, where the glycosyltransferases that transfer the saccharide units reside. In yeast, the biosynthesis of dolichol begins along the same path as sterol and ubiquinone biosynthesis up to the farnesylpyrophosphate intermediate, and then synthesis is completed by a *cis*-prenyltransferase-catalyzed condensation of isopentenylpyrophosphate groups.^{29, 30} Pre-steady state kinetics and X-ray crystallographic data for the *cis*-prenyltransferase family are beginning to reveal how chain length is controlled in polyisoprene biosynthesis, and site-directed mutations have been demonstrated to produce altered chain lengths.^{31,32} To convert the polyisoprenoid to dolichol, a polyprenol reductase reduces the double bond in the α -isoprene unit, though the details of this step remain unclear.³³ To initiate entry into the dolichol pathway, dolichol is then phosphorylated by a CTP-dependent kinase, an activity that has been assigned to *SEC59* in *S. cerevisiae* and *hDK1* in humans.^{34,35} The subsequent pool of Dol-P is available for Man-P-Dol, Glc-P-Dol, and GlcNAc-PP-Dol synthesis, and it has been shown that all three synthases compete for the same pool of Dol-P.³⁶

Recycling of Dol-P can occur via three sources (Figure I-6). Following the transfer of the tetradecasaccharide donor to nascent proteins, Dol-PP is generated. A dolichyl pyrophosphate phosphatase has now been identified in both *S. cerevisiae* (*CWH8*) and in mammalian cells. This enzyme removes the terminal phosphate and, at a slower rate, the remaining phosphate to generate dolichol.^{37, 38} Similarly, the luminal glycosyltransferases generate Dol-P upon transfer of Man or Glc from Man-P-Dol or Glc-

P-Dol, respectively. Dol-P can then be dephosphorylated, and dolichol is believed to freely diffuse through the ER membrane to return to the cytosolic face, where the dolichol kinase regenerates Dol-P.

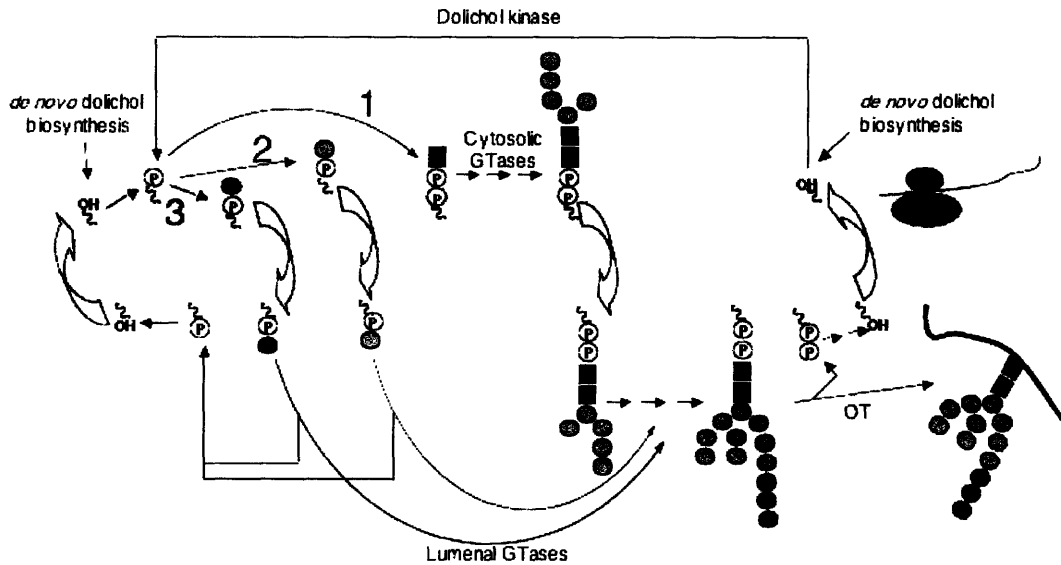

Figure I-6. The three possible paths of dolichyl phosphate are conversion to GlcNAC-PP-Dol (1), Man-P-Dol (2), or Glc-P-Dol (3), and the byproducts of these reactions are used to recycle dolichol through the action of a pyrophosphatase. (black squares, GlcNac; gray circles, Man; black circles, Glc; P, phosphate; wavy lines, dolichyl group; open arrows indicate translocation; straight arrows indicate recycling pathway).

The glycosyl-1-phosphate transferase and glycosyltransferases of the dolichol pathway

The first GlcNAc is added to the dolichyl phosphate carrier by the transfer of GlcNAc-phosphate from UDP-GlcNAc by the enzyme GlcNAc phosphotransferase (GPT), also known as Enzyme I.³⁹ This step is inhibited by the natural product tunicamycin. Exploiting the specific inhibition by this natural product, *ALG7* was identified as the gene responsible for this transformation by screening segments of the *S. cerevisiae* genome to find the sequence that, upon overexpression, conferred resistance to tunicamycin.⁴⁰ Alg7 is a 448-residue, 50 kDa, enzyme with nine predicted transmembrane domains (Table I-1).⁴¹ Oligomerization of this enzyme has been proposed based on chemical crosslinking studies and dominant negative effects of co-expressing wild-type with mutant GPT enzymes from hamster microsomal membranes.⁴² While partial purification from solubilized microsomes has enabled some biochemical characterization, the large number of transmembrane domains makes it challenging to overexpress and purify using current technologies.

The enzyme responsible for the second GlcNAc transfer, referred to as Enzyme II due to its position in the pathway,³⁹ had remained elusive until very recently, despite numerous genetic screens for defects in this pathway. Bioinformatics has become a powerful tool for identifying genes based on sequence homology to enzymes with a similar function. In the case of Enzyme II, an analogous step is carried out in bacterial cell wall peptidoglycan biosynthesis by the UDP-GlcNAc undecaprenyl-PP-MurNAc pentapeptide: *N*-acetylglucosaminyltransferase known as MurG.⁴³⁻⁴⁵ Due to the similarity

in function with Enzyme II, the sequence of MurG was used to search for homologous sequences that may correspond to that of Enzyme II. A small yeast protein, YGL047w, was identified by searching within the protein family (PF03033) to which the C-terminal domain of MurG belongs.⁴⁶ However, due to the small size and the lack of a signal sequence and transmembrane domains, YGL047w initially seemed an unlikely candidate for Enzyme II activity. A search for mammalian sequences in the PF03033 family that are similar to the N-terminal domain of MurG was carried out with no success. Cps14g, a glycosyltransferase involved in bacterial capsular polysaccharide biosynthesis, also bears similarities to the C-terminal domain of MurG, and has an accessory protein, Cps14f, that is critical for full activity.⁴⁷ Thus, by homology to Cps14f, the yeast protein YBR070c was identified, which contains a signal sequence and 1-2 predicted transmembrane domains.⁴⁶ Down-regulation of either YBR070c or YGL047w in yeast leads to defects in growth and glycosylation.^{46, 48} Evidence that an accumulation of GlcNAc-PP-Dol results from down-regulation of either of these genes implicated both gene products in the second step of the dolichol pathway.^{46, 48} Thus, the Enzyme II activity was assigned to YGL047w and YBR070c, which were designated *ALG13* and *ALG14* (Table I-1). Physical interaction between Alg13 and Alg14 was demonstrated by co-fractionation of these proteins upon affinity chromatography of Alg14, and localization studies showed that Alg14 is capable of recruiting the soluble Alg13 to the cytoplasmic face of the ER membrane.^{48, 49} Current work in the Imperiali lab is focused on validating the function of these proteins *in vitro*, and research has shown that both subunits are necessary and sufficient for the transfer of GlcNAc from UDP-GlcNAc to Dol-PP-GlcNAc to form the disaccharide intermediate in the dolichol pathway.⁵⁰

Table I-1. Summary of dolichol pathway enzymes

ALG1, the yeast gene responsible for the first mannosylation step that forms the Man β 1,4-GlcNAc β 1,4-GlcNAc-PP-Dol intermediate was identified by a yeast genetic screen known as mannose suicide selection that isolates mutants deficient in *N*-linked glycoprotein biosynthesis.⁵¹ Mutants with temperature-sensitive phenotypes were identified by the ability to grow at the permissive temperature after metabolic labeling with tritiated mannose followed by long-term storage. Cells with normal levels of glycosylation were less likely to survive the prolonged radiation damage due to the high-

mannose characteristic of yeast glycoproteins. Alg1 is a 449-residue, 52-kDa, enzyme with one predicted transmembrane domain at the N-terminus (Table I-1).⁴¹ Based on immunoprecipitation and gel filtration experiments of detergent-solubilized Alg1, it appears that this enzyme oligomerizes, though the extent to which this occurs and the physiological relevance are not yet known.⁵² Alg1 is discussed further with respect to substrate specificity in Chapter III.

For the final four cytosolic mannosylation steps, only two candidate genes have been identified. It has been suggested that Alg2 is responsible for either the first, second, or both the first and second mannosylation steps,⁵³⁻⁵⁷ and that Alg11 is responsible for either the third, fourth, or both the third and fourth mannosylation steps (Figure I-4).^{7, 52, 58} The fact that both *ALG2* and *ALG11* are essential genes precludes the use of complete deletion strains to clarify the roles of these enzymes, although plasmids containing these genes were able to complement the defects in *alg2* and *alg11* yeast mutants, respectively.^{54, 58} The use of bioinformatics has greatly facilitated the identification of missing enzymes such as Alg12 and Alg13/14, but no candidates have been generated for any remaining mannosyltransferase activities.

Although Alg2 mutants have been identified and characterized in *S. cerevisiae*,⁵³ *R. pusillus*,⁵⁶ and human,⁵⁷ the results have not been entirely consistent. The yeast mutants, *alg2-1* and *alg2-2*, which have a temperature-sensitive phenotype, each contain two point mutations, with one in common, G377R, that is sufficient to confer temperature-sensitivity.⁵⁵ The human mutation results in a truncated gene product due to a frame shift that introduces a premature stop codon. None of these mutations, in yeast or human, affects the part of a conserved signature sequence

(XHXGXXXXEXXXGXXP) that is shared by a number of other glycosyltransferases involved in a wide range of functions in carbohydrate metabolism, including Alg11 and MurG.⁵⁹ In the Alg2 sequence, as well as Alg11 and many other glycosyltransferases from the same Pfam family,⁶⁰ the signature sequence also contains a conserved EX₇E motif (Figure I-7). The first Glu residue of this motif corresponds to the residue immediately N-terminal to the His residue in the signature sequence, and the second Glu corresponds to the conserved Glu in the signature sequence. Both the human and yeast mutants, with intact signature sequences, accumulate dolichylpyrophosphate-linked trisaccharide and tetrasaccharide intermediates. In contrast, the mutation found in the filamentous fungi, *R. pusillus*, leads to a truncation of Alg2 that is more severe than that found in the human mutant, resulting in a loss of the signature sequence and an accumulation of only the trisaccharide intermediate.⁵⁶ Interestingly, *ALG2* is not an essential gene in this organism, and due to the severity of the mutation described in this study, the mutant may in effect represent an *ALG2* deletion strain. Alg2 from *S. cerevisiae* is a 503-residue, 58-kDa mannosyltransferase containing four predicted transmembrane domains, with one pair of domains at the extreme C-terminus, and another pair of domains located near the N-terminus, as predicted by the TMHMM server, v. 2.0 (Table I-1).⁴¹ Chapter IV describes the biochemical validation that was carried out to show that Alg2 is responsible for both the α 1,3- and the α 1,6-mannosylation steps to form the core pentasaccharide, Man α 1,3-(Man α 1,6)-Man β 1,4-GlcNAc β 1,4-GlcNAc-PP-Dol.

Figure I-7. Summary of Alg2 mutants characterized to date, highlighting the conserved signature sequence also shared by Alg11.

A yeast mutant, *alg11*, was isolated based on resistance to sodium vanadate and shown to affect glycosylation at an early step in the pathway.^{61, 62} Efforts to define the precise step for which Alg11 is responsible included extensive characterization of accumulated dolichylpyrophosphate-linked saccharide intermediates and glycoproteins extracted from *alg11* mutant cells.⁵⁸ While non-specific translocation into the lumen and elongation by the luminal glycosyltransferases complicated the interpretation of these studies, Alg11 was proposed, based on these results, to catalyze the fourth or fifth mannosylation. In later studies on the translocation of intermediates from the cytosol to the lumen by Rft1, *alg11* mutant yeast cells were found to accumulate the dolichylpyrophosphate-linked GlcNAc₂Man₃ intermediate prior to the flipping step, suggesting that Alg11 may be responsible for the fourth mannosylation.²² Alg11 from *S. cerevisiae* is a 548-residue, 63-kDa, protein with one predicted transmembrane domain at the N-terminus, as predicted by the TMHMM server, v. 2.0 (Table I-1).⁴¹ Alg2 and Alg11 have been found to interact in separate subcomplexes with Alg1, though not with one another.⁵² Chapter V describes the biochemical characterization that was carried out

to show that Alg11 is responsible for the two α 1,2-mannosylation steps that convert the pentasaccharide intermediate to the heptasaccharide intermediate, $\text{Man}\alpha$ 1,2- $\text{Man}\alpha$ 1,2- $\text{Man}\alpha$ 1,3-($\text{Man}\alpha$ 1,6)- $\text{Man}\beta$ 1,4-GlcNAc- β 1,4GlcNAc-PP-Dol.

The luminal glycosyltransferases are all multi-transmembrane spanning enzymes that use dolichyl-linked substrates as both glycosyl donor and glycosyl acceptor. Since the later steps in the dolichol pathway are not essential for viability, and the glycosylation defects are much more mild, it is more difficult to identify phenotypes associated with defects in these later steps. This limitation can be overcome by generating synthetic lethal mutants. In these screens, mutants are made in combination with mutations in OT subunits that decrease the efficiency of transfer of the truncated saccharides to protein, leading to underglycosylation and a pronounced effect of the desired phenotype.

The first Man-P-Dol dependent mannosyltransferase was discovered by a number of yeast genetic screens. The *alg3* mutant was characterized by accumulation of $\text{Man}_5\text{GlcNAc}_2\text{-PP-Dol}$.⁵³ The *ALG3* gene was later isolated, and found to be a 53.5-kDa enzyme with multiple predicted membrane-spanning domains (Table I-1).⁶³ Isolation of Alg3 by immunoprecipitation from a yeast solubilized extract enabled the validation of Alg3 as the mannosyltransferase responsible for the first luminal mannosyltransfer to form $\text{Man}_6\text{GlcNAc}_2\text{-PP-Dol}$.⁶⁴ Alg3 was further found to act, surprisingly, in a metal-independent fashion, making it the only metal-independent transferase in the pathway.

An *alg9* mutant was isolated that had a synthetic lethal phenotype at 30 °C with a mutant of the OT subunit, *wbp1*.⁶⁵ This mutant was found to accumulate the $\text{Man}_6\text{GlcNAc}_2\text{-PP-Dol}$ intermediate, and *ALG9* was therefore assigned the function of the α 1,2-mannosyltransferase directly following the Alg3 step. Recently, microsomes from

an *alg9* mutant strain were shown to elongate a Man₇GlcNAc₂-PP-Dol intermediate to Man₈GlcNAc₂-PP-Dol, with no evidence of further elongation, suggesting that Alg9 may also carry out the second α 1,2-mannosylation step in the lumen to form the Man₉GlcNAc₂-PP-Dol intermediate.⁶⁶ While historically it has been assumed that one glycosyltransferase can only be responsible for the formation of one glycosidic linkage, examples are now emerging that challenge this view. For example, in *S. cyanogenus*, Landomycin A biosynthesis involves the assembly of a hexasaccharide moiety by two monofunctional and two bifunctional glycosyltransferases.⁶⁷ In *Campylobacter jejuni*, the α 1,4-*N*-acetylgalactosaminyltransferase, PglH, acts iteratively to transfer three GalNAc units to the growing oligosaccharide chain in the recently discovered Pgl pathway of *N*-linked glycoprotein biosynthesis, which has many similarities to the dolichol pathway.⁶⁸

The remaining mannosyltransferase in the pathway is encoded by *ALG12* and is assigned to the α 1,6-mannosyltransferase activity in between the two Alg9-mediated steps based on the accumulation of the Man₇GlcNAc₂-PP-Dol intermediate. This gene was first identified in a yeast screen for mutants that affected cell surface biosynthesis.⁶⁹ The role of Alg12 in the dolichol pathway was later uncovered by using the Alg9 sequence in a database searching algorithm used to identify candidate luminal mannosyltransferases.²⁷ The phenotype of the *alg12* mutant is very mild, and full glucosylation is often observed.⁷⁰

Finally, *ALG6*, *ALG8*, and *ALG10* are responsible for the three glucosylations that complete the biosynthesis of the core oligosaccharide.⁷¹⁻⁷³ While Alg6 and Alg8 are highly homologous and catalyze the same linkage formation, they do not complement one another *in vivo*. Similarly, Alg10 is not able to glucosylate the monoglucosylated

saccharide intermediate. Further highlighting the specificity of the glucosyltransferases, an *alg3* mutant strain transfers the accumulated heptasaccharide intermediate to protein, and only trace amounts of the glycan were found to be glucosylated.⁷⁴

Oligosaccharyltransferase

The dolichol pathway culminates in the OT-catalyzed transfer of the complete tetradecasaccharide structure to Asn in nascent polypeptides in the reaction shown in Figure I-8.

Figure I-8. The glycosylation reaction catalyzed by OT.

While OT has a strong preference for the complete tetradecasaccharide, transfer of truncated saccharides is observed in the analysis of glycoproteins in mutants that are deficient in some step of the dolichol pathway.⁷⁵ In yeast, there is evidence for transfer of intermediates as limited as the trisaccharide, ManGlcNAc₂, which also highlights the relaxed specificity of the flippase, Rft1, in mutant yeast strains.⁷⁵ However, the efficiency of glycosylation is severely reduced in these cases, and *in vitro* studies have revealed a significant degree of specificity for the full donor oligosaccharide. For

example, the absence of the three Glc units causes a reduction in the rate of transfer by 5 to 20-fold.⁷⁶ More detailed kinetic studies using purified OT from yeast and canine microsome sources have suggested that cooperativity in oligosaccharide donor binding accounts for the observed preference for the fully assembled form.^{7, 76, 77} It has been proposed that there is both a regulatory and a catalytic binding site for the dolichylpyrophosphate-linked donors, and that occupation of the regulatory site tunes the selectivity of the catalytic site by changing the preference for the full-length donor over assembly intermediates. The regulatory site has a similar affinity for the tetradeca- and undecasaccharide donors, and thus, in a mixed population of intermediates, will bind a representative sample of the population. In the presence of incomplete intermediates, binding in the regulatory site changes the preference of the catalytic site for the full-length over truncated intermediates from 1.5-fold to 7 to 10-fold higher. This modulation would ensure that in the presence of truncated sugars, the binding of the full-length donor is favored.

GlcNAc₂-PP-Dol is a well-established substrate for OT *in vitro* and it is commonly used for activity assays.⁷⁸ The specificity of OT for the GlcNAc units on the glycosyl donor has been investigated *in vitro* using synthetic analogs.⁷⁹ These studies revealed that GlcNAc-PP-Dol, while being a poor substrate (11% compared to GlcNAc₂-PP-Dol), is the minimal donor. Synthetic disaccharide derivatives in which the *N*-acetyl group of the GlcNAc directly linked to pyrophosphate was replaced with either a fluoro- or trifluoroacetamido- group were not substrates. These results suggested that the *N*-acetyl group is a critical determinant for catalysis. The synthetic disaccharide derivatives do, however, display inhibitory behavior, with K_i values for the fluoro- and

trifluoroacetimido-derivatives of 252 μM and 154 μM , respectively. Many details of the recognition of the acceptor substrate, which is the nascent polypeptide, have also been elucidated through the use of peptide-based OT substrate and inhibitor analogs by comparison to substrate peptides with the native consensus sequence for glycosylation.⁸⁰⁻

⁸² Our recent contributions to these studies are discussed in more detail in Chapter VI.

The oligosaccharyltransferase complex is composed of membrane-bound subunits, which have been assigned to subcomplexes by a combination of biochemical and genetic studies.^{7, 83} The specific number of subunits varies according to species, but in yeast, there are nine subunits that each belong to one of three subclusters, as depicted in Figure I-9. Five subunits are essential for viability (Stt3, Swp1, Wbp1, Ost1, and Ost2), and biochemical approaches such as photo-crosslinking have been employed to identify which is the catalytic subunit.

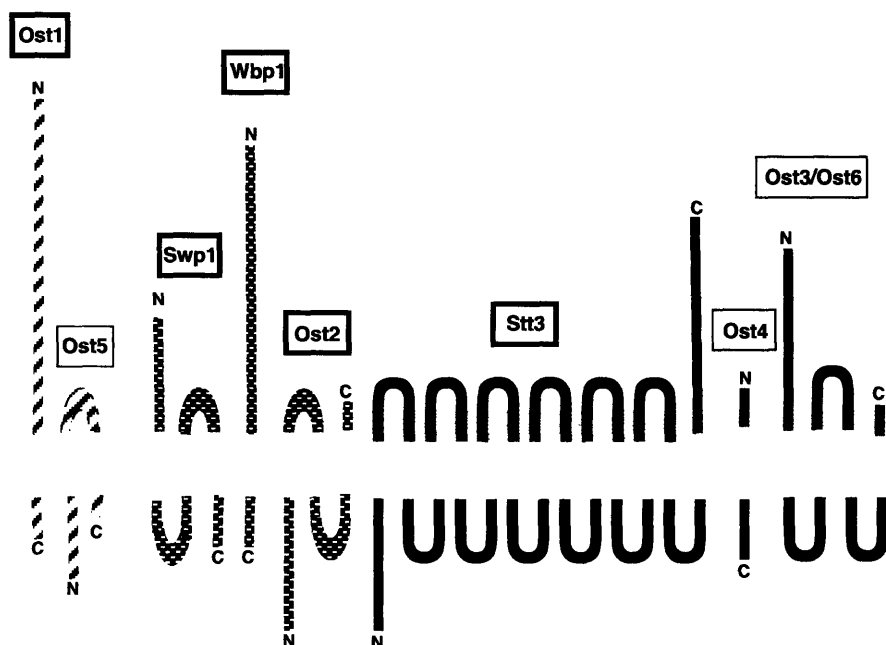

Figure I-9. OT subunits identified in yeast. Subcomplexes are distinguished by pattern.

Dark boxes around names indicate essential subunits.

Homology searches have found that Stt3 is the most highly conserved subunit, although the large number of transmembrane-spanning regions casted doubt on using this criterion as evidence that Stt3 is the catalytic domain. However, the recent discovery of the Pgl pathway of *N*-linked glycosylation in the gram-negative bacteria, *Campylobacter jejuni*, with many similarities to the eukaryotic dolichol pathway, revealed a single OT-like protein, PglB, which is a homologue of Stt3.⁸⁴ The Pgl gene cluster includes, in addition to PglB, all of the genes necessary for the biosynthesis of the oligosaccharide donor. Expression of the Pgl gene cluster in *E. coli* led to native glycosylation of the *C. jejuni* protein AcrA.⁸⁵ Since *N*-linked glycosylation is not present in *E. coli*, these results suggested that PglB is sufficient to carry out the glycan transfer. Due to the high degree of homology between PglB and Stt3, this result makes Stt3 the likely candidate for the catalytic subunit of OT. Interestingly, PglB appears to recognize an expanded version of the known consensus sequon for eukaryotic glycosylation that includes Asp-Xaa-Asn-Xaa-Ser/Thr. Residues within PglB that are critical for catalysis have been localized to a WWDYG motif, which is highly conserved. Mutations in this region have lead to a loss of transferase activity.⁸⁶ Efforts are now underway to biochemically confirm that the Stt3 subunit alone is sufficient to carry out protein glycosylation.

Regulation of the dolichol pathway

Aspects of the regulation of tetradecasaccharide donor biosynthesis were briefly introduced previously, including the competition of the Dol-P dependent GlcNAc-1-P transferase, GPT-1 (Alg7 in *S. cerevisiae*), Dol-P-Man synthase, and Dol-P-Glc synthase

for the available pool of Dol-P. Interestingly, further support for this model was provided by the more recent observation that in gently permeabilized Chinese hamster ovary cells, treatment with compounds that block protein translation causes an accumulation of Glc₃Man₉GlcNAc₂-PP-Dol with a concomitant loss of activity of the dolichol pathway enzymes.⁸⁷ In contrast, full activity of the enzymes was confirmed in microsomes prepared from these treated cells, suggesting that this inhibition of *in vivo* activity is due to the sequestration of Dol-P in the form of the full-length tetradecasaccharide.

Exogenous addition of Man-P-Dol to the retina of embryonic chicks or mouse lymphoma cell line stimulates the synthesis of GlcNAc-PP-Dol by allosteric regulation of GPT enzyme activity,⁸⁸⁻⁹¹ and the reciprocal relationship was also found in the chick retina.⁹² Glc-P-Dol did not show the same stimulatory effect, and rather inhibited the stimulation by Man-P-Dol.⁹⁰ GPT-1 activity has also been shown, in retinas from embryonic chicks, to be inhibited both by product inhibition by GlcNAc-PP-Dol as well as feedback inhibition by GlcNAc₂-PP-Dol.⁹²

A number of studies have been carried out to show that the early genes in the dolichol pathway, *ALG7*, *ALG1*, and *ALG2* are early growth-response genes.⁹³ *ALG7* expression is intimately linked to the cell cycle in *S. cerevisiae*, with its activity being regulated with respect to stages of cell proliferation. Due to different check points for *ALG7* in the G1 phase of the cell cycle, the dolichol pathway genes are either differentially or co-ordinately regulated.⁹³⁻⁹⁸ Retinoic acid, a potent regulator of growth and differentiation, was found to enhance the activity of the Alg7 homologue in a mouse teratocarcinoma cell line.⁹⁹ A 3-fold activity increase was accompanied by similar increases in transcription and translation of the gene, as well as an elevation of

Glc₃Man₉GlcNAc₂-PP-Dol and protein glycosylation levels. Similarly, in a study examining the effect of 8-bromo-cAMP on glycosylation of a short peptide acceptor, a significant increase in glycosylation, accompanied by an increase in the pool of tetradecasaccharide donor, was observed upon pretreatment with the cyclic AMP derivative.¹⁰⁰

The ER unfolded protein response (UPR) is a system that eukaryotic cells invoke in response to certain stress signals, particularly involving the accumulation of unfolded proteins in the ER, which leads to an increase in expression of ER proteins such as folding chaperones.¹⁰¹ Using small molecules to induce UPR in human fibroblasts, it was found that the dolichol pathway is also regulated in response to this stress, stimulating the biosynthesis of Glc₃Man₉GlcNAc₂-PP-Dol.¹⁰²

Congenital Disorders of Glycosylation (CDG)

Defects in various steps of *N*-linked glycoprotein biosynthesis in humans can cause severe medical conditions. There are two main types of Congenital Disorders of Glycosylation, CDGI and CDGII, which comprise a series of rare but serious diseases resulting from aberrant glycosylation. Members of the CDGI family are specifically characterized by defects in *N*-linked glycoprotein biosynthesis.¹⁰³⁻¹⁰⁵ The molecular basis for disease stems from mutations in biosynthetic genes, which leads to loss or truncation of dolichylpyrophosphate-linked saccharides, and these incomplete intermediates are transferred to protein by OT at a significantly reduced rate.¹⁰⁶ The consequence in the patient is expression of proteins in which entire oligosaccharide moieties are missing

from natively glycosylated sequons. The clinical presentations are extremely broad, and can include a range of severities of mental retardation, liver dysfunction, and intestinal disorders.^{103, 107} These are summarized in Table I-2, along with the eleven human genes that have been identified to date in which mutations have been linked to different forms of the disease. Some success in treating the symptoms of these disorders has been achieved through the administration of mannose.^{108, 109}

Gene	Enzyme	Typical symptoms
<i>PMM2</i>	Phosphomannomutase II	Mental retardation (MR), hypotonia, esotropia, lipodystrophy, cerebellar hypoplasia, seizures
<i>MPI</i>	Phosphomannose isomerase	Hepatic fibrosis, protein-losing enteropathy (PLE), coagulopathy, hypoglycemia
<i>ALG6</i>	DoI-P-Glc: Man ₉ GlcNAc ₂ -PP-Dol glucosyltransferase	MR, hypotonia, epilepsy
<i>ALG3</i>	DoI-P-Man: Man ₅ GlcNAc ₂ -PP-Dol mannosyltransferase	Severe MR, optic nerve atrophy
<i>DPM1</i>	DoI-P-Man Synthase I GDP-Man: DoI-P-Mannosyltransferase	Severe MR, epilepsy, hypotonia, mildly dysmorphic, coagulopathy
<i>MPDU1</i>	Mannose-P-Dolichol utilization defect 1/Lec35	Short stature, ichthyosis, MR, retinopathy
<i>ALG12</i>	DoI-P-Man: Man ₇ GlcNAc ₂ -PP-Dol mannosyltransferase	Hypotonia, MR, facial dysmorphism, microcephaly, frequent infections
<i>ALG8</i>	DoI-P-Glc: Glc ₁ Man ₉ GlcNAc ₂ -PP-Dol glucosyltransferase	Hepatomegaly, coagulopathy, PLE, renal failure
<i>ALG2</i>	Putative GDP-Man: ManGlcNAc ₂ -PP-Dol mannosyltransferase	Normal at birth, hepatomegaly, coagulopathy, MR, hypomyelination, intractable seizures
<i>DPAGT1</i>	UDP-GlcNAc: -dolichol phosphate <i>N</i> -acetylglucosamine-1 phosphate transferase	Severe MR, hypotonia, seizures, microcephaly
<i>ALG1</i>	GDP-Man: GlcNAc ₂ -PP-Dol mannosyltransferase	Severe MR, hypotonia, acquired microcephaly, intractable seizures, fever, coagulopathy, nephrotic syndrome
<i>ALG9</i>	DoI-P-Man: Man _{6 and 8} GlcNAc ₂ -PP-Dol mannosyltransferase	Severe microcephaly, hepatomegaly, hypotonia, seizures

Table I-2. Summary of CDGs characterized to date. In some cases, the nomenclature for human and yeast genes is identical. Table adapted from Freeze and Aebi.¹⁰⁶

Glycosyltransferase families and structural motifs

The CAZy database includes classification of over 12,000 glycosyltransferases (known or putative), divided into 81 families based on sequence similarities. The large number of families highlights the low level of sequence homology among glycosyltransferases. Alg2 and Alg11 both belong to the CAZy glycosyltransferase family 4, which, in addition to GDP-Man α -mannosyltransferase activity, also includes sucrose and sucrose phosphate synthases, α -glucosyltransferase, lipopolysaccharide *N*-acetylglucosaminyl transferase, diacylglycerol 3-glucosyltransferase, diglucosyl diacylglycerol synthase, digalactosyldiacylglycerol synthase, trehalose phosphorylase, phosphatidylinositol α -mannosyltransferase, and UDP-galactose α -galactosyltransferase activity.¹¹⁰

X-ray crystal structures of glycosyltransferases were not available until the first structure was reported in 1994 for bacteriophage T4-glucosyltransferase.¹¹¹ There are now structures for at least 23 different glycosyltransferases, spanning 17 distinct glycosyltransferase families.¹¹² In contrast to the low sequence homology, a high degree of structural homology exists among the known structures of glycosyltransferases, with only two major folds, GT-A and GT-B,¹¹³ and one recently identified novel fold for a sialyltransferase from *C. jejuni* (Figure I-10).¹¹⁴ Glycosyltransferase folds are largely comprised of $\alpha/\beta/\alpha$ sandwiches, with GT-A folds consisting of a Rossman fold, in which the active site is located in a space between the central β -sheet and a smaller β -sheet, and GT-B folds maintain the catalytic site between two distinct Rossman folds separated by a linker region.¹¹² The Rossman fold is a common motif found in nucleotide-binding

proteins.¹¹⁵ A common element of the GT-A fold family is a conserved Asp-Xaa-Asp motif, where Xaa can be any amino acid, which is involved in binding of the glycosylacceptor phosphate moiety *via* a divalent metal,¹¹² and is distinct from the EX₇E motif shared by Alg2, Alg11, and a number of other enzymes in the same Pfam protein family database.⁶⁰ As discussed earlier, Alg2 and Alg11, which share 22% homology to each other, also contain an extended signature sequence that is found in over 60 other glycosyltransferases. X-ray crystal structures have been solved for three of the glycosyltransferases from this group, all of them revealing a GT-B fold, and an involvement of these conserved residues in binding of the nucleotide sugar donor.^{111, 116, 117} In Alg2 and Alg11, the signature sequence of each lies within the soluble cytosolic region. Threading analysis with sequences of glycosyltransferases for which structures have not been solved reveal that most fall within either the GT-A or GT-B fold family. For Alg2, Alg11, and other members of the same family, threading analysis predicts the GT-B fold. Another emerging commonality among several glycosyltransferases is ordered substrate binding, in which donor substrate binding induces a loop motion, which creates the binding site for the glycosyl acceptor.¹¹⁸

Mechanisms of Glycosyltransferases

Due to the difficulty in expressing and stabilizing glycosyltransferases, many of which are membrane-bound and have a significant amount of flexibility in their two-domain structures, X-ray crystallographic information is still quite scarce. For the same

reasons, the mechanistic details of this class of enzymes are unclear. The formation of glycosidic bonds can be described as retaining or inverting, depending on whether there is a change in configuration with respect to the anomeric center of the glycosyl donor. To understand these mechanisms, clues were taken from the better understood glycosylhydrolases.¹¹⁹ The mechanism of inverting glycosyltransferases, based on structural and mechanistic studies, is believed to be similar to the inverting glycosylhydrolases, in which an active site base deprotonates the nucleophilic hydroxyl group of the glycosyl acceptor, facilitating an S_N2 displacement of the activating group of the glycosyl donor (Figure I-11A). In the case of retaining glycosyltransferases, it is not yet clear whether the mechanism involves a double displacement or rather an S_N1 -type reaction. The double displacement mechanism requires a nucleophilic active site residue and a covalent intermediate (Figure I-11B), while the S_N1 -type mechanism would involve stabilization by the enzyme of the oxocarbenium ion-like transition state of the glycosyl donor after release of the activating group and prior to bond formation with the glycosyl acceptor (Figure I-11C). Mechanistic studies employing secondary kinetic isotope effects, fluorinated derivatives of glycosyl donors, and inhibition by glycosyl donor analogs with positively charged nitrogen species to mimic the oxocarbenium ion transition state all provide evidence for the oxocarbenium ion-like transition state.¹²⁰ To date, X-ray crystal structures of retaining glycosyltransferases only represent six families, the majority of which have not been solved in the presence of an enzyme-bound glycosyl donor. Therefore, no candidate nucleophiles have been identified, and despite great efforts, evidence for a covalent intermediate to support the double displacement mechanism has not been found. However, a stable glycosyl-enzyme intermediate was

recently observed in a Gln189Glu mutant of the *Neisseria meningitidis* α -galactosyltransferase, LgtC.¹²¹ Residue Gln189 in the wild-type enzyme is positioned properly to be a nucleophilic residue, but no modification was found for the wild-type enzyme. Thus, mutation of this residue to the more nucleophilic Glu and subsequent evidence for a covalent modification of this mutant suggested modification of Glu189 in the mutant. Surprisingly, however, Asp190, and not Glu189, was the modified residue in this mutant. Mutating Asp190 to an Ala residue in the wild type enzyme resulted in a 3,000-fold decrease in activity. Thus, it is still unclear whether the wild-type enzyme acts through a double-displacement mechanism.

Figure I-11. Proposed mechanisms of glycosyltransferases. The inverting glycosyltransferases use general acid (A)/ general base (B) catalysis in a direct displacement S_N2 reaction to invert the anomeric configuration (A). The retaining glycosyltransferases are proposed to act through either a double displacement S_N2 -like reaction, involving the formation of a covalent intermediate (B), or an S_N1 -like reaction, without a covalent intermediate (C). These mechanisms were taken from Lairson, et al.¹¹⁹

Conclusion

Since the discovery of the Alg enzyme genes began over 20 years ago, many advances have been made in the functional assignment of the glycosyltransferase genes through genetics and bioinformatics, as well as in understanding the regulation and the role of the dolichol pathway in cellular processes. However, with the exception of Alg1, very few biochemical studies have been attempted with these enzymes. These advances have been primarily limited by the same challenges that are responsible for the small number of X-ray crystal structures and the incomplete mechanistic picture of this class of enzymes, which include membrane-association in many cases, and structural flexibility. Both of these features help to make glycosyltransferases notoriously unstable. In order to gain a deeper understanding of the biosynthesis as a whole, it is necessary to unambiguously define the function of each glycosyltransferase in the pathway. Only then can the concerted actions of these enzymes be studied in a controlled manner. Overcoming the inherent obstacles of this system will allow many insights into the structural and mechanistic challenges of bifunctional glycosyltransferases, and continue the improvement of the chemoenzymatic syntheses of valuable oligosaccharide structures.

Chapter II: Substrate specificity of the UDP-GlcNAc: GlcNAc-PP-Dolichol, *N*-
acetylglucosamine transferase (Enzyme II)

A significant portion of this chapter was published in Tai, et al, *Bioorg. Med. Chem. Lett.*
2001, 9, 1133-1140.

Introduction

In the second step of the dolichol pathway, an *N*-acetylglucosamine unit (GlcNAc) is transferred from a UDP-GlcNAc glycosyl donor to a dolichylpyrophosphate-linked GlcNAc acceptor (GlcNAc-PP-Dol) by the UDP-GlcNAc: GlcNAc-PP-dolichol, *N*-acetylglucosamine transferase that has been traditionally known as Enzyme II (Scheme II-1).¹ Recently this activity has been assigned to the heterooligomeric complex, Alg13/Alg14.² Analogous to the other glycosyltransferases involved in the assembly of Man₅GlcNAc₂-PP-Dol, this membrane-bound enzyme is localized in the endoplasmic reticulum (ER) membrane with the active site facing the cytosol, where the reaction occurs.³

Scheme II-1. Glycosyltransfer reaction catalyzed by Enzyme II.

The product of the Enzyme II reaction, GlcNAc₂-PP-Dol, is a competent substrate for oligosaccharyl transferase (OT),⁴ and is frequently employed for *in vitro* assays due to the difficulty in isolation of the complete tetradecasaccharide donor from native sources. For this purpose, radiolabeled (³H)GlcNAc-GlcNAc-PP-Dol, where one of the C-6 protons of the terminal GlcNAc is replaced by a tritium, was previously prepared by an

efficient chemoenzymatic synthesis using Enzyme II from a partially purified preparation of porcine liver microsomes. In the interest of evaluating OT with dolichylpyrophosphate-linked disaccharides bearing non-natural substitutions at the C-2 position of the proximal GlcNAc,⁵ Enzyme II was chosen as a tool to prepare these analogues chemoenzymatically. This chapter describes how the attempts to prepare non-natural OT substrate analogues using Enzyme II have revealed the tolerance of Enzyme II with respect to substrate modification, and thus the limits of the utility of this enzyme for such chemoenzymatic purposes. Thus, modifications to the C-2 position of the proximal monosaccharide can provide information about both Enzyme II and, as described elsewhere,⁵ OT (Figure II-1).

Figure II-1. Modification of the C-2 of GlcNAc-PP-Dol can be used to probe two distinct enzymes.

The observation that UDP-Glc inhibits the Enzyme II reaction suggests that the C-2 acetamido group on the glycosyl donor, UDP-GlcNAc, is a key determinant.⁶ In contrast, the importance of the acetamido group on the glycosyl acceptor, GlcNAc-PP-Dol, had not yet been evaluated. There is a great deal of interest, and there have been many advances, in using chemoenzymatic methods to prepare synthetically challenging carbohydrates using glycosyltransferases that exhibit relaxed substrate specificity.⁷ Thus,

in addition to studying substrate specificity as a means to unravel mechanistic details, understanding the tolerance of glycosyltransferases for various substrates is crucial to expanding the repertoire of tools for chemoenzymatic carbohydrate synthesis.

There have been a number of reports on the solubilization and partial purification of Enzyme II from natural sources such as mung bean seedling,⁶ yeast,⁸⁻¹¹ and rat¹ and pig¹² liver, however, until the very recent discovery of the Alg13/Alg14 complex,² the identity of the gene(s) encoding Enzyme II had remained elusive. Nevertheless, characterization of this enzyme has been possible through the use of microsomal preparations, which exhibit no detectable background reactivity from unrelated native enzymes with dolichylpyrophosphate-linked pathway intermediates.¹³⁻¹⁵ Partially purified Enzyme II from solubilized yeast microsomes was used to determine an apparent K_m of 40 μM for the GlcNAc₂-PP-Dol acceptor at a fixed concentration of 4.9 μM UDP-GlcNAc.

Results and Discussion

Non-natural dolichylpyrophosphate-linked monosaccharides used in this study

A variety of substrate analogues with substituents replacing the C-2 acetamido group of dolichylpyrophosphate-linked GlcNAc (**1a**), including the fluoro, *O*-ethyl, trifluoroacetamido, and amino functionalities (**1b-e**, respectively) (Scheme II-2) were investigated. Compounds **1a-d** were synthesized and compounds **1a-c** evaluated as substrates by Dr. Vincent W.-F. Tai. Because the synthesis of **1e** directly followed from

the synthesis of **1d**, both the synthesis and biological evaluation of **1d** and **1e** will be described in detail herein.

Scheme II-2. Non-natural monosaccharide acceptors used in the Enzyme II reaction.

Synthesis of GlcNHTFA-PP-Dol (**1d**) and GlcNH₂-PP-Dol (**1e**)

The general scheme for the synthesis of GlcNHTFA-PP-Dol (**1d**) is outlined in Scheme II-3. GlcNH₂-PP-Dol (**1e**) was synthesized using **1d** as a precursor. 3,4,6-Tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido- α -D-glucopyranosyl phosphate (**4d**) has recently been prepared by two groups.¹⁶ In the method used by the Tanner group, the α -phosphate, **4d**, was prepared from the corresponding reducing sugar using the phosphorochloridate method in 52% yield.¹⁶ Alternatively, Busca and Martin showed that both the α - and β -phosphates could be obtained in high yield from ring opening of oxazoline, **6**, with dibenzyl phosphate under different conditions.¹⁷

Scheme II-3. Retrosynthetic analysis of GlcNHTFA-PP-Dol (**1d**).

Following the Martin protocol, ring opening of the oxazoline **6**^{17, 18} with dibenzyl phosphate in refluxing 1,2-dichloroethane afforded the thermodynamic product **8** in 65% yield (Scheme II-4).¹⁷ The α -anomeric stereochemistry of **8** was confirmed based on the coupling constant between C-1 and C-2 protons in the ¹H NMR spectrum ($J_{1,2} = 3.3$ Hz). Catalytic hydrogenolysis of **8** with 10% palladium on charcoal gave the α -phosphate, **4d**, in quantitative yield. The resulting phosphate was then condensed with Dol-P (**5**) to afford the protected GlcNHTFA-PP-Dol (**9**) in 63% yield. Chemoselective deprotection of the *O*-acetates in **9** with guanidine/guanidinium nitrate solution¹⁹ yielded GlcNHTFA-PP-Dol (**1d**) in 47% yield after silica gel chromatography. Alternatively, treatment of **9** with lithium hydroxide (10 equivalents) provided the amine derivative GlcNH₂-PP-Dol (**1e**) in 63% yield.

Scheme II-4. Synthesis of GlcNHTFA-PP-Dol (**1d**) and GlcNH₂-PP-Dol (**1e**)^a.

^aReagents and conditions: (i) dibenzyl phosphate, 1,2-dichloroethane, Δ , 65% (ii) H₂, 10% Pd/C, MeOH, 100% (iii) (1) CDI, DMF; (2) Dol-P (**5**), 63% (iv) guanidine/guanidinium nitrate, CH₂Cl₂/MeOH, 47%; (v) LiOH, CH₂Cl₂/MeOH, 63%.

Biological Evaluation

Non-natural dolichylpyrophosphate-linked monosaccharides (**1b-e**) were evaluated as glycosyl acceptors for Enzyme II using a partially-purified pig liver microsome preparation and radiolabeled UDP-(³H)GlcNAc as the glycosyl donor. The radioactive assay used to evaluate this glycosyltransferase, as well as other glycosyltransferases on the pathway, is shown in Figure II-2.

Figure II-2. Radioactive assay used for the dolichol pathway enzymes.

Product formation was quantified by measuring the amount of tritium label transferred to an organic extract [unreacted UDP-(³H)GlcNAc partitions into the aqueous layer] after successive aqueous-organic extractions.²⁰ Percent conversion was calculated by dividing the disintegrations per minute (dpm) of tritium in the organic layer by the total number of dpms in the vial, and therefore represents the percent of radiolabeled monosaccharide transferred from nucleotide-activated sugar (0.2 μM in this assay) to the dolichylpyrophosphate-linked substrate. Assuming similar kinetic parameters for the non-natural disaccharide derivatives, all assays were performed with the acceptor substrate concentration above K_m . However, due to the fact that the dolichylpyrophosphate-linked substrate is in an unknown physical state in the detergent-containing assay, considering that the critical micelle concentration (CMC) is unknown, this assay is not used to derive kinetic constants, but rather to detect enzyme activity and to make comparisons of activity under varying sets of reaction conditions. In this case, the assay provided information to enable a qualitative comparison among the series of natural and non-natural substrates in order to gain insight into specificity.

Non-natural analogues 2DFGlc-PP-Dol (**1b**) and 2OEtGlc-PP-Dol (**1c**) did not display any significant transferase activity.²¹ In contrast, the GlcNHTFA-PP-Dol (**1d**) and GlcNH₂-PP-Dol (**1e**) derivatives were shown to be relatively poor and moderate substrates for Enzyme II (Figure II-3), respectively. Even at higher concentrations of **1d** (1.5 mM) and **1e** (600 μM), only 13% and 41% conversion were observed after 14 hours, respectively. These yields are low compared to the 70% conversion achieved after only 30 minutes using 150 μM of the natural substrate and keeping the concentration of the

glycosyl donor constant. They do, however, indicate the feasibility of using these substrates for the chemoenzymatic preparation of non-natural disaccharide analogues.

Figure II-3. Activity assays of relative rates of dolichylpyrophosphate-linked GlcNAc (**1a**), GlcNHTFA (**1d**), and GlcNH₂ (**1e**) analogues.

Derivatives **1b-d** were further shown to be inhibitors when competed with the natural substrate **1a**. As shown in Table II-1, the percent conversion of GlcNAc-PP-Dol (**1a**) was reduced by 27-32% when equivalent amounts of the non-natural derivatives **1b-1d** were added.

compounds ^a	Relative % conversion ^b
1a	1
1a + 1b^c	0.68
1a + 1c	0.73
1a + 1d	0.68

^a 150 μ M of each compound and 5 μ L of pig liver microsomes were used.

^b % conversion after 10 minutes of reaction.

^c 10 μ L of pig liver microsomes was used in this case.

Table II-1. Inhibitory activity of non-natural monosaccharide acceptors. Relative % conversion of **1a** when competed with **1b-d**.

Conclusion

In summary, Enzyme II demonstrates high specificity for the glycosyl acceptor. It is noted that even a relatively minor modification of the GlcNAc C-2 position in the GlcNAc-PP-Dol substrate diminishes the activity of this enzyme. Indeed, the electronic effects of the substituents at the C-2 position should induce minimal effects on the nucleophilicity of the C-4 hydroxyl group. Therefore, the acetamido group is postulated to act as a critical binding determinant for this transferase reaction through highly specific hydrogen bonding interactions between the N-H and C=O groups and the enzyme. Neither the 2-deoxy-2-fluoro analogue (**1b**) nor the 2-O-ethyl analogue (**1c**) function as substrates to the limits of detection of this assay (background is approximately 1% conversion),²¹ perhaps due to the lack of the proposed essential

acetamido group. The strong electronic effects of the trifluoromethyl group of the trifluoroacetamide analogue (**1d**) may be a cause of detrimental effects on binding. The fact that the amine analogue GlcNH₂-PP-Dol (**1e**) is a substrate suggests that the minimal recognition element for this transferase reaction is a C-2 amine substituent.

The substrate specificity observed for Enzyme II is different from that of a 'core-2' GlcNAc transferase reported by Tanner.¹⁶ In this case, UDP-GlcNHTFA was found to be a substrate for 'core-2' GlcNAc transferase but neither the 2-amino (UDP-GlcNH₂) nor the 2-hydroxyl (UDP-Glc) derivatives exhibited substrate behavior.

Acknowledgments

This work was done in collaboration with Dr. Vincent W.-F. Tai, who carried out the synthesis of **1a-d** and the biological evaluation of **1a-c**.

Experimental Procedures

General Methods for Synthesis.

Melting points were uncorrected. Optical rotations were measured with a JASCO DIP-1000 automatic digital polarimeter operating at 589 nm at 25 °C and are reported in degrees. Concentration (*c*) is indicated as units of 10 mg/mL. IR spectra were recorded on a Perkin-Elmer 1600 FT-IR spectrometer. NMR spectra were measured on a Varian

500, Bruker AM-500 (500.15 MHz for ^1H , 125 MHz for ^{13}C), or General Electric QE300 (75 MHz for ^{13}C). All chemical shifts were recorded in ppm downfield from tetramethylsilane on the δ scale. ^{31}P NMR chemical shifts are reported in ppm relative to 85% phosphoric acid external standard. Multiplicities are reported in the following abbreviations: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), dd (doublet of doublets), *etc.* Mass spectra were obtained either at the Mass Spectrometry Laboratory, operated by the College of Chemistry, California Institute of Technology, Pasadena, CA91125, at the UCR Mass Spectrometry Facility, Department of Chemistry, University of California, Riverside, CA92521, or with a Mariner electrospray mass spectrometer from Applied Biosystems using the negative ion mode. All reactions were monitored by analytical thin-layer chromatography (TLC) on glass precoated with silica gel 60F₂₅₄ (E. Merck) and compounds were visualized with 20% w/v dodecamolybdophosphoric acid in ethanol and subsequent heating. Phosphorous compounds were visualized with Molybdenum blue spray reagent.²² All columns were packed wet with E. Merck silica gel 60 (230-400 mesh) as the stationary phase and eluted by flash chromatography. All solvents were reagent grade. Methylene chloride and triethylamine were distilled from calcium hydride. Tetrahydrofuran and toluene were distilled from sodium/benzophenone ketyl. Other reagents were purchased from commercial suppliers and used without further purification.

Mono(triethylammonium) salt of 3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido- α -D-glucopyranosyl phosphate (4d).¹⁷

A solution of the protected phosphate **8**¹⁷ (145 mg, 0.220 mmol) and 10% Pd/C (20 mg) was stirred under H₂ in MeOH (8 mL) until no starting material remained as shown by TLC. The catalyst was filtered through a pad of Celite and washed with EtOH (15 mL). Et₃N (1 mL) was added followed by the evaporation of solvent *in vacuo* to give the mono-(triethylammonium) salt of the phosphate (136 mg, quantitative yield) as a foam; IR (neat) cm⁻¹ 3411, 2995, 1748, 1560, 1458, 1369, 1224, 1189, 1157, 1040, 962, 921, 840, 718; ¹H NMR (CDCl₃, 500 MHz) δ 1.08 [t, 9H, *J* = 7.3 Hz, N(CH₂CH₃)], 1.75 (s, 3H, Ac), 1.79 (s, 3H, Ac), 1.85 (s, 3H, Ac), 2.87 [q, 6H, *J* = 7.3 Hz, N(CH₂CH₃)], 3.90 (dd, 1H, *J* = 2.0, 12.4 Hz, H-6a), 4.03 (dd, 1H, *J* = 3.4, 12.4 Hz, H-6b), 4.07 (dt, 1H, *J* = 2.9, 10.2 Hz, H-5), 4.14 (dt, 1H, *J* = 2.6, 10.5 Hz, H-2), 4.92 (t, 1H, *J* = 9.6 Hz, H-3/H-4), 5.19 (t, 1H, *J* = 9.6 Hz, H-4/H-3), 5.32 (dd, 1H, *J* = 3.3, 6.8 Hz, H-1); ¹³C NMR (CDCl₃, 125 MHz) δ 7.9, 19.8, 20.0, 20.1, 45.7, 52.3 (d, *J* = 7.5 Hz), 61.3, 67.9, 68.0 (2x), 70.6, 92.8, 157.9 (q, *J* = 37 Hz), 169.7, 170.4, 171.0; ³¹P NMR (CDCl₃, 162 MHz) δ -0.9; [α]_D +33.9 ° (*c* = 0.9, CHCl₃); MS (-ve FAB): 480 (M⁻); HRMS: Calcd for C₁₄H₁₈NO₁₂F₃P: *m/z* = 480.051874; Found: 480.051500.

P¹-Dolichyl P²-[3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido- α -D-glucopyranosyl] diphosphate (9).

To a solution of the **4d** (0.04 mmol) in DMF (1 mL) at room temperature was added 1,1'-carbonyldiimidazole (CDI, 0.2 mmol) in one portion. After 2 hours, MeOH (0.36 mmol) was added (to quench excess CDI) to the mixture and stirred for 30 min. Dolichylmonophosphate (**5**)²³ (tri-*n*-butyl ammonium form, 0.028 mmol) in CH₂Cl₂ (1 mL) was then added and the mixture was allowed to stir for 3 days at room temperature. The crude mixture was concentrated followed by chromatography with DE-52 [acetate form, eluted with increasing concentration of NH₄OAc in CHCl₃, MeOH (2:1 v/v)]. The products were concentrated and further purified by silica gel chromatography.

¹⁹F NMR (CDCl₃, 470 MHz) δ -76.4; ³¹P NMR (CDCl₃, 162 MHz) δ -10.1, -12.4; MS (-ve ESI): 825.7, 859.8, 893.8, 927.9, 961.9, 995.9, 1030.0 ($m/2$ for $n = 12 - 18$).

P¹-Dolichyl P²-[2-deoxy-2-trifluoroacetamido- α -D-glucopyranosyl] diphosphate (1d).

To a stirred solution of **9** (3 μmol) in CH_2Cl_2 (1.5 mL) at room temperature was added a solution of guanidine/guanidinium nitrate (1 mL). [Stock solution of the guanidine/guanidinium nitrate reagent was prepared by dissolving guanidinium nitrate (122.1 mg, 1 mmol) and sodium methoxide (10.8 mg, 0.2 mmol) in $\text{MeOH}/\text{CH}_2\text{Cl}_2$.] After 20 min, cation exchange resin (Dowex 50X8, pyridinium form, 200 mg) was added and the mixture was stirred for 10 min. The resin was then filtered and washed with $\text{CHCl}_3/\text{MeOH}$ (2:1 v/v). Concentration of the solvent followed by column chromatography afforded the corresponding dolichylpyrophosphate-linked saccharide **1e** in 47% yield.

MS (–ve ESI): 1593.1, 1661.2, 1729.6, 1797.7, 1865.2 (M^- for $n = 13 - 17$).

P¹-Dolichyl P²-[2-amino- α -D-glucopyranosyl] diphosphate (1e).

To a stirred solution of peracetylated dolichylpyrophosphate-linked saccharide **9** (4.4 μmol) in $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (1.2 mL, 5:1 v/v) at room temperature was added aqueous lithium hydroxide solution (3 M, 11 μmol). After 20 min, the mixture was worked up as in the preparation of **1d** to yield **1e** in 63% yield.

MS (–ve ESI): 1498.5, 1566.6, 1634.6, 1702.7, 1736.7 (M^- for $n = 13 - 17$).

Biological Methods

Crude porcine liver microsomes were prepared from fresh pig liver based on a protocol developed for rat liver.^{24, 25} Briefly, a 100 g sample of fresh pig liver typically affords 2.5-5 mL of a microsomal preparation (~ 100 mg/mL protein in crude microsomal membranes) that can be stored at -80 °C in the presence of 30% glycerol. This material can be used for several months without significant loss of transferase activity. The natural substrate GlcNAc-PP-Dol **1a** was prepared according to literature procedure.²⁰ Radiolabeled uridine diphosphate *N*-acetyl-D-glucosamine-6-³H [UDP-(³H)GlcNAc, **2**, specific activity of 60 Ci/mmol, concentration = 1 mCi/mL] was obtained from American Radiolabeled Chemicals, Inc., St. Louis, MO.

Enzyme II Assay

The assay buffer consisted of 50 mM Tris acetate, pH 7.0, 3 mM dithiothreitol (DTT), 5 mM MgCl₂, 0.25 M sucrose and 1% Nonidet P-40. Dolichylpyrophosphate-linked monosaccharides (**1a-e**) were aliquoted from a chloroform/methanol stock solution of weighed material into an Eppendorf tube, and the solvent was evaporated under a stream of nitrogen. To this Eppendorf tube was added UDP-(³H)GlcNAc (60 Ci/mmol for the study of 2DFGlc-PP-Dol (**1b**), and 0.6 Ci/mmol for the other analogues, final concentration = 0.167 μM) in ethanol/water, and the solvent was again evaporated under nitrogen. Assay buffer was added (final volume = 100 μL) to the Eppendorf tube and vortexed vigorously. The reaction was initiated by the addition of freshly thawed pig liver microsomes (5 or 10 μL) and shaken at 180 rpm. Aliquots (10 μL) of the reaction mixture were quenched with 0.6 mL of chloroform/methanol/2.5 mM MgCl₂ (3 : 2 : 1

v/v) at different times. The upper aqueous phase was removed and the lower phase washed twice with 100- μ L aliquots of chloroform/methanol/water (2.75 : 44 : 53.25 v/v/v). The combined aqueous phases were then mixed with Ecolite (ICN Biomedicals, Inc.) (5.5 mL) and counted on a Beckman LS-5000TD scintillation counter to give the amount of unreacted UDP-(3 H)GlcNAc. The organic layer was dried and mixed with Betamax (ICN Biomedicals, Inc.) (5.5 mL) and counted as well. The percent conversion of dolichylpyrophosphate-linked disaccharide was based on $[\text{}^3\text{H}_{\text{org}} / (\text{}^3\text{H}_{\text{aq}} + \text{}^3\text{H}_{\text{org}}) \times 100]$.

Chapter III: Alg1: Specificity studies and chemoenzymatic synthesis of
ManGlcNAc₂-PP-Dol

Introduction

ALG1 was first discovered in *Saccharomyces cerevisiae* through the use of a genetic screen for mutants defective in *N*-linked glycosylation.¹ One isolated temperature-sensitive mutant, *alg1-1*, was found to accumulate dolichylpyrophosphate-linked GlcNAc₂ (GlcNAc₂-PP-Dol) at the non-permissive temperature. The mutation in *alg1-1* was therefore postulated to affect the β1,4-mannosyltransferase that catalyzes the third step in the dolichol pathway, transferring a mannose residue (Man) from GDP-Man to yield Manβ1,4-GlcNAcβ1,4-GlcNAc-PP-Dol (Scheme III-1). The change in configuration at the anomeric center of the mannosyl residue from the α-anomer in the GDP-Man donor to the β-anomer in the ManGlcNAc₂-PP-Dol product makes Alg1 an inverting glycosyltransferase.

Scheme III-1. β1,4-Mannosylation reaction catalyzed by Alg1.

By complementation of the temperature-sensitive mutation *alg1-1* with a total genomic yeast DNA library, the region of sequence containing *ALG1* was cloned, and *E. coli* lysates containing the expressed protein demonstrated the ability to transfer a mannose residue from GDP-Man to GlcNAc₂-PP-Dol.² This work led to the subsequent sequencing of the *ALG1* gene, which revealed an open reading frame of 449 amino acids,

and a predicted molecular weight of 51.9 kDa.³ Further examination of the sequence and topology has revealed that Alg1 has at least one predicted transmembrane domain at the N-terminus, as predicted by the TMHMM server, v. 2.0 (Figure III-1).⁴ This domain anchors Alg1 into the ER membrane, and the catalytic domain faces the cytosolic side of the ER membrane,⁵ making it a type II membrane protein belonging to the PFAM glycosyltransferase 1 family.⁶

Figure III-1. Predicted topology of Alg1. Plot of the probability that Alg1 residues are in a membrane-spanning region.

The human homologue of Alg1, Hmt-1, was found by using the amino acid sequence of yeast Alg1 to search the expressed sequence tag (EST) database.⁷ This study further showed that *HMT1* complemented the temperature-sensitive defect of *alg1-1*. Mutations in *HMT1* have been linked to a recently discovered congenital disorder of glycosylation, CDG1k, which can lead to death in early infancy, and is specifically characterized by reduced Hmt-1 activity and accumulation of GlcNAc₂-PP-Dol in

patients.⁸⁻¹⁰ Interestingly, it was recently demonstrated that overexpression of the yeast gene *MPG1*, which encodes a GDP-Man pyrophosphorylase, a key enzyme in the biosynthesis of GDP-Man, largely overcame the temperature-sensitive glycosylation defect of the *alg1-1* mutant by increasing the available pool of GDP-Man.¹¹

Alg1 has also received considerable attention due to the challenge of preparing β -mannosides by chemical synthesis, and therefore it has been one of the most characterized of the enzymes on the pathway to date. Early studies with solubilized and partially purified enzyme from yeast membranes revealed a distinct pH optimum of 7.5, a specific activity of $21.4 \text{ nmol} \times \text{h}^{-1} \times \text{mg}^{-1}$ with a fixed, non-saturating GlcNAc₂-PP-Dol concentration, and a requirement for a divalent cation, specifically Mg²⁺ or Mn²⁺, with a 1.7-fold preference for the former.¹² The K_m values of both substrates were also found in this study to be 17 μM (apparent) and 7 μM for GlcNAc₂-PP-Dol and GDP-Man, respectively. Interestingly, it was found that substitutions could be made with respect to the isoprenoid, as the same acceptor K_m was also found for GlcNAc₂-PP-phytanyl (Figure III-2) using crude yeast microsomes as an enzyme source.¹³ In addition to the lack of a requirement for the dolichyl moiety, deletion of the predicted transmembrane domain (residues 1-35) of Alg1 did not result in a significant loss in transferase activity from *Escherichia coli* expression, and both the phytanyl-linked variant and the native substrate were accepted to a similar degree.^{14, 15} Immobilization of a His-tagged version of the truncated Alg1 on Ni-NTA beads provided a tool for preparative-scale synthesis of phytanylpolyphosphate-linked ManGlcNAc₂ that remained stable at 4 °C for several weeks.^{16, 17} To our knowledge there has not been any previous work on the specificity of Alg1 for the saccharide portion of the dolichyl-linked substrate.

Figure III-2. Structure of GlcNAc₂-PP-phytanyl.

Using a variety of mutant yeast strains deficient in various steps in the assembly of the tetradecasaccharide donor, Glc₃Man₉GlcNAc₂-PP-Dol, it has been found that the dolichol pathway enzymes follow a defined order of addition of saccharides, and this behavior was attributed to strict substrate specificity of the glycosyltransferases.¹⁸ However, this study does not rule out the possibility that complexation of these enzymes may play a crucial role in the observed fidelity. Recent gel filtration and immunoprecipitation studies on Alg1, Alg2, and Alg11 have shown that Alg1 homooligomerizes, and also immunoprecipitates Alg2 and, separately, Alg11.¹⁹ Interestingly, Alg2 and Alg11 were not found to co-immunoprecipitate with one another. In the same study, the genetic basis for the phenotype of the *alg1-1* yeast temperature-sensitive mutant was found to be a mutation that leads to a premature stop codon and the subsequent truncation of the protein, deleting the final sixteen amino acids at the C-terminus. Using an identically truncated Alg1 construct in the same immunoprecipitation experiments, it was revealed that while this minor truncation has a moderately detrimental effect on Alg2 and Alg11 complexation, it completely abolishes Alg1 homooligomerization. Further, mutations at residues E278, G310, and H356 of Alg1 were found to disrupt catalytic activity without affecting the oligomerization properties. Thus,

as expected, complex formation and catalytic function are determined by different parts of the protein sequence.

One of our goals in the study of Alg1 was to further probe substrate specificity from two different perspectives. One approach began with the question of whether a synthetic glycopeptide with an asparagine-linked GlcNAc₂ moiety would be accepted as a substrate of Alg1, which normally recognizes a dolichylpyrophosphate-linked GlcNAc₂ substrate (Figure III-3). The ability of Alg1 to mannosylate the glycopeptide would be of particular value due to the need for new methods of building homogenous glycoproteins. This capability would facilitate biochemical studies of glycoproteins as well as the production of glycoproteins for therapeutics, which cannot be administered with the glycan heterogeneity that is found in glycoproteins isolated from native sources. We also wanted to directly address the question of whether specificity drives the fidelity of the pathway. Dolichylpyrophosphate-linked GlcNAc (GlcNAc-PP-Dol) (Figure III-3) was tested as a substrate of Alg1 using purified enzyme to determine whether this earlier intermediate could be accepted and a new product detected.

Figure III-3. Comparison of the Alg1 substrate with alternate substrates that were tested.

The ultimate goal was to establish an expression system for an active, pure, and stable full-length Alg1 preparation. Such a preparation enables both the chemoenzymatic synthesis of the trisaccharide intermediate, ManGlcNAc₂-PP-Dol, as well as future studies toward understanding the coordinated functions of a consecutive series of enzymes in the pathway.

Results and Discussion

Cloning and expression of Alg1 constructs

Expression systems for three different Alg1 constructs were established, including a soluble, truncated Alg1 lacking the N-terminal transmembrane domain (Alg1 Δ 1-35) expressed in *E. coli*, a thioredoxin fusion protein of full-length Alg1 in *E. coli*, and the full-length Alg1 in *S. cerevisiae*. *ALG1 Δ 1-35* encodes the Alg1 sequence 36-449, which comprises the full-length protein with the first 35 residues omitted. This gene was cloned into a pET-15b expression vector (Novagen), and therefore bears an N-terminal His tag. This feature enabled Ni-NTA purification of the enzyme from clarified lysate in the presence of the detergent Triton X-100 (1%). Expression of Alg1 in the absence of the transmembrane domain enabled isolation and purification, as described in “Experimental Procedures”, of 0.45 mg of Alg1 Δ 1-35 from a 100-mL expression culture (Figure III-4a).

For expression of full-length Alg1, a cloning strategy was chosen that provided the flexibility to test expression in a variety of different systems from a single clone by homologous recombination with vectors specified for expression in different host organisms. Thus, the Gateway Cloning Technology (Invitrogen) was used to provide

ALG1 constructs in both of the vectors, pBAD-DEST49 and pYES-DEST52, for expression in *E. coli* and *S. cerevisiae*, respectively. Expression of yeast genes in *E. coli* is complicated by the difference in codon usage in these two genomes. In the yeast *ALG1* sequence, 36 of the 450 codons (8.0%) are considered “rare”, due to the significant under representation of these codons in the coding sequence of the *E. coli* genome. Similarly, the yeast *ALG2* and *ALG11* genes contain 35 out of 504 (6.9%) and 30 out of 549 (5.5%) rare codons, respectively. Appending thioredoxin to the N-terminus of sequences has been shown to improve expression and solubility of many protein targets.²⁰ Thus, the pBAD-DEST49 vector, which encodes a fusion protein whereby thioredoxin (TRX) is fused to the N-terminus, was chosen for *ALG1* expression in *E. coli*. A C-terminal His tag enables purification, and the V5 epitope, a 14-amino acid sequence from the P and V proteins of the paramyxovirus,²¹ is also included at the C-terminus for detection by Western blot analysis. Another advantage of this expression system is that the arabinose-induction enables very tightly regulated expression. This feature makes the pBAD vector ideal for expression of highly insoluble and/or toxic proteins. The pYES-DEST52 vector does not include the TRX domain, but bears the same C-terminal tags, and is designed to enable regulated, galactose-inducible expression.

TRX-Alg1-V5-His was expressed in *E. coli* and purified by Ni-NTA using procedures analogous to those used for Alg1 Δ 1-35, as described in “Experimental Procedures”. Due to modest expression levels and relatively weak binding of the expressed protein to Ni-NTA (significant amounts washed away with 20 mM imidazole), less than 1 mg per liter of expression culture was isolated (Figure III-4b-c). Several attempts were made to remove the TRX domain from the expressed protein by taking

advantage of a proteolytic cleavage site for enterokinase that had been engineered between TRX and the target protein. Unfortunately, the proteolysis reaction was very low yielding, and generally led to the rapid precipitation of protein.

Similarly low yields were obtained from the expression of Alg1-V5-His in *S. cerevisiae*, despite the fact that this is the homologous host. Expression was induced by exchanging the glucose in the growth media with galactose as the main carbon source in the yeast culture. The Alg1 construct was isolated by fractionating crude yeast microsomes, and then purifying detergent-solubilized microsomes by Ni-NTA affinity chromatography, as described in “Experimental Procedures”. Less than 1 mg of purified Alg1 was consistently isolated from 4-L expression cultures (Figure III-4d-e). However, the amount isolated proved to be ample for the experiments described here, based on the activity of this preparation.

Figure III-4. SDS-PAGE and Western blot analysis of Alg1 constructs from *E. coli* and *S. cerevisiae* expression. A) Coomassie stain of purified Alg1 Δ 1-35, B) Coomassie stain of purified TRX-Alg1 from *E. coli* expression, C) Western blot analysis of TRX-Alg1, D) Coomassie stain of purified Alg1 from *S. cerevisiae* expression, E) Western blot analysis of Alg1. Molecular weights of the markers are shown in kDa. Western blots were probed with the α -V5 antibody (Invitrogen).

Characterization of Alg1Δ1-35 from *E. coli* expression

Mannosyltransferase activity of Alg1Δ1-35 was detected by the radioactive assay described in Chapter II (Figure II-2), whereby aqueous/organic extractions were used to separate tritiated GDP-(³H)Man from tritiated product, (³H)ManGlcNAc₂-PP-Dol, at a number of time points. In order to demonstrate the enzyme dependence of this reaction, initial assays were carried out with different amounts of Alg1Δ1-35 (Figure III-5).

Figure III-5. Alg1Δ1-35 activity assays, varying enzyme concentration (0.48 or 4.8 pM) to show enzyme dependence. Both assays contained 0.15 mM GlcNAc₂-PP-Dol and 1.67 μM GDP-(³H)Man (10,000 dpm/assay). Approximated specific activity, based on the first three time points of the assay with 0.023 μg enzyme, is 23 μmol × hr⁻¹ × mg⁻¹.

To further demonstrate that the activity seen in this assay was specifically the result of mannosyl transfer to GlcNAc₂-PP-Dol, and not an artifact of the extraction

procedure, UDP-(³H)GlcNAc and UDP-(³H)Glc were used in place of GDP-(³H)Man and shown not to be transferred to the organic-soluble layer by Alg1Δ1-35 (Figure III-6).

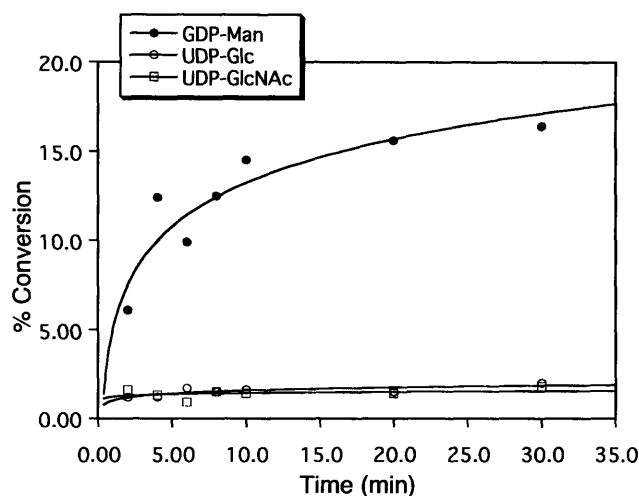

Figure III-6. Activity assays of Alg1Δ1-35 in the presence of UDP-(³H)GlcNAc, (³H)UDP-Glc, or (³H)GDP-Man.

In order to confirm the product of the reaction, organic-soluble products of an Alg1Δ1-35 reaction were analyzed by gel filtration chromatography on BioGel P-2 (BioRad). Products were isolated from a reaction containing 0.23 μg Alg1Δ1-35, 0.45 μM (³H)GDP-Man (22 Ci/mmol), and approximately 5 μM GlcNAc₂-PP-Dol, in which 31% conversion with respect to the GDP-(³H)Man substrate was achieved, corresponding to approximately 85,000 dpm of product. Following mild acid hydrolysis of the glycan, as described in “Experimental Procedures”, half of this glycan sample was loaded onto the column in a volume of 250 μL. As shown in Figure III-7, a peak was detected that corresponded to a product larger than a disaccharide. Since Alg1 is known to catalyze

the conversion of GlcNAc₂-PP-Dol to ManGlcNAc₂-PP-Dol, this product was thus characterized as (³H)ManGlcNAc₂.

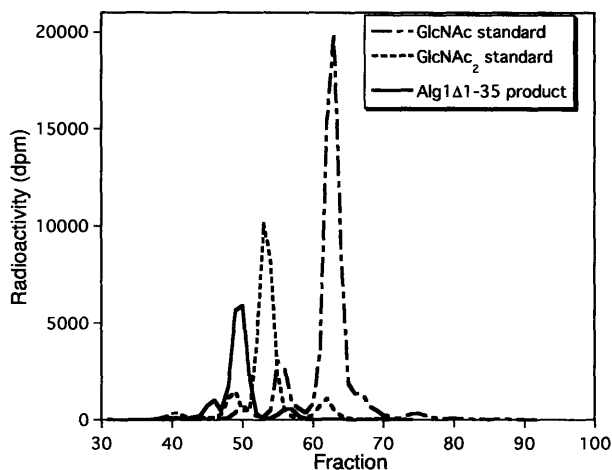

Figure III-7. Gel filtration analysis of the product of the Alg1Δ1-35 reaction. GlcNAc and GlcNAc₂ standards are shown superimposed for comparison.

To test the ability of Alg1Δ1-35 to transfer a mannose residue to a glycopeptide substrate, an *N*_α-Fmoc-protected GlcNAcβ1,4-GlcNAcβ1,*N*_δ-Asn amino acid building block for solid-phase peptide synthesis was synthesized in nine steps as described previously.²² Briefly, the chitobiose moiety was isolated from enzymatically-degraded chitin, aminated at the anomeric position, and coupled to the activated carboxylate side chain of an Fmoc-Asp-OAlloc residue. Finally, the hydroxyl groups of the chitobiose were protected with *t*-butyldimethylsilyl (TBDMS) groups in preparation for solid phase peptide synthesis. The building block was incorporated into a peptide sequence derived from interferon-β in the position of a natively-glycosylated Asn (Figure III-8). The free N-terminus of the peptide was treated with the reactive fluorescein isothiocyanate derivative to incorporate fluorescein for sensitive detection and quantitation *via* HPLC.

Figure III-8. Structure of the glycopeptide tested as a putative Alg1 substrate.

This glycopeptide was subsequently tested as a substrate of Alg1. Prior to, and following, incubation with Alg1 Δ 1-35 in the presence of GDP-Man, the glycopeptide was analyzed on an analytical C₁₈ HPLC column, monitoring UV absorbance, in order to detect mannosylation by a change in retention time. A range of Alg1 Δ 1-35 concentrations were used, up to 110 μ M, which is 400 times the amount necessary to achieve nearly 50% conversion with the native substrate. A shift in retention time was not observed in the HPLC trace of the glycopeptide from the reaction mixture, and mass spectrometry of the collected peak revealed only starting material (Figure III-9). Therefore, Alg1 did not accept this alternate substrate to a degree that reached the detection limit of this assay, suggesting that even in the absence of the transmembrane domain, which is most likely the region that interacts with the dolichyl unit, replacement of dolichylpyrophosphate with a peptide is not tolerated by the enzyme.

Figure III-9. HPLC and ESI-MS results of Alg1 glycopeptide assays. HPLC traces show starting material and Alg1Δ1-35-treated glycopeptide. The expected masses are indicated below the starting material and product.

Characterization of TRX-Alg1 from *E. coli* expression

The Alg1 fusion protein, with thioredoxin (TRX) at the N-terminus, and a His-tag and V5 epitope at the C-terminus, demonstrated activity in the same radioactive assay described in the previous section (Figure III-10). The results of these assays, performed in the presence of either MgCl₂ or MnCl₂, suggest that TRX-Alg1 has a preference for Mg²⁺ over Mn²⁺ under these conditions. Thus, MgCl₂ was used in all subsequent Alg1 assays, and from the data shown in Figure III-10 with Mg²⁺ as the divalent metal, a specific activity of 1.2 nmol × hr⁻¹ × mg⁻¹ for this Alg1 preparation was estimated with

GDP-Man at a concentration of 0.18 μM . It should be noted that in these experiments, the enzyme concentration is in excess of the GDP- ^{3}H Man concentration.

Figure III-10. Activity assays of TRX-Alg1 (0.8 μM) with GlcNAc₂-PP-Dol, GDP- ^{3}H Man (0.2 μM), and 5 mM of either MgCl₂ or MnCl₂.

TRX-Alg1 (4.5 μM) was also assayed with the preceding intermediate in the pathway, GlcNAc-PP-Dol, to examine the specificity of TRX-Alg1 for the glycosyl acceptor substrate. This truncated version of the native substrate of Alg1 was found to be a substrate of TRX-Alg1 in the presence of GDP- ^{3}H Man, but not when UDP- ^{3}H GlcNAc was used in place of GDP- ^{3}H Man (Figure III-11). As shown with the native substrate, Alg1 is specific for the nucleotide-sugar donor, GDP-Man, and the observed activity is therefore not an artifact of the assay. Thus, it appears that TRX-Alg1 is capable of accepting a truncated version of the native substrate, GlcNAc₂-PP-Dol.

Figure III-11. Activity assays of TRX-Alg1 (4.5 μM) with GlcNAc-PP-Dol (approx. 0.3 mM) and either GDP-(^3H)Man (0.18 μM) or UDP-(^3H)GlcNAc (0.17 μM).

The rates for TRX-Alg1 reactions containing GlcNAc₂-PP-Dol or GlcNAc-PP-Dol were measured as shown in Figure III-12. From these data, an activity of 0.44 nmol \times hr⁻¹ \times mg⁻¹ was estimated for TRX-Alg1 in the non-specific reaction with GlcNAc-PP-Dol and 0.18 μM GDP-Man, while the activity for TRX-Alg1 with the native substrate, GlcNAc₂-PP-Dol in the presence of 0.23 μM GDP-Man was 2.8 nmol \times hr⁻¹ \times mg⁻¹. A direct comparison between the two dolichylpyrophosphate-linked substrates should be interpreted carefully, due to the difficulty in quantifying these substrates accurately, and the unknown physical properties of the substrates in detergent solution. For instance, the critical micellar concentration (CMC) values are not known for either of the substrates, and may differ.

Figure III-12. GlcNAc-PP-Dol vs. GlcNAc₂-PP-Dol in the TRX-Alg1 reaction.

Activity assays included TRX-Alg1 (4.5 μ M) and either GlcNAc-PP-Dol (closed circles) or GlcNAc₂-PP-Dol (open circles).

In order to identify the product of this non-specific Alg1 reaction, gel filtration analysis was employed, which separates glycan molecules on the basis of the number of monosaccharide units they comprise. The radiolabeled glycan product was hydrolyzed from dolichylpyrophosphate and compared to (³H)GlcNAc, (³H)GlcNAc₂, and (³H)ManGlcNAc₂ standards by gel filtration chromatography on BioGel P-4 (BioRad) (Figure III-13). This study indicated that the product of the non-specific Alg1 reaction to be a trisaccharide, suggesting that two mannose residues are transferred to GlcNAc-PP-Dol to afford the non-native intermediate, Man₂GlcNAc-PP-Dol. This product could not be confirmed by mass spectrometry due to the lack of sufficient material.

Figure III-13. Gel filtration analysis of the non-native TRX-Alg1 product (solid line) after incubation with GlcNAc-PP-Dol and GDP-(³H)Man.

There are several possible explanations for the observed non-specific behavior of TRX-Alg1. The enzyme concentrations in these assays were in the micromolar range, and the presence of the TRX domain may have influenced the structure enough to affect the function. Similarly, the C-terminal tags of this construct may interfere with homooligomerization, considering that the removal of the final 16 residues of the Alg1 sequence was found to abrogate this complexation.¹⁹ Finally, the enzyme has been removed from the membrane and any possible interacting partners. Therefore, we sought to test this non-specific behavior in a more native-like environment, specifically in a yeast microsomal preparation. Microsomes are prepared by differential centrifugation of yeast cell lysate, and consist of non-solubilized ER and Golgi membranes. To simplify the experiment, a crude microsomal preparation from the temperature-sensitive yeast strain, *alg2*, was employed, which accumulates the trisaccharide intermediate *in vitro*.

Thus, to evaluate native Alg1 specificity in this system, GlcNAc-PP-Dol was incubated with the microsomal preparation in the presence of both UDP-(³H)GlcNAc and GDP-(³H)Man, as a positive control, or in the presence of only GDP-(³H)Man. The expected product in the positive control was ManGlcNAc₂-PP-Dol. The products of these reactions, extracted into the organic phase and hydrolyzed from dolichol, were analyzed by gel filtration on Bio Gel P-4 (BioRad). As shown in Figure III-14, in the presence of both nucleotide-activated sugars, GlcNAc-PP-Dol is elongated through the sequential action of Enzyme II, using UDP-(³H)GlcNAc to produce (³H)GlcNAc₂-PP-Dol, and Alg1, using GDP-(³H)Man to produce (³H)ManGlcNAc₂-PP-Dol. In contrast, no elongation of GlcNAc-PP-Dol was detected upon incubation with microsomes in the presence of only GDP-(³H)Man. Therefore, Alg1 in the native system does not accept GlcNAc-PP-Dol to the extent that any product could be detected in this experiment.

Figure III-14. Gel filtration analysis of *alg2* assay products. The Man peak is from Man-P-Dol synthase activity in the microsomes with residual Dol-P, and provides an internal standard for overall activity of the microsome preparation. The peak at 62-64 minutes is a shoulder of the Man peak, which is a recurring feature of all peaks on this column, but not further investigated. Shoulder and peak sizes were always proportional.

Characterization of Alg1-V5-His from *S. cerevisiae* expression

While the isolated yield of Alg1-V5-His from *S. cerevisiae* expression was not much greater in yeast than in bacteria, the activity was improved by three orders of magnitude in the presence of the native substrate GlcNAc₂-PP-Dol. From the data shown in Figure III-15 for the reaction with GlcNAc₂-PP-Dol as well as three separate assays, the specific activity of this preparation of Alg1 from *S. cerevisiae* was 1.8 $\mu\text{mol} \times \text{hr} \times$

mg ($\pm 0.99 \mu\text{mol} \times \text{hr} \times \text{mg}$ standard deviation based on four assays). Two of the possible sources of the non-specific behavior of TRX-Alg1, specifically high enzyme concentration and the presence of the TRX, could now be tested. Thus, Alg1 ($0.025 \mu\text{M}$) was also assayed with GlcNAc-PP-Dol in the presence of $2 \mu\text{M}$ GDP-Man. As shown in Figure III-15, turnover of the non-native substrate, GlcNAc-PP-Dol, also occurs, with an activity of $0.11 \mu\text{mol} \times \text{hr}^{-1} \times \text{mg}^{-1}$. In this case also, using GlcNAc-PP-Dol as the acceptor substrate, the activity of the Alg1 preparation from *S. cerevisiae* was approximately three orders of magnitude higher than that of TRX-Alg1. These results suggest that the observed non-specific activity was not a result of using high concentrations of enzyme or a perturbation of the structure due to the presence of the TRX domain.

Figure III-15. Alg1 ($0.025 \mu\text{M}$) assays with GlcNAc-PP-Dol or GlcNAc₂-PP-Dol in the presence of $2 \mu\text{M}$ GDP-Man.

Chemoenzymatic preparation of ManGlcNAc₂-PP-Dol using Alg1

The Alg1 preparation from *S. cerevisiae*, stored in 50% glycerol at -20 °C, is extremely stable, with no detectable loss of activity after nearly two years. Therefore, this preparation was chosen to be used as a tool for the chemoenzymatic preparation of Man β 1,4-GlcNAc β 1,4-GlcNAc-PP-Dol. As the putative substrate of Alg2, this intermediate was crucial for characterization of the later steps in the dolichol pathway. The synthesis began with the enzymatic degradation of chitin and subsequent modification to yield peracetylated chitobiose.²³ The remaining steps leading to dolichyl-linked chitobiose were carried out as described previously.²⁴

To monitor mannosylation of GlcNAc₂-PP-Dol, a new non-radioactive assay was implemented, in which hydrolyzed glycan products were labeled by reductive amination with the fluorophore, 2-aminobenzamide (2-AB) (Figure III-16),²⁵ and then separated by normal-phase HPLC and observed by fluorescence detection ($\lambda_{\text{Ex}} = 330 \text{ nm}$, $\lambda_{\text{Em}} = 420 \text{ nm}$).²⁶

Figure III-16. Labeling of reducing sugars with 2-aminobenzamide.

The Alg1-catalyzed conversion of GlcNAc₂-PP-Dol to ManGlcNAc₂-PP-Dol was detected by this method, and was found to occur in greater than 95% yield, as estimated by the relative HPLC peak sizes (Figure III-17). The peak with retention time of 40

minutes was characterized by MALDI-MS, and the β 1,4-linkage was verified by sensitivity to a β 1,4-mannosidase. The expected mass of the 2-AB labeled ManGlcNAc₂ [M+H]⁺ is 707.7, and the observed masses in the MALDI spectrum of the 40-minute peak are [M + H]⁺ = 707.5 and [M + Na]⁺ = 729.4.

Figure III-17. HPLC trace of ManGlcNAc₂-PP-Dol preparation using Alg1.

Using the HPLC assay to test the non-specific behavior of Alg1 from *S. cerevisiae* expression, no product formation was detected when Alg1 was incubated with GlcNAc-PP-Dol in the presence of 1 mM GDP-Man. This result suggested that the highly sensitive radiolabeled assay is necessary to observe the non-specific behavior, and that while this behavior does appear to be real, it does not translate to a high degree of turnover, and is likely why it has not been observed previously. Importantly, this activity does not interfere with the HPLC assay, which was subsequently used to annotate the correct activity of Alg2 (Chapter IV) and Alg11 (Chapter V).

Conclusion

Through the cloning and expression of various Alg1 constructs, some of the details of the inherent substrate specificity of this mannosyltransferase, in the absence of possible participation from the membrane and/or neighboring dolichol pathway glycosyltransferases, have been described. Despite several attempts to mannosylate an Asn(GlcNAc₂)-containing synthetic glycopeptide, the specificity of Alg1, even in the absence of the predicted transmembrane domain, does not allow this transformation to occur at a detectable level. It is likely that the pyrophosphate moiety is an important binding determinant, and while it is known that the dolichyl group can be replaced by a phytanyl group, the limits of tolerance for further truncation and/or completely divergent saccharide-presenting scaffolds is still unknown. It is possible that optimization for recognition may be achieved by modifying the peptide sequence, however, such manipulation would limit the general application of Alg1 for the chemoenzymatic synthesis of glycoproteins.

Alg1, isolated from the native membrane environment as well as the rest of the enzymes of the pathway, appears to accept GlcNAc-PP-Dol to carry out two non-specific reactions, resulting in the formation of a non-native trisaccharide intermediate. A specific activity of $0.44 \text{ nmol} \times \text{hr}^{-1} \times \text{mg}^{-1}$ was estimated for TRX-Alg1, with respect to the turnover of the GDP-Man substrate. If indeed two Man units are transferred to the GlcNAc-PP-Dol acceptor, then turnover of the GlcNAc-PP-Dol substrate would be half of this value. Using an Alg1 preparation that exhibited approximately three orders of magnitude greater activity with the native substrate, a similar increase in activity was

observed toward the non-native substrate, for which a specific activity of $0.11 \mu\text{mol} \times \text{hr}^{-1} \times \text{mg}^{-1}$ was estimated. The possible formation of $\text{Man}_2\text{GlcNAc-PP-Dol}$ from the GlcNAc-PP-Dol intermediate in the non-specific Alg1 reaction is understandable, considering the chemistry of the two corresponding steps in the native system. Each of the two steps requires the formation of a $\beta 1,4$ -linkage, and the ability of Alg1 to accept the non-native disaccharide is plausible since the Man and GlcNAc residues only differ from each other at the C-2 position (highlighted in gray, Figure III-18), which is far from where the chemistry occurs.

Figure III-18. Native and proposed non-native trisaccharide intermediates.

Therefore, in the first non-specific step, Alg1 needs only accept a slightly truncated version of the native substrate, and in the second step, needs only to accept a substrate with a modified C-2 substituent on the residue that is being acted upon.

While this non-specific behavior appears to be significant when compared to reaction with the native substrate, and occurs even at nanomolar concentrations of Alg1 and in the absence of the TRX domain, it is restricted to detection only by the sensitive radiolabeled assay. Such activity could not be detected in the fluorescence-based HPLC

assay, which monitors absolute turnover of the dolichylpyrophosphate-linked substrate. Also, this non-specific behavior was not observed in a yeast microsomal preparation. These results suggest that the membrane may play a key role, positioning the enzyme and dolichyl-linked substrate in the correct position relative to one another, or perhaps complexation with other glycosyltransferases ensures the proper order.

Finally, expression and purification of Alg1 from the native source, *S. cerevisiae*, yielded a stable enzyme preparation with activity comparable to that of detergent solubilized native Alg1 from yeast microsomes. This preparation has proved invaluable as a tool to gain access to the trisaccharide intermediate for studies of Alg2 (Chapter IV) and, ultimately, Alg11 (Chapter V).

Acknowledgements

The plasmid containing *ALG1Δ1-35* cloned into the pET-28a expression vector was provided by the laboratory of Professor P. George Wang at Wayne State University. The temperature-sensitive *alg2* yeast strain was provided by the laboratory of Professor Maria Kukuruzinska at Boston University. The yeast strain PRY46, from which genomic DNA was isolated for amplification of *ALG1*, was provided by the laboratory of Professor Phillip Robbins at Boston University. The yeast strain, NDY 13.4, used for HPLC standardization, was provided by the laboratory of Professor Neta Dean at the State University of NY, Stonybrook. The resin-bound peptide Fmoc-Glu-Thr-Ile-Val-Glu-Asn-Leu-Lys-PAL-PEG-PS was provided by Dr. Carlos Bosques. Dr. Eranthie Weerapana provided much assistance in the synthesis of GlcNAc₂-PP-Dol.

Experimental Procedures

Media and buffers

Minimal Media (1 L): 6.7 g yeast nitrogen base (Difco) (- amino acids, + salts), 0.6 g CSL-His-Leu-Trp (Bio101, Inc.), 50 mg His, 100 mg Leu, 100 mg Trp, 2% D-glucose.

Induction Media (1 L): 6.7 g yeast nitrogen base (Difco) (- amino acids, + salts), 0.6 g CSL-His-Leu-Trp (Bio101, Inc.), 50 mg His, 100 mg Leu, 100 mg Trp, 2% galactose and 1% raffinose.

Buffer A: 50 mM NaH₂PO₄, pH 8.0, 300 mM NaCl, 10 mM imidazole, pH to 8.0 with NaOH.

Buffer B: 50 mM Tris-Cl pH 7.5, 2.5 mM MgCl₂

Buffer C: 50 mM Tris, pH 7, 0.25 M sucrose, 3 mM DTT, 5 mM MgCl₂, 0.13 % NP-40.

2× Buffer D: 38 mM Tris-Cl, pH 7.2, 1.8 mM DTT, 0.28 mM EDTA, 0.26% NP-40.

TUP: CHCl₃: MeOH: 4 mM MgCl₂ (2.75:44:53.25)

Expression and purification of Alg1Δ1-35

Competent BL21(DE3) cells transformed with *ALGA1-105* (pET-15b) were grown overnight in 6 mL of LB culture containing 0.1 mg/mL ampicillin. The overnight culture was used to inoculate 100 mL of LB containing 0.1 mg/mL ampicillin, and this culture was shaken at 37 °C until the optical density reached 2.9. Expression was induced with 1 mM IPTG and allowed to proceed at 30 °C for 4 hr. Cells were then harvested by centrifugation (20 min, 3836 × g, 4 °C), and the cell pellet stored at -80 °C.

For the purification, cells were incubated on ice in 10 mL of Buffer A containing 1% Triton X-100 and 1 mg/mL lysozyme for 30 min, followed by sonication (6 pulses, 10 sec/ea with 10-sec cooling intervals). Lysed cells were then centrifuged to pellet insoluble debris (30 min, 3.800 × g, 4 °C). The supernatant from this spin was added to 2.5 mL of pre-equilibrated agarose-bound Ni-NTA (Pierce, provided as a 50% slurry) for 1 mL resin slurry/4 mL lysate. This mixture was incubated for 1 hr at 4 °C with rocking to allow binding to occur, then poured into a plastic 1-cm diameter Econo-column (Pierce). Flow-through was collected at a rate of less than 1 mL/min and the resin was washed twice with 10 mL/ea of wash buffer (Buffer A containing 20 mM imidazole and 1% Triton X-100). Protein was then eluted from the column by adding 5 mL of elution buffer (Buffer A containing 250 mM imidazole and 1% Triton X-100) and collecting 1-mL fractions. Fractions containing purified Alg1Δ1-35 were pooled and dialyzed against 50 mM Tris-OAc, pH 7.0, 0.25 M sucrose, 5 mM MgCl₂ for 8 hours total with 2 buffer changes. Protein concentration was determined by the micro-BCA assay (Pierce).

F1-Ahx-Arg-Gly-Trp-Asn(GlcNAc₂)-Glu-Thr-Ile-Val-Glu-Asn-Leu-Lys-NH₂

The synthesis began with Fmoc-Glu-Thr-Ile-Val-Glu-Asn-Leu-Lys-PAL-PEG-PS, which had been prepared previously by Carlos Bosques. The PAL-PEG-PS resin was purchased from PerSeptive Biosystems. The Fmoc-Asn[GlcNAc₂(TBDMS₅)]-OH building block²² (1.2 equivalents) was activated with the coupling reagent 7-azabenzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyAOP) (2 equivalents), dissolved in 2 mL of CH₂Cl₂, and added to the resin-bound peptide. To initiate the coupling reaction, 4 equivalents of collidine were added and the mixture was

allowed to shake overnight at room temperature. The extent of coupling was analyzed by a small-scale cleavage/deprotection and HPLC/ESI-MS (see Experimental section of Chapter VI for general procedures) revealed approximately 60% conversion by HPLC. Unreacted peptide was capped with acetic anhydride to prevent further elongation. Acetic anhydride (30 equivalents) and collidine (60 equivalents) were added to the resin and allowed to shake for 10 minutes at room temperature. Tryptophan, glycine, and arginine were coupled using standard solid phase peptide synthesis methods (Chapter VI), and the peptide was then capped using Fmoc-aminohexanoic acid (2 equivalents) with PyAOP (2 equivalents) and collidine (4 equivalents) in DMF for two hours. Capping of the N-terminus with fluorescein was accomplished by adding 2 equivalents of fluorescein isothiocyanate to the resin-bound peptide in the presence of 4 equivalents of collidine. The reaction proceeded overnight in the dark at room temperature. These conditions were repeated twice more before nearly complete coupling was achieved. The peptide was released from the resin as described in Chapter VI (General procedures for peptide release and deprotection) using a cocktail of 92% trifluoroacetic acid (TFA), 2% triisopropylsilane (TIS), 3% H₂O, and 3% ethanedithiol (EDT). Following preparative HPLC purification of the glycopeptide, analytical HPLC revealed the presence of an additional more-polar product with a mass of +16 compared to the desired peptide. This modification was found to be reversible with the addition of 10 mM dithiothreitol (DTT). Therefore, the glycopeptide was henceforth stored in 40 mM Mes-NaOH, pH 6.6 containing 10 mM DTT. Quantification of the fluorescent glycopeptide took advantage of the extinction coefficient of fluorescein (78,000 M⁻¹ cm⁻¹).

Alg1Δ1-35 glycopeptide assays

To a mixture of 3.0 – 4.5 μM glycopeptide and 3 - 30 μM of GDP-Man in Buffer C containing 0 or 0.25% Triton X-100, 2.8 to 112 μM of Alg1Δ1-35 was added, for a final volume of 100 μL. Reaction mixtures were incubated overnight at 30°C or 37°C. Following the addition of 100 μL of acetonitrile, samples were centrifuged at high speed to remove any insoluble material, and then analyzed on a Waters analytical C₁₈ HPLC column. Peptide was eluted with a linear gradient of 20-60% acetonitrile (0.1% TFA) in water (0.1% TFA) over 30 min at a flow rate of 1 mL/min. Peaks were collected, concentrated on a Sc110 Speed-Vac (Savant), and characterized by ESI-MS.

Cloning of full-length *ALG1*

Genomic DNA was extracted from the *S. cerevisiae* strain PRY46 using the Yeast DNA Extraction Reagent (Y-DER) from Pierce, Inc. *ALG1* was amplified from yeast genomic DNA by PCR using the following primers and Vent polymerase for the extension: 5'-CAC CAT GTT TTT GGA AAT TCC T-3' and 5'-TCA ATG AAT TAG CTT CAA-3'. The *ALG1* PCR product was first cloned into pENTR/SD/D-TOPO entry vectors (Invitrogen) using the Gateway System to yield constructs bearing stop codons. This entry vector was then transferred by homologous recombination using LR Clonase enzymes (Invitrogen) to either of the destination vectors, pBAD-DEST49 or pYES-DEST52, for expression in *E. coli* or *S. cerevisiae*, respectively. To enable the addition

of the His₆ tag and the V5 epitope as C-terminal tags in the expressed product, the stop codon in the *ALG1* entry vector was later changed to a Gly residue by site-directed mutagenesis using the QuikChange kit (Stratagene), using the following primers, in which the underlined sequence indicates the STOP to Gly mutation.

5'-ATT TGA AGC TAA TTC ATG GAA AGG GTG GGC GCG C-3'

5'-GCG CGC CCA CCC TTT CCA TGA ATT AGC TTC AAA T-3'.

The *ALG1*-containing entry vector was verified by DNA sequencing at the MIT Biopolymers Laboratory using M13 sequencing primers (Invitrogen):

M13 Forward: 5'-GTAAAACGACGGCCAG-3'

M13 Reverse: 5'-CAGGAAACAGCTATGAC-3'

Expression in *E. coli* and purification of TRX-Alg1

One Shot Top 10 competent cells (Invitrogen) were transformed with 1 μ L/ea of *ALG1*-containing pBAD-DEST49 *E. coli* expression vector as well as plasmid isolated from BL21(DE3) codon-plus RIL cells, both of which had been prepared from mini-preparation of 3 mL of overgrown culture using the Eppendorf Perfect Prep Plasmid Mini Kit. Since this vector uses an *araBAD* (P_{BAD}) promoter for tightly controlled expression, an *E. coli* strain deficient in the *ara* operon, such as the TOP10 strain, was necessary. Plasmids were selected for based on the carbenicillin resistance of pBAD-DEST49 and chloramphenicol resistance of the codon-plus plasmid. Cells were shaken at 37 °C in 1 L of Terrific Broth (Invitrogen) until growth had reached the stationary phase ($A_{600} > 1$). Expression was induced with the addition of arabinose to a final concentration of 0.02% (w/v) followed by shaking at 37 °C for two hours. Cells were then harvested by

centrifugation (10 min, $15,344 \times g$, $4\text{ }^{\circ}\text{C}$), and pellets were stored at $-80\text{ }^{\circ}\text{C}$ until purification.

The expressed TRX-Alg1-V5-His tag construct was purified by Ni-NTA affinity chromatography. All steps were performed at $4\text{ }^{\circ}\text{C}$. Cell pellets from 1-L expressions were resuspended in 40 mL of Buffer A containing 1% Triton X-100, 1 x protease inhibitor cocktail III (Calbiochem), and 1 mg/ mL lysozyme (Sigma). The cell mixture was allowed to incubate on ice for 30 minutes and then lysed by sonication for 2 minutes or until the solution clarified. Cell debris was pelleted by centrifugation (30 min, $11,625 \times g$, $4\text{ }^{\circ}\text{C}$). The supernatant from this spin was filtered through a 0.2- μm syringe-filter and was added to Ni-NTA slurry (2 or 4 mL of a 50% slurry, Qiagen). This mixture was rocked at $4\text{ }^{\circ}\text{C}$ for 1 hr, then poured into a 20-mL plastic Econo-column (BioRad). After collecting the flow-through and washing the resin twice with 20 mL of Buffer A containing 20 mM imidazole and 1% Triton X-100, bound protein was eluted using a step-wise gradient of Buffer A containing 40 mM, 80 mM, and 160 mM imidazole, respectively. In the first step, four 5-mL fractions were collected from the 40 mM imidazole buffer, then three 3-mL fractions were collected from the 80 mM imidazole buffer, and ten 1-mL fractions were collected from the 160 mM imidazole buffer.

Fractions containing purified TRX-Alg1 were concentrated by dialyzing pooled fractions against Buffer C, followed by incubation with 0.5 mL of Ni-NTA slurry at $4\text{ }^{\circ}\text{C}$ for 1 hr. Protein was eluted with two 0.5-mL aliquots of Buffer A containing 200 mM imidazole and 1% Triton X-100. Elutions were then dialyzed as above to remove imidazole and protein concentrations for each fraction were determined using the BioRad Protein Assay to be 0.25 and 0.48 mg/mL, for a yield of 0.37 mg from a 1-L expression.

Expression in *S. cerevisiae* and purification of Alg1

For *S. cerevisiae* expression, the yeast strain INVSc1 was made competent and transformed with pYES-DEST52 constructs using the *S. cerevisiae* EasyComp Transformation Kit (Invitrogen) according to the manufacturer's instructions. Starting from glycerol stocks of pYES-DEST52 clones in InvSc1 *S. cerevisiae* yeast strains, *ALG1*-containing cells were grown in minimal media, starting with 10-mL cultures and diluting to 500 mL of minimal media. The 500-mL cultures were grown to an O.D. of 4-5, and then four equal aliquots were removed, the volumes of which were chosen to enable resuspension of the cells from each aliquot in 1-L batches of induction media to achieve an O.D. of 0.4. Aliquots were pelleted by centrifugation (2,500 × g, 5 minutes, 4°C), the supernatant discarded, and pellets were then resuspended in 3-5 mL of induction media and added to 1-L batches of induction media. Expression cultures were shaken at 30°C for 24 hours, and then harvested by centrifugation (2,500 × g, 5 minutes, 4°C), washing once with cold Buffer B, and stored at -80°C or left on ice in the cold room (for use within 16 hours). All subsequent steps were performed at 4°C. To prepare solubilized microsomes, the cell pellet was resuspended in 200 mL of Buffer B containing the protease inhibitors AEBSF (0.1 mM), pepstatin A (0.5 µg/mL), and leupeptin (0.5 µg/mL), and lysed using glass beads in a bead beater (16 × 20 sec, with 40-sec cooling intervals). Cell debris was pelleted at 7K rpm for 8 minutes. Supernatant was centrifuged again as in the last step to remove residual debris. Supernatant from the second spin was centrifuged at 117734 × g for 1 hour to pellet the crude microsomes. Crude microsomes were homogenized in 50 mL of Buffer A containing 1% NP-40 using

a homogenizer with a Teflon stopper, shaken on ice for 15 minutes, and then centrifuged for 1 hour $117734 \times g$. Supernatant was saved as solubilized microsomes, which were subsequently filtered through a $0.2 \mu\text{m}$ syringe filter and incubated with Ni-NTA for 1 hour prior to affinity purification. Following incubation, the flow-through was collected by pouring the mixture into a 20-mL plastic Econo column (BioRad) with the outlet open, and then the resin was washed twice with 20 mL of Buffer A containing 20 mM imidazole and 0.1% NP-40. Protein was eluted with a step-wise gradient using 5-mL aliquots of 40, 120, and 240 mM imidazole in Buffer A containing 0.1% NP-40. Two of the most concentrated pure protein-containing fractions were pooled and dialyzed against Buffer C, then brought to 50% glycerol and stored at $-20 \text{ }^\circ\text{C}$. Protein concentration was estimated using the BioRad Protein Assay Reagent, using BSA to generate a standard curve, to be 0.13 mg/mL, for a yield of 0.26 mg of protein from a 4-L yeast expression.

Radioactive activity assays

For each reaction, GlcNAc-PP-Dol or GlcNAc₂-PP-Dol (approximately 60 μg) was added to a 0.5 mL eppendorf tube in CHCl_3 : MeOH (3:2) and dried under a stream of nitrogen. Next, 10-20 μL of GDP-(³H)Man (2 μM , approx. 1,000 dpm/ μL) was added and dried under nitrogen. Buffer C containing 1% NP-40 or Triton X-100 was added to the tube and vortexed well to disperse substrates. (For the metal comparison assay, this buffer was prepared without MgCl_2 and to it was added either no metal, MgCl_2 (5 mM final), or MnCl_2 (5 mM final). Reactions were initiated with the addition of enzyme (amounts as indicated in “Results and Discussion”) for a final volume of 100 μL and proceeded at room temperature. Aliquots of 10 μL were removed at intervals of time and

quenched by adding to 600 μL of CHCl_3 :MeOH:4 mM MgCl_2 (3:2:1) and vortexing. In endpoint assays (for gel filtration), the entire 100- μL reaction mixture was quenched after 30 minutes by adding it to CHCl_3 :MeOH (3:2) (0.5 mL) and vortexing. Extractions and scintillation counting were completed as described in Chapter II (Enzyme II assay).

Gel filtration of radiolabeled saccharides

Bio-Gel P2 resin (BioRad) (29.3 g) was added to degassed 50 mM acetic acid (200 mL) and allowed to swell overnight. Half of the buffer was poured off, and the resin slurry was transferred to an Erlenmeyer flask to be degassed for 10-15 minutes. To remove gel fines, fresh buffer was added and the resin was swirled. When most of the resin had settled, the buffer was poured off. This step was repeated three additional times. All of the gel slurry was poured into a 1-cm diameter glass Econo-column (BioRad) to a height of 117 cm. Once the gel had settled, the column was equilibrated with degassed 50 mM HOAc containing 150 mM NaCl. To determine the exclusion volume of the column, 250 μL of an 8 mg/mL solution of blue dextran in the same buffer was loaded on the column and eluted with the same buffer. Fractions were collected at 44 drops (1.05 mL)/tube, and the blue dextran came out in fractions 34-36.

Bio-Gel P4 resin was prepared in the same way as Bio-Gel P2, except that 18.3 g of resin was used, and the buffer used to remove gel fines also contained 150 mM NaCl. The height of the settled column was 107 cm, and blue dextran (loaded as 250 μL of an 8 mg/ml solution) eluted in fractions 29-32.

Dolichol-linked saccharides to be analyzed by gel filtration were dissolved in 0.5 mL of *n*-propanol, followed by addition of 0.5 mL of 2 N HCl. This mixture was heated

to 50°C for 15 minutes, and then concentrated under a stream of nitrogen. The remaining acid was neutralized with NaOH and further concentrated to approximately 250 µL before loading the sample onto the column. The products were eluted with 50 mM HOAc containing 150 mM NaCl. The first 30 fractions (31.5 mL) were collected in a graduated cylinder before connecting the column to a fraction collector and collecting 44 more fractions (40 drops, 1.05 mL) in 7-mL scintillation vials. To each of these fractions, 5 mL of EcoLite scintillation cocktail (ICN Biomedicals, Inc.) were added and the vials counted on a scintillation counter (Beckman, Inc.) (5 minutes/vial). Monosaccharide (GlcNAc) and disaccharide (GlcNAc₂) standards were run on the column after hydrolyzing UDP-(³H)GlcNAc and (³H)GlcNAc-GlcNAc-PP-Dol, respectively.

Preparation of ManGlcNAc₂-PP-Dol with Alg1 expressed in *S. cerevisiae*.

To a dried aliquot of approximately 15-20 nmol of GlcNAc₂-PP-Dol, 500 µL of 2× Buffer D was added and sonicated in a water bath sonicator for 1 min to disperse substrate. To this solution was added 10 µL of 1 M MgCl₂, 40 µL of 50 mM GDP-Man, 440 µL of dH₂O, and 10 µL of Alg1 (2.5 µM). The reaction mixture was incubated at 37 °C for 1 hr, then quenched by addition to 11 mL of CHCl₃: MeOH: 4 mM MgCl₂ (6:4:1). The dolichylpyrophosphate-linked product partitions into the organic phase, which was washed twice with TUP, then concentrated to dryness, redissolved in 1 mL of CHCl₃: MeOH (3:2) and aliquoted 10 µL/tube for assays. Aliquots were stored dry at -80 °C.

Hydrolysis of glycans from dolichylpyrophosphate for HPLC assay

Dried aliquots of samples to be hydrolyzed were resuspended in 500 μL of 0.1 M trifluoroacetic acid in dH_2O : *n*-propanol (1:1) and incubated at 50 $^\circ\text{C}$ for 15 min. Samples were then concentrated to dryness on a Speed-Vac (Sc110, Savant, Inc.) in preparation for labeling.

2-AB labeling of saccharides²⁵

To prepare the dye-labeling reagent, a 150- μL aliquot of acetic acid was added to a 350- μL aliquot of DMSO, and then a 100- μL aliquot of this mixture was used to dissolve 5 mg of 2-aminobenzamide (2-AB). The entire dye solution was added to 6 mg of sodium cyanoborohydride and mixed well to dissolve the reductant. Aliquots of 5 μL of this reagent were then added to dried samples of hydrolyzed, dried glycans, and heated to 65 $^\circ\text{C}$ for 2-4 hours. Post-labeling cleanup was accomplished by using GlykoClean S cartridges (ProZyme Inc.).

Normal-phase HPLC²⁶

The normal phase analytical HPLC column (GlykoSepN) was purchased from ProZyme, Inc. The solvents used were 50 mM ammonium formate, pH 4.4 (Solvent A) and acetonitrile (Solvent B). A linear gradient of 20-52% Solvent A in Solvent B over 80

minutes was used to elute the 2AB-labeled glycans. Standardization of the column was done first with commercial standards (ProZyme, Inc.), including a glucose homopolymer and the pentasaccharide core, Man₅GlcNAc₂, each labeled with the 2-aminobenzamide (2-AB) fluorophore. Additionally, every dolichyl-linked intermediate from GlcNAc to Man₅GlcNAc₂ was prepared as the hydrolyzed and derivatized species, analyzed by HPLC, and confirmed by MALDI-MS. Mono- and disaccharides were hydrolyzed from synthetic preparations, the trisaccharide from the chemoenzymatic Alg1 preparation, and tetra- through heptasaccharides were obtained by elongating the trisaccharide intermediate using microsomes from wild-type yeast (INVSc1, Invitrogen) as well as a temperature-sensitive *alg11* yeast strain (NDY 13.4). Typically 5-20 pmol of material was loaded for HPLC analysis. Up to 10× more was loaded if material was being collected for MALDI-MS or for mannosidase cleavage analysis.

MALDI-MS

Mass spectrometric analysis was performed on a PE Biosystems Voyager System 4028 using the reflector, positive mode as described.²⁷ 2, 5-Dihydroxybenzoic acid was used as the matrix. A solution of dihydroxybenzoic acid (DHB) (10 mg) in acetone (0.5 mL) was prepared, and applied to the target as a thin film. The glycans from HPLC fractions were dried on a Sc110 Speed-Vac (Savant, Inc.), then redissolved in 5-10 μL of dH₂O. A 1-μL drop of each glycan sample was spotted onto the target and dried under a slight airstream. A second solution of DHB (10 mg) was prepared by dissolving the matrix in 333 μL of acetonitrile, 167 μL dH₂O, 10 μL 5% perfluorinated Nafion (Sigma-Aldrich), and 0.5 μL TFA. A 0.5-μL drop of this solution was added to each of the dried

glycan spots and dried under a slight airstream. Calibration mixture #1 from the Sequazyme mass standards kit (Applied Biosystems) was used for standardization.

Chapter IV: Studies toward defining the function of Alg2

Introduction

Although *ALG2* mutants have been identified and characterized in *Saccharomyces cerevisiae*,¹ the zygomycete fungus *Rhizomucor pusillus*,² and humans,³ the results have not been entirely consistent. It has been suggested that Alg2 is responsible for either the second, third, or both the second and third mannosylation steps of the dolichol pathway (Scheme IV-1).¹⁻⁵

Scheme IV-1. $\alpha 1,3$ - and $\alpha 1,6$ -Mannosylation reactions putatively catalyzed by Alg2.

The *alg2-1* yeast mutant was isolated by the mannose suicide selection screen described in Chapter III, and was characterized by a temperature-sensitive phenotype, in which an accumulation of both ManGlcNAc₂-PP-Dol and Man₂GlcNAc₂-PP-Dol was

detected.¹ The genetic basis for this phenotype was later mapped to two point mutations, G377R and Q386K. By complementing *alg2-1* with the two corresponding single mutants of the *R. pusillus* *ALG2* homolog, one of the mutations (G377R in the yeast Alg2) was found to be sufficient to support the phenotype (Figure IV-1).⁵ From these results, which must take into account that temperature-sensitive mutants can retain low levels of activity even at the non-permissive temperature, it could only be concluded that Alg2 is a mannosyltransferase that acts early on the dolichol pathway.

Figure IV-1. Summary of Alg2 mutants characterized to date, highlighting the position of the conserved EX₇E motif, which is shown for each organism with the Glu residues in bold.

Interestingly, *ALG2* in *R. pusillus* is not an essential gene, and when a natural mutant was isolated with nearly the entire C-terminal half of the sequence deleted (Figure IV-1), the only accumulated intermediate was ManGlcNAc₂-PP-Dol.² This result suggested that Alg2 is responsible for the second mannosylation step, although it does not address any possible involvement of Alg2 in the third mannosylation.

A newly discovered congenital disorder of glycosylation (CDGII) resulting from mutated human *ALG2* has provided an additional example to consider.³ In this case, the mutation causes a frame shift that introduces a premature stop codon, leading to a significant deletion of the C-terminal portion of the protein, but not the loss of a conserved EX₇E motif (Figure IV-1). By metabolically labeling CDGII patient fibroblasts with radiolabeled mannose, a phenotype similar to that found in the yeast mutant was revealed. Specifically, accumulation of both ManGlcNAc₂-PP-Dol and Man₂GlcNAc₂-PP-Dol was observed.

From these results it was concluded that Alg2 carries out only the second mannosylation to form Man α 1,3-ManGlcNAc₂-PP-Dol. The tetrasaccharide product formed in the patient fibroblasts was proposed to be the non-native Man α 1,6-ManGlcNAc₂-PP-Dol, as opposed to the native intermediate, Man α 1,3-ManGlcNAc₂-PP-Dol, and that the non-specific step to get to this non-native product was carried out by the unidentified mannosyltransferase following Alg2. In the absence of the α 1,3-linked mannose residue, the non-native intermediate would fail to be further elongated (Figure IV-2). However, no structural characterization of this tetrasaccharide was reported to support the hypothesis that the accumulated tetrasaccharide was the α 1,6-mannosylated tetrasaccharide. Taken together, the genetic data are consistent with a role for Alg2 as a mannosyltransferase early in the pathway, however the precise function of the enzyme required *in vitro* biochemical validation.

Figure IV-2. Sequence of glycosylation steps on the cytosolic face of the ER membrane. GlcNAc residues are depicted as black squares, Man residues as gray circles, phosphate groups as **P**, and dolichyl moieties as wavy lines.

Alg2 from *S. cerevisiae* is a 503-residue, 58-kDa mannosyltransferase containing four predicted transmembrane domains, as predicted by the TMHMM server, v. 2.0 (Figure IV-3).⁶ These domains are grouped into two pairs of closely-spaced domains, with one pair at the extreme C-terminus, and the other pair located near the N-terminus. Our goal for the studies described in this chapter was to find an expression system for active Alg2 that would enable an *in vitro* assay with defined Dol-PP-linked substrates to unambiguously define the function of this enzyme. Alg2 mutants were also used to probe the importance of the Glu residues within the conserved EX₇E motif.

Figure IV-3. Predicted topology of Alg2. Plot of the probability that Alg2 residues are in a transmembrane-spanning region.

Results and Discussion

Cloning and expression of TRX-Alg2-V5-His in *E. coli*

Initially, *ALG2* was amplified from *Saccharomyces cerevisiae* genomic DNA and cloned into the pET-15b vector (Novagen) for a construct encoding an N-terminal His tag. However, no significant expression of this construct was achieved, even using cells that provide extra copies of tRNA for certain codons to compensate for differences in codon usage between *E. coli* and *S. cerevisiae*. To improve expression, *ALG2* was cloned into the pBAD-DEST49 expression vector for *E. coli* expression of a construct that encodes an N-terminal thioredoxin (TRX) tag. This construct also included a C-terminal V5 epitope for detection and C-terminal His tag for purification. Cloning and expression was carried out using the Gateway[®] Cloning Technology (Invitrogen), as described for Alg1 in Chapter III. Cells were lysed in the presence of detergent, and the clarified lysate

was purified by Ni-NTA chromatography to obtain the TRX-Alg2 fusion protein with a predicted molecular weight of 70 kDa as shown in Figure IV-4.

Figure IV-4. Purified TRX-Alg2-V5-His from *E. coli* expression. Molecular weight markers are labeled on the left in kDa. A) Coomassie stain B) Western blot analysis with α -Thio antibody (Invitrogen) for detection of the TRX domain.

TRX-Alg2-V5-His mannosyltransferase activity assays

HPLC assays were carried out on this TRX-Alg2-V5-His preparation, as described in Chapter III, whereby the organic-soluble extracts of reaction mixtures were hydrolyzed and labeled with 2-aminobenzamide prior to HPLC analysis on a normal-phase column with fluorescence detection ($\lambda_{\text{Ex}} = 330 \text{ nm}$, $\lambda_{\text{Em}} = 420 \text{ nm}$). Assays were carried out with ManGlcNAc₂-PP-Dol prepared using Alg1, as described in Chapter III, or with GlcNAc₂-PP-Dol in combination with Alg1. Conditions varied in detergent and phospholipid composition and concentration, as well as temperature, GDP-Man concentration, and time. In all cases, however, no activity was detected under any of the conditions tested. Phospholipids used included phosphatidylcholine and phosphatidylethanolamine, and detergents tested included the nonionic detergents Triton

X-100, Nonidet P-40, TWEEN 20, and dodecylmaltoside, as well as steroid-based zwitterionic detergents such as CHAPS and CHAPSO. Detergent concentrations tested ranged from 0.02% to 1% (w/v) or (v/v), but were used in concentrations above the critical micelle concentration (CMC). While the CMC values of the dolichol substrates are not known, Alg1 activity had been observed to be sensitive to high concentrations of GlcNAc₂-PP-Dol, and therefore a wide range of ManGlcNAc₂-PP-Dol concentrations were tested with Alg2 to avoid the possibility that the concentrations used were inhibitory.

There are numerous possible reasons for the failure to demonstrate activity. ManGlcNAc₂-PP-Dol may not be the native substrate of Alg2, an accessory protein may be necessary for activity, or Alg2 itself may only be an accessory protein. Therefore, a separate *in vitro* assay was used whereby expressed Alg2 was added to microsomes prepared from the *alg2* yeast strain, and complementation of the *alg2* mutant defect was tested. This complementation assay would be expected to report Alg2 activity by elongation of the GlcNAc₂-PP-Dol substrate to the heptasaccharide intermediate. No further elongation would be expected since the subsequent mannosyltransferases require Man-P-Dol as the glycosyl donor, which was not added. The advantage of this assay is that it does not require prior knowledge of the native Alg2 substrate, since the only component missing is active Alg2. Even if Alg2 were only an accessory protein, addition of an intact Alg2 preparation should complement the defect.

As shown by the HPLC trace in Figure IV-5, the microsomal preparation from *alg2* mutant yeast elongates GlcNAc₂-PP-Dol to ManGlcNAc₂-PP-Dol in the presence of GDP-Man, with no evidence for the accumulation of larger intermediates. Unfortunately,

all of the Alg2 preparations tested were unable to complement the defect, though many of the same strategies used in the original Alg2 assays to optimize the conditions were also employed in these complementation assays.

Figure IV-5. Elongation of GlcNAc₂-PP-Dol with *alg2* microsomes used in the complementation assay for Alg2 activity. A product with the retention time of authentic ManGlcNAc₂-2AB appears. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

Cloning and expression of Strep-Alg2-V5-His in *S. cerevisiae*

Since expression of Alg1-V5-His in *S. cerevisiae* yielded a preparation with improved activity, a similar approach was taken for Alg2. The Alg2 construct, which was prepared from the same vector used for Alg1 expression in yeast (Chapter III), also included the C-terminal V5 epitope and His tag. At the N-terminus, a Strep tag (Qiagen) was included, which is a short peptide that binds with micromolar affinity to an engineered Streptavidin (Qiagen). This tag was incorporated into the construct by using a PCR primer encoding the tag in the cloning step. The use of this N-terminal tag was chosen to allow an additional purification step following Ni-NTA chromatography. For

Alg2 expression in the native host, *S. cerevisiae*, purity is crucial to preclude the detection of activity from other dolichol pathway enzymes, which would complicate the interpretation of the results. The *ALG2* construct was under the control of a galactose-inducible promoter, and expression was alternatively repressed by glucose. Therefore, for tightly regulated expression, cells were grown using glucose as the primary carbon source, and then expression was induced by exchanging the growth media with galactose-containing induction media. Following expression, crude microsomes were prepared by fractionation of the yeast cell lysate and then detergent-solubilized. Affinity purification with Ni-NTA followed by resin-bound Streptactin in detergent solution yielded the preparation shown in Figure IV-6.

Figure IV-6. Purified Strep-Alg2-V5-His from *S. cerevisiae* expression. A) Coomassie stain and B) Western blot analysis of Ni-NTA purified Strep-Alg2-V5-His. C) Coomassie stain and D) Western blot analysis of sequential Ni-NTA and Streptactin-purified Strep-Alg2-V5-His. Western blots were probed with α -V5 antibody (Invitrogen).

Strep-Alg2-V5-His mannosyltransferase activity assays

Enzyme activity of crude microsomes from the Alg2 purification was tested with ManGlcNAc₂-PP-Dol, which was prepared using Alg1 as described in Chapter III. The HPLC assay was used to detect elongation of this intermediate in the presence of GDP-Man and microsomes. Indeed, activity of all of the cytosolic mannosyltransferases following Alg1 could be detected at this stage based on the elongation of ManGlcNAc₂-PP-Dol to Man₃GlcNAc₂-PP-Dol, with an observed accumulation of Man₃GlcNAc₂-PP-Dol (Figure IV-7). In contrast, no elongation was observed under the same conditions using microsomes from yeast that was not exposed to galactose, and thus did not express the *ALG2* construct.

Figure IV-7. Elongation by crude microsomes from Strep-Alg2 preparation A) Fluorescence HPLC trace showing elongation products of ManGlcNAc₂-PP-Dol with microsomes from the Strep-Alg2-V5-His expression. B) MALDI-MS of pentasaccharide product corresponding to Man₃GlcNAc₂-2AB. C) MALDI-MS of heptasaccharide product corresponding to Man₅GlcNAc₂-2AB. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

Upon purification of Alg2, however, no activity was detected under any of the assay conditions described above. It should be noted that due to the presence of native dolichol pathway enzymes in microsomal preparations, the observed activity in the induced preparation could not be ruled out as native Alg2 rather than expressed Strep-

Alg2-V5-His. It also cannot be ruled out that the lack of observed activity in the uninduced microsomes may be due to the alternate growth conditions of the yeast (ie. glucose rather than galactose as the main carbon source), or loss of activity in the preparation.

***E. coli* membrane fraction preparation of TRX-Alg2**

Since numerous attempts at purification of a variety of Alg2 constructs consistently yielded inactive forms of the enzyme, it was postulated that the two remote regions of predicted transmembrane domain pairs (Figure IV-3) may require the membrane to maintain the proper structure and function of the soluble portion of the enzyme. One approach to address the problem of membrane requirement is through the use of proteoliposomes, in which proteins are reconstituted into artificial phospholipid bilayers. This method relies on the proper refolding of proteins upon reintroduction into the membrane. Another approach is to isolate the protein in native intact membranes. For our purposes, this method would require the use of a heterologous system, to avoid the previously mentioned problem of background activity in assigning enzyme function. Isolation of Alg2 in the *E. coli* cell membrane fraction was thus used as a way to preserve the membrane environment of Alg2 while offering a heterologous system that could enable the assignment of function. *E. coli* provides an ideal platform, as dolichol pathway homologs do not exist in this organism.

TRX-Alg2 was expressed in *E. coli* as described above, except that by excluding detergent from the lysis buffer, and using differential centrifugation, this construct could be isolated in the cell membrane fraction. Since this procedure does not include affinity

purification, the construct was simplified by incorporating a stop codon at the 3' end of the *ALG2* sequence to eliminate the C-terminal tags. In order to assess the requirement of the N-terminal TRX domain for expression, expression and isolation of Alg2 constructs either with or without inclusion of the N-terminal TRX domain were carried out. For this experiment, a His-Alg2 construct and the TRX-Alg2-V5-His construct (without the stop codon) were used in order to directly compare expression levels using the α -His tag antibody. Figure IV-8 shows that TRX-Alg2-V5-His was successfully expressed and isolated in the cell membrane fraction (Lane 3), as detected by an antibody to the His tag. However, in the absence of the TRX domain (Lane 4), no full-length Alg2 was detected, and only a smaller product, presumably a truncation product, was observed.

Figure IV-8. Isolated TRX-Alg2 and His-Alg2 from *E. coli* expression. Equivalent amounts of cell membrane fraction were used for SDS-PAGE and Western blot analysis. Gelcode protein stain (Pierce Co.) of TRX-Alg2-V5-His (lane 1) and His-Alg2 (lane 2), Western blot analysis of TRX-Alg2-V5-His (lane 3) and His-Alg2 (lane 4). The Western blot was visualized using α -His tag antibody (GE Healthcare Bio-Sciences Co.).

TRX-Alg2 elongates ManGlcNAc₂-PP-Dol to Man₃GlcNAc₂-PP-Dol

The membrane fraction containing TRX-Alg2 was assayed for activity with ManGlcNAc₂-PP-Dol in the presence of GDP-Man. Incubation with these substrates led to the appearance of two new peaks in the fluorescence HPLC trace, corresponding to the retention times of authentic Man α 1,3-ManGlcNAc₂-2AB (minor) and Man α 1,3-(Man α 1,6)-ManGlcNAc₂-2AB (major) (Figure IV-9A). These standards represent the tetrasaccharide and pentasaccharide dolichol pathway intermediates, respectively.

Figure IV-9. HPLC of TRX-Alg2 products. Fluorescence HPLC traces show labeled products from reaction mixtures containing ManGlcNAc₂-PP-Dol and cell membrane fraction containing A) TRX-Alg2 or B) TRX-Alg11. The retention times of the TRX-Alg2 products (A) match those of Man₂GlcNAc₂-2AB and Man₃GlcNAc₂-2AB authentic standards. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

In order to preclude the possibility that the products observed were the result of background *E. coli* enzymes, the experiment was repeated in a manner that is similar to an empty vector control. Instead of removing the gene, however, *ALG2* was replaced with *ALG11*, which encodes a later mannosyltransferase in the pathway and would not be expected to accept the trisaccharide intermediate. Indeed, a membrane fraction containing TRX-Alg11 did not show any reactivity with the trisaccharide intermediate (Figure IV-9B).

Subjecting these products to analysis by MALDI-MS confirmed the identities as the tetrasaccharide, $\text{Man}_2\text{GlcNAc}_2\text{-2AB}$ (expected $[\text{M}+\text{Na}]^+ = 891.3$ and found $[\text{M}+\text{Na}]^+ = 891.4$), and the pentasaccharide, $\text{Man}_3\text{GlcNAc}_2\text{-2AB}$ (expected $[\text{M}+\text{Na}]^+ = 1053.4$ and found $[\text{M}+\text{Na}]^+ = 1053.3$), suggesting that Alg2 catalyzes the addition of two mannose residues (Figure IV-10).

Figure IV-10. MALDI-MS of TRX-Alg2 products. A) Pentasaccharide product (major) of TRX-Alg2, corresponding to $\text{Man}_3\text{GlcNAc}_2\text{-2AB}$ B) Tetrasaccharide product (minor) of TRX-Alg2, corresponding to $\text{Man}_2\text{GlcNAc}_2\text{-2AB}$.

To confirm that these saccharides have the same structures as the dolichol pathway intermediates, the glycosidic linkages were mapped by specific mannosidase treatment using an α 1-2,3-mannosidase (*Xanthomonas manihotis*, New England Biolabs) and an α 1,6-mannosidase (*Xanthomonas* sp., Calbiochem).⁷ Treatment of the pentasaccharide with the α 1-2,3-mannosidase yielded a tetrasaccharide, which was sensitive to an α 1,6-mannosidase (Figure IV-11A-C). These cleavage products were also confirmed by MALDI-MS (Figure IV-11D,E).

Figure IV-11. Mannosidase mapping of $Man_3GlcNAc_2-2AB$ from TRX-Alg2. Fluorescence HPLC traces of A) the pentasaccharide product of TRX-Alg2, $Man_3GlcNAc_2-2AB$, B) the product from α 1-2,3-mannosidase treatment of $Man_3GlcNAc_2-2AB$, and C) the product from α 1,6-mannosidase treatment of the tetrasaccharide cleavage product of $Man_3GlcNAc_2-2AB$. MALDI-MS results of D) the tetrasaccharide cleavage product (from Panel B) and E) the trisaccharide cleavage product (from Panel C). (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide).

The tetrasaccharide intermediate formed in trace amounts in the TRX-Alg2 reaction was shown to be sensitive to an α 1-2,3-mannosidase to yield a trisaccharide (Figure IV-12).

Figure IV-12. Mannosidase mapping of $\text{Man}_2\text{GlcNAc}_2\text{-2AB}$ from TRX-Alg2. Fluorescence HPLC traces of A) the tetrasaccharide intermediate from TRX-Alg2 reaction, $\text{Man}_2\text{GlcNAc}_2\text{-2AB}$ and B) the cleavage product from treatment of the tetrasaccharide with α 1-2,3-mannosidase. (M, Man; N, GlcNAc; 2-AB, 2-aminobenzamide).

These glycoside linkage mapping results are consistent with previous biochemical analysis of accumulated dolichylpyrophosphate-linked intermediates in wild-type and mutant yeast strains, which suggested that the order of addition of mannose residues proceeds by α 1,3-mannosylation of the trisaccharide intermediate, followed by α 1,6-

mannosylation of the β 1,4-linked mannose residue to yield the branched core pentasaccharide product.^{3,8}

The pentasaccharide, $\text{Man}_3\text{GlcNAc}_2\text{-2AB}$, was resistant to the α 1,6-mannosidase (Figure IV-13), which is consistent with the documented inability of this mannosidase to cleave branched structures.⁷ This result supports the branched structure of the pentasaccharide, in accord with the natural pentasaccharide intermediate.

Figure IV-13. Treatment of the pentasaccharide product with α 1,6-mannosidase. Equal portions of $\text{Man}_3\text{GlcNAc}_2\text{-2AB}$ were incubated overnight in the presence or absence of the α 1,6-mannosidase, as described in “Experimental Procedures”, except that incubation proceeded for 16 hours.

The only other possible structure based on the pentasaccharide linkage analysis would be a linear structure in which the α 1,6-linkage is closer to the reducing end and the terminal mannose is α 1,3-(or α 1,2-)linked. However, the demonstration that the

tetrasaccharide intermediate that bears a terminal α 1,3-(or α 1,2-) linkage negates this possibility. In addition, while the α 1-2,3-mannosidase does not necessarily distinguish between α 1,2- and α 1,3-linkages, prior knowledge of the structure of the pentasaccharide intermediate in the dolichol pathway as well as the established role of Alg2 in the early steps of the tetradecasaccharide biosynthesis support the presence of an α 1,3-linked mannose and a branching of the α 1,6-linked mannose from the β 1,4-linked mannose. Taken together, these results suggest that TRX-Alg2 catalyzes the mannosylation of Man β 1,4-GlcNAc β 1,4-GlcNAc-PP-Dol to produce Man α 1,3-(Man α 1,6)-Man β 1,4-GlcNAc β 1,4-GlcNAc-PP-Dol *via* the intermediate, Man α 1,3-Man β 1,4-GlcNAc β 1,4-GlcNAc-PP-Dol.

In order to provide evidence for enzyme dependence as well as to quantitate substrate turnover, it is necessary to measure enzyme activity over a range of TRX-Alg2 concentrations. These types of experiments have proven difficult for a number of reasons. Typically, the cell membrane fraction containing TRX-Alg2 was used in assays at 2-5% (v/v) with respect to the detergent-containing assay buffer. At these concentrations, complete turnover of the dolichylpyrophosphate-linked substrate was observed after one hour. In contrast, when 0.2 % (v/v) cell membrane fraction was used, no product formation was observed. This dramatic difference in product formation may not reflect the difference in enzyme concentration, but rather the dilution of stabilizing phospholipids present in the membrane fraction. In assays containing 50% (v/v) cell membrane fraction, product formation corresponded to less than 50% conversion. Therefore, the mannosyltransferase activity also appears to be sensitive to higher concentrations of the membrane fraction in the assay. These results suggest that there is

an additional parameter affecting activity, specifically the concentration of the membrane fraction, which complicates any attempt to correlate TRX-Alg2 concentration with activity. Possible ways of addressing this limitation include titration of the membrane fraction containing TRX-Alg2 into a blank membrane fraction, for instance from uninduced cells, or from the TRX-Alg2 double mutant. However, it would be difficult to assess how well the composition of the blank membranes matches that of the enzyme-containing membranes. In other words, the ability of blank membranes to stabilize TRX-Alg2 to the same extent, or conversely, the extent of the apparent inhibitory behavior of the membranes at higher concentrations, may not be comparable. Therefore, the studies described within were designed to include a variety of controls to relate the observed product formation specifically with the presence of intact TRX-Alg2.

Mannosyltransferase activity of site-directed TRX-Alg2 mutants

The single site-directed mutants, TRX-Alg2 E335A and TRX-Alg2 E343A, as well as the double mutant, TRX-Alg2 E335A/E343A were constructed to determine the importance of the Glu residues in the conserved EX₇E motif (Figure IV-1), and also as further controls to support the specific role of Alg2 in the observed activity. The relative expression levels of each Alg2 mutant were compared to that of the wild-type by analyzing equivalent amounts of each cell membrane fraction by Western blot analysis, as shown in Figure IV-14A. It has been proposed that the first Glu residue of this motif may be involved in catalysis.⁹ In the case of one member of this family, mutation of the first Glu residue of the EX₇E motif resulted in loss of all detectable activity, while residual activity could be seen upon mutation of the second Glu residue.¹⁰ Thus, the

TRX-Alg2 E335A mutant was expected to affect activity, and, indeed, a significantly lower level of product formation was observed (Figure IV-14B) compared to that seen for wild-type TRX-Alg2 (Figure IV-9). More notable, however, is that the tetrasaccharide intermediate formed ($[M+Na]^+ = 890.9$, $[M+K]^+ = 906.7$) (Figure IV-15A) is present in greater proportion than the pentasaccharide product, suggesting that perhaps mutation of the first Glu residue impairs the second step more severely than the first.

Figure IV-14. Analysis of expression and activity of TRX-Alg2 mutants. A) Western blot analysis showing relative amounts of wild type and mutants of TRX-Alg2 in equivalent amounts of cell membrane fraction from expressions. Fluorescence HPLC traces of elongation assays with B) TRX-Alg E335A, C) E343A, or D) the double mutant, E335A/E343A. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

To ensure that the tetrasaccharide intermediate formed by the TRX-Alg2 E335A mutant is the natural intermediate in the pathway, and that the mutation did not cause the

α 1,6-mannosylation to occur first, the $\text{Man}_2\text{GlcNAc}_2\text{-2AB}$ was shown to be sensitive to the α 1-2,3-mannosidase and resistant to the α 1,6-mannosidase (Figure IV-15B,C).

Figure IV-15. Characterization of $\text{Man}_2\text{GlcNAc}_2\text{-2AB}$ from TRX-Alg2 E335A. A) MALDI-MS of tetrasaccharide product of TRX-Alg2 E335A, corresponding to $\text{Man}_2\text{GlcNAc}_2\text{-2AB}$. Fluorescence HPLC traces show that this product is B) resistant to α 1,6-mannosidase treatment and C) sensitive to α 1-2,3-mannosidase treatment. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

The second Glu mutant, E343A, did not show any detectable activity (Figure IV-14C). From this assay, it is impossible to know whether this mutation affects both steps, or only the first mannosylation. In an attempt to address this question, the E335A and E343A single mutants were assayed together. If the latter mutant was able to carry out the α 1,6-mannosylation, then the combination of these mutants should yield the pentasaccharide product. However, the only activity observed was that of the E335A

substrate. As shown in Figure IV-17, the disaccharide substrate was elongated to the pentasaccharide intermediate, with accumulation of the trisaccharide and tetrasaccharide intermediates. While there is a preference for Dol-PP, both Alg1 and Alg2 are capable of accepting the Und-PP derivatives of the native substrates.

Figure IV-17. Alg1 and TRX-Alg2 accept Und-PP-linked substrates. Fluorescence HPLC showing elongation of GlcNAc₂-PP-undecaprenyl by Alg1 and TRX-Alg2. *This peak was not characterized, but has the retention time of peracetylated GlcNAc₂, and may be residual product from the synthesis of the acetyl-protected GlcNAc₂-PP-Und.

Conclusion

The results presented here provide evidence for the dual function of Alg2, specifically the ability of this enzyme to catalyze an α 1,3-mannosylation followed by an α 1,6-mannosylation to convert the trisaccharide intermediate, ManGlcNAc₂-PP-Dol to the pentasaccharide intermediate, Man₃GlcNAc₂-PP-Dol. Other examples of bifunctional

glycosyltransferases that catalyze the formation of more than one type of linkage and/or transfer more than one type of monosaccharide unit include the chondroitin synthases, which display both β 1,3-*N*-acetylgalactosamine transferase and β 1,4-glucuronic acid transferase activities,¹²⁻¹⁶ and hyaluronan synthase,^{16, 17} having β 1,3-*N*-acetylglucosamine transferase and a β 1,4-glucuronic acid transferase activity. In addition, the enzyme FT85 from *Dictyostelium* displays both β 1,3-galactosyltransferase and α 1,2-fucosyltransferase activity,¹⁸ and the *E. coli* enzyme, KfiC, polymerizes a repeat structure of a bacterial capsular polysaccharide by alternating α 1,4- and β 1,4-additions of *N*-acetylglucosamine and glucuronic acid, respectively.¹⁹ A common feature of all of these bifunctional glycosyltransferases, in addition to being larger than Alg2, is the apparent presence of two separate glycosyltransferase domains that isolate the two distinct activities. This characteristic may be necessary due to the fact that, unlike Alg2, two different types of glycosyl donors must be recognized. The results of the Alg2 mutants presented here suggest that only one active site is used for both transformations, since the first Glu residue of the EX₇E motif seems to be important for the α 1,6-mannosylation, and the second Glu residue affects (at least) the α 1,3-mannosylation. To our knowledge there is no other documented example of a glycosyltransferase that uses one active site to catalyze the formation of glycosidic linkages with different regioselectivity.

As described in Chapter I, nearly all known glycosyltransferase structures can be characterized by one of two major folds, the GT-A or the GT-B fold. The GT-A fold is characterized by two dissimilar subdomains separated by a hinge region, one of which is responsible for binding the nucleotide sugar, while the other binds the acceptor.⁹ The structure of the *E. coli* glycosyltransferase, MurG, a β 1,4-*N*-acetylglucosaminyl

transferase, has been solved in the presence and absence of the glycosyl donor, UDP-GlcNAc, and is a member of the GT-B superfamily.^{20, 21} This enzyme, like those on the dolichol pathway, is membrane-associated and the glycosyl acceptor is activated by a long-chain polyisoprene pyrophosphate. In this case also, two domains separated by a deep cleft comprise the architecture of this glycosyltransferase. As increasing numbers of glycosyltransferase structures are available, there is mounting evidence that nucleotide-sugar donor utilizing glycosyltransferases have a flexible loop above the donor binding site that closes upon donor binding, creating the binding site of the acceptor.²² These results are consistent with an ordered binding of the glycosyl donor followed by the glycosyl acceptor. Additional studies of glycosyltransferases have demonstrated that constraining glycosyl acceptors into a variety of conformations can have a significant impact on the kinetic parameters of the glycosyltransferases that recognize them.²³ These results, as well as observed conformational changes and the presence of a flexible linker between acceptor and donor binding sites of glycosyltransferases suggests that a certain amount of plasticity exists in the active sites of these enzymes.

Just as the chemoenzymatic preparation of the core trisaccharide has been accomplished,²⁴ it is now possible to prepare the core pentasaccharide in a chemoenzymatic fashion. This structure is a valuable intermediate in the preparation of homogenous glycoproteins, since it is found as the core of every *N*-linked glycan, regardless of the Golgi-mediated elaboration. The chemical synthesis of these oligosaccharides is extremely challenging,²⁵ and while efforts toward the automated synthesis of oligosaccharides are yielding improvements,²⁶ glycosyltransferases are often

employed in chemoenzymatic syntheses due to the precise control over the stereo- and regioselectivity of glycosidic bond formation.²⁷

Acknowledgements

The *alg2* strain was provided by the laboratory of Professor Maria Kukuruzinska at Boston University. Langdon Martin and Dr. Matthieu Sainlos collected all of the MALDI-MS data reported here. Dr. Eranthie Weerapana synthesized the undecaprenylpyrophosphate-linked disaccharide (GlcNAc₂-PP-Und) used for the specificity study. I am also grateful to Dr. Jebrell Glover for sharing his expertise in cell membrane fraction preparation.

Experimental Procedures

Media and buffers

Minimal Media (1 L): 6.7 g yeast nitrogen base (Difco) (- amino acids, + salts), 0.6 g CSL-His-Leu-Trp (Bio101, Inc.), 50 mg His, 100 mg Leu, 100 mg Trp, 2% D-glucose.

Induction Media (1 L): 6.7 g yeast nitrogen base (Difco) (- amino acids, + salts), 0.6 g CSL-His-Leu-Trp (Bio101, Inc.), 50 mg His, 100 mg Leu, 100 mg Trp, 2% galactose and 1% raffinose.

Buffer A: 50 mM NaH₂PO₄ pH 8.0, 300 mM NaCl, 20 mM imidazole, 0.1% Nonidet P-40.

Buffer B: 50 mM Tris-Cl pH 7.5, 0.25 M sucrose, 2.5 mM MgCl₂

Buffer C: 50 mM Tris-Cl pH 7.5, 2.5 mM MgCl₂

Buffer D (2×): 38 mM Tris-Cl pH 7.2, 1.8 mM DTT, 0.28 mM EDTA, 0.26% NP-40.

Buffer E: 50 mM Tris-acetate pH 8.5, 1 mM EDTA.

TUP: CHCl₃: MeOH: 4 mM MgCl₂ (2.75:44:53.25)

Cloning of ALG2 constructs

(See Chapter V for cloning of ALG11)

Genomic DNA was extracted from the *S. cerevisiae* strain PRY46 using the Yeast DNA Extraction Reagent (Y-DER) (Pierce, Inc.). *ALG2* was amplified by PCR from the yeast genomic DNA by PCR using Vent polymerase and the following primers:

Forward 5'-CAC CAT GAT TGA AAA GGA TAA A-3'

Reverse 5'-TAT TTC TTC ATA AGG GTA-3' (reverse)

The underlined sequence is recognized by topoisomerase, which mediates the ligation of the PCR product into the vector. The rest of the primer sequence corresponds to native *ALG2* sequence. Ligations were carried out using the Gateway Cloning Technology (Invitrogen) that was described in Chapter III, according to the manufacturer's instructions. A stop codon was later inserted into this construct for cell membrane preparations by site-directed mutagenesis, and the mutant was verified by DNA sequencing as above. Primers for site-directed mutagenesis were the following, in which underlined sequence indicates the change.

Forward primer 5'-GAA GAA ATA TAG GGT GGG CGC GCC G-3'

Reverse primer 5'-CGG CGC GCC CAC CCT ATA TTT CTT C-3'.

Cloning and subsequent transfer by homologous recombination to an appropriate destination vector for expression in either *E. coli* or *S. cerevisiae* was accomplished using the Gateway® Cloning Technology (Invitrogen) as described in Chapter III.

Both *ALG2* constructs, including or omitting the stop codon, were recombined with pBAD-DEST49 for *E. coli* expression. The Strep tag for yeast expression was introduced into the *ALG2* entry vector by amplifying the gene from pBAD-*ALG2*-DEST49 using Pfu Turbo DNA polymerase with a forward primer designed to include the sequence for the Strep tag followed by the first nine codons of the *ALG2* coding sequence (as above), and the reverse primer used for amplification of *ALG2* without the stop codon (above). No spacer was incorporated between the Strep tag and native *ALG2* sequence. The reverse primer was the same as indicated above. Cloning and homologous recombination with pYES-DEST52 for expression in *S. cerevisiae* were carried out as for the *ALG1* yeast expression vector (Chapter III).

All mutants were prepared at the entry vector stage (pENTR-*ALG2*), using the construct with a stop codon, by site-directed mutagenesis using the QuikChange Kit (Stratagene). The following primers were used for mutagenesis, with underlined nucleotides indicating the site of mutation:

E335Afor: 5'-CACCAGCATATGCGCACTTTGGTATTGTTCC-3'

E335Arev: 5'-GGAACAATACCAAAGTGCGCATATGCTGGTG-3'

E343Afor: 5'-GGTATTGTTCTTTAGCAGCCATGAAATTAGG-3'

E343Arev: 5'-CCTAATTTTCATGGCTGCTAAAGGAACAATACC-3'

The *ALG2* double mutant was prepared by changing the codon corresponding to E343A in the E335A mutant background.

All plasmids in the pENTR/SD/D-TOPO vector were verified by sequencing at the MIT Biopolymers Laboratory using the forward and reverse M13 primers as for *ALG1* constructs (Chapter III).

Expression in *E. coli* and purification of TRX-Alg2-V5-His

One Shot Top 10 competent cells were transformed with pBAD-*ALG2*-DEST49 *E. coli* expression vector as well as plasmid isolated from BL21(DE3) codon-plus RIL cells. Cells were shaken at 37 °C in 1 L of Terrific Broth (Invitrogen) until growth had nearly reached the stationary phase ($A_{600} = 0.9-1.0$), and the culture was then induced with 0.2% L-arabinose. Upon induction, cells were moved to a 15 °C water bath shaker, and expression was allowed to proceed overnight at this temperature. Cells were then harvested by centrifugation (10 min, 15,344 × g, 4 °C), and pellets were stored at -80 °C until purification.

The expressed TRX-Alg2-V5-His tag construct was purified by Ni-NTA affinity chromatography. A cell pellet from 250 mL of expression culture was resuspended in 35 mL of Buffer A containing 1% Dodecyl-D-maltoside (DDM), 1× protease inhibitor cocktail III (Calbiochem), and 1 mg/ mL lysozyme and allowed to incubate on ice for 30 minutes. Cells were then lysed by sonication for 2 minutes or until the solution clarified using a Branson 250 Sonifier with a 3/8” diameter tip (Branson Ultrasonics Co.), and then centrifuged (30 min, 11,625 × g, 4 °C). The supernatant from this spin was filtered through a 0.2-µm syringe-filter and was added to Ni-NTA slurry (5 mL of a 50% slurry, Qiagen). This mixture was rocked at 4 °C for 1 hr. After collecting the flow-through and washing the resin twice with 20 mL of Buffer A containing 20 mM imidazole and 1% DDM, bound protein was eluted using a step-wise gradient of 5-mL Buffer A aliquots containing 1% DDM and 40 mM, 80 mM, 120 mM, 160 mM, and 200 mM imidazole, respectively. Fractions of 1 mL were collected, and protein-containing fractions were dialyzed against Buffer B and concentrated by incubation with 0.5 mL of Ni-NTA slurry at 4 °C for 1 hr. Protein was eluted with two 0.5-mL aliquots of Buffer A containing 200 mM imidazole and 1% Triton X-100. Elutions were then dialyzed as above to remove imidazole.

Expression in *S. cerevisiae* and purification of Strep-Alg2-V5-His

The yeast strain INVSc1 was transformed with pYES-(*StrepALG2*)-DEST52 using the *S. cerevisiae* EasyComp Transformation Kit (Invitrogen). Transformants were selected based on uracil prototrophy using SC-U plates lacking uracil. A 10-mL overnight culture in minimal media (containing 2% raffinose instead of glucose) was

added to 500 mL of minimal media. Once the 500-mL cultures had grown at to an O.D. of 7 with shaking at 30 °C, four equal aliquots were added to four flasks, each containing 1 L of induction media, for a final O.D. of 0.4 in each culture. Cultures were shaken at 30 °C for 16 hours, and then harvested by centrifugation (2455 × g, 5 minutes, 4°C), washing once with cold Buffer C. All subsequent steps were performed at 4°C. To prepare crude microsomes, the cell pellet was resuspended in 200 mL of Buffer C containing the protease inhibitors 0.1 mM AEBSF, 0.5 µg/mL pepstatin A, 0.5 µg/mL leupeptin (added immediately before use) and lysed using glass beads in a bead beater (16 × 20 sec, with 40-sec cooling intervals). Cell lysate was centrifuged for 8 minutes at 7520 × g, and this step was repeated with the consequent supernatant. Crude microsomes were pelleted by centrifugation of the supernatant from the second spin for 1 hr at 186,000 × g using a type 45Ti rotor in an ultracentrifuge (Beckman). The pellet was homogenized in 50 mL of Buffer A containing 1% Nonidet P-40, shaken on ice for 15 minutes, and then centrifuged for 1 hour at 186,000 × g. The supernatant was saved as solubilized microsomes, which were subsequently filtered through a 0.2 µm syringe filter and incubated with 1 mL of Ni-NTA resin (Qiagen) for 1 hour prior to column purification. The flow-through was collected, and then the resin washed twice with 20 mL of Buffer A. Protein was eluted with Buffer A containing 100 mM imidazole and 0.1% Nonidet P-40. Alg2-containing fractions were added to 1 mL of Streptactin resin (Stratagene) and incubated overnight at 4 °C with shaking. After collecting the flow-through and washing the resin twice with 10 mL of Buffer A containing 1 mM DTT, Alg2 was eluted with 5 mL of Buffer A containing 1 mM DTT and 2.5 mM desthiobiotin,

collecting 0.5-mL fractions. Purified Alg2-containing fractions were pooled and dialyzed against Buffer B.

Preparation and assays of *alg2* mutant and induced and uninduced wild-type Alg2 microsomes

Yeast cultures were grown, and the wild-type pYES-(*StrepALG2*)-DEST52 strain expressed, as described in the previous section. For the uninduced pYES-(*StrepALG2*)-DEST52, galactose and raffinose were replaced by glucose, and otherwise growth was the same. Crude microsomes were prepared from these cultures, also as described for the *Strep-Alg2-V5-His* preparation, but at the crude microsome stage, rather than homogenizing in detergent solution, glycerol was added to 30% and microsomes were stored at $-80\text{ }^{\circ}\text{C}$. Elongation assays were carried out as described below, using 5- μL aliquots of microsomes and 1 \times Buffer D for each assay.

Preparation of crude microsomes from the *alg2* yeast strain

Starting from a single colony of the *alg2* strain[19, 20] on a YPAD plate, cells were grown in YPAD by fermentation in a 10-L BioFlow fermentor (New Brunswick Scientific), harvested by centrifugation ($3836 \times g$, 20 min, $4\text{ }^{\circ}\text{C}$), and then stored at $-80\text{ }^{\circ}\text{C}$ until use. Crude microsomes were prepared from a 100-g cell pellet as described in the previous section. This preparation yielded 9.5 mL of crude microsomes, which were mixed well with 2.5 mL of glycerol, aliquoted, and stored at $-80\text{ }^{\circ}\text{C}$ until use.

For complementation assays with the *alg2* mutant strain, a range of concentrations (nanomolar to micromolar) of purified TRX-Alg2-V5-His or Strep-Alg2-V5-His were included in the assays.

Expression and isolation of TRX-Alg2 in *E. coli* membranes

For *E. coli* expression, One Shot Top 10 competent cells were transformed with pBAD(*ALG2*)-DEST49 (containing the stop codon) together with the plasmid from BL21(DE3)RIL codon-plus competent cells (Stratagene). Aliquots of 10 mL from overnight cultures were added to 2.5-L batches of Terrific Broth (Invitrogen) and grown at 37 °C with shaking to an OD₆₀₀ of 0.8-1.0. Cultures were then adjusted to 16 °C prior to induction of protein expression with the addition of L-arabinose to 0.2 % (w/v). After 24 hours, cells were harvested at 4 °C by centrifugation (25 minutes, 5,000 × g), washing once with 0.9 % (w/v) NaCl. The resulting pellet was then either used directly for a cell membrane preparation, or stored at –80 °C until use. To prepare the membrane fraction, all steps were performed at 4 °C. Cell pellets from 2.5-L expression cultures were resuspended in 50 mL of Buffer E containing 1× protease inhibitor cocktail III (Calbiochem). Cells were lysed by sonication using a Branson 250 Sonifier with a 3/8” diameter tip (Branson Ultrasonics Co.). Cells were subjected to three 15-sec pulses at the highest output control setting, with 3-min cooling intervals in between pulses. The lysate was then centrifuged for 30 minutes at 5,697 × g. The membrane fraction was pelleted by centrifugation of the supernatant for 1 hr at 142,414 × g using a 45Ti rotor in an ultracentrifuge (Beckman). The resulting brown, translucent pellet was rinsed with

Buffer E, then homogenized in 0.5 mL of Buffer E, and stored at $-20\text{ }^{\circ}\text{C}$ in 30% (v/v) glycerol.

Assay for elongation of dolichyl-linked saccharide intermediates

Reaction mixtures contained approximately 40 μM dolichyl-linked starting material, 2 mM GDP-Man, and 5 μL of the cell membrane fraction containing TRX-Alg2 (195 μg total protein). For assays with the mutants, equivalent amounts (5 μL) were used. Starting with a dried aliquot of the dolichyl-linked starting material, a 50- μL aliquot of Buffer D (2 \times) was added and the mixture sonicated for 1 min to resuspend the substrate. GDP-Man (2 mM final), MgCl_2 (10 mM final), dH_2O , and enzyme were added to a final volume of 100 μL . Incubation proceeded for 1 hour at room temperature, followed by quenching into a biphasic mixture of CHCl_3 : MeOH: 4 mM MgCl_2 (6:4:1). (Purified Alg2 assays were also attempted using a buffer that had been commonly used for Enzyme II assays, which was composed of 50 mM Tris, pH 7, 0.25 M sucrose, 3 mM DTT, 5 mM MgCl_2 , 0.13 % NP-40.) The dolichyl-linked saccharides, partitioned into the organic phase, were subsequently washed twice with 200- μL aliquots of TUP. The extracted organic phase was then concentrated to dryness.

Hydrolysis, fluorescent labeling, HPLC, and MALDI were carried out as described in Chapter III.

Mannosidase cleavage reactions

2-AB labeled glycans were collected from HPLC separation, taking advantage of the fluorescence detection, and then concentrated to dryness using a Sc110 Speed-Vac

(Savant, Inc.). Dried glycans were redissolved in 5 μ L of dH₂O, and 1 μ L-aliquots were treated with 2 Units (1 μ L) of α 1-2,3-mannosidase (New England BioLabs, Inc.) in 50 mM sodium citrate, pH 6.0, 5 mM CaCl₂, 100 mg/mL BSA, or with 1 milliUnit (1 μ L) of α 1,6-mannosidase (Calbiochem) in 50 mM sodium phosphate, pH 5.0 at 37 °C for 5 hours. For the α 1-2,3-mannosidase reactions, 0.5- μ L aliquots each of commercial buffer (10 \times) and BSA (10 \times) were used, which were supplied with the enzyme, in a final reaction volume of 5 μ L. α 1,6-Mannosidase reactions were performed in a final volume of 10 μ L, using 1 \times buffer.

Chapter V: Studies toward defining the function of Alg11

Introduction

The results from yeast genetic studies have assisted in narrowing down the possible functions of Alg11 to either the fourth, fifth, or both the fourth and fifth mannosylation steps of the dolichol pathway (Scheme V-1).¹⁻³ This assignment has been primarily based on the characterization of *alg11* yeast mutants, the first of which was isolated based on resistance to sodium vanadate, which is a common, though not fully understood, feature of mutants with glycosylation defects.^{4,5}

Scheme V-1. α1,2-Mannosylation reactions putatively catalyzed by Alg11.

Similar to the study of other *alg* mutants, oligosaccharide structural studies of dolichylpyrophosphate-linked saccharide intermediates extracted from a yeast strain that lacks Alg11 function have helped to narrow down the possible roles of Alg11.¹ First, *ALG11* was shown to be essential for viability. Since it is known that the lumen-oriented glycosyltransferases are not essential, this feature suggests that Alg11 is a cytosolic-oriented enzyme in the pathway. Due to the essential nature of *ALG11*, a complete deletion strain would be inviable, therefore a diploid strain, *alg11Δ*, heterozygous for the *ALG11* deletion, was constructed and used for oligosaccharide lumenal structural studies. However, unlike the characterization of *alg1* and *alg2* mutants, the results of these studies were greatly complicated by the ability of lumenal transferases to elongate truncated saccharide intermediates containing the minimal core pentasaccharide. Although the *alg11Δ* mutant accumulates Man₃GlcNAc₂-PP-Dol as a significant intermediate, approximately 80% of the extracted lipid corresponded to Hex₇GlcNAc₂-PP-Dol, where Hex (hexose) could refer to Man or Glc.¹ Using mannosidase mapping in conjunction with known rules concerning the order of saccharide addition, it was proposed that this intermediate is Man₇GlcNAc₂-PP-Dol, although the precise structure could not be distinguished between forms missing one or both of the mannose residues putatively added by Alg11 (Scheme V-I). Taken together, these results suggested a role for Alg11 in the addition of the fourth mannose. However, the additional accumulation of a Man₄GlcNAc₂-PP-Dol intermediate as well as a presumed elongation product of this hexasaccharide that contained eight mannose residues suggests that the fifth mannosylation is also impaired in the *alg11Δ* mutant. From exhaustive saccharide structural studies of every extracted intermediate, as well as of glycans released from

glycoproteins in this strain, it is apparent that Alg11 is involved in formation of $\text{Man}_4\text{GlcNAc}_2\text{-PP-Dol}$ and/or $\text{Man}_5\text{GlcNAc}_2\text{-PP-Dol}$.¹

The contribution of activity from luminal transferases in this study as well as the inability to distinguish between different isoforms in some cases greatly complicated the interpretation of these results, and there has been no biochemical support to establish the validity of these proposals. The fact that extensive genetics screens and bioinformatics searches have not yielded any additional candidates for cytosolic dolichol pathway mannosyltransferases raised the question of whether Alg11, like Alg2 and Alg9,⁶ may be responsible for more than one step in the pathway.

Alg11 from *S. cerevisiae* is a 548-residue, 63-kDa protein with one predicted transmembrane domain at the N-terminus and a large soluble domain, as predicted by the TMHMM server, v. 2.0 (Figure V-1).⁷

Figure V-1. Predicted topology of Alg11. Plot of the probability that Alg11 residues are in a transmembrane-spanning region.

From the topology prediction, this enzyme is not expected to be as challenging to express and analyze *in vitro* as Alg2 has proven to be. The difficulty in studying Alg11

has been that the putative substrate, Man₃GlcNAc₂-PP-Dol, is not readily available. Chemical synthesis is prohibitively complicated, and no mutant strain exists that accumulates this intermediate predominantly, since it is sufficient for elongation by luminal glycosyltransferases. Fortunately, the discovery that Alg2 catalyzes elongation of the ManGlcNAc₂-PP-Dol to Man₃GlcNAc₂-PP-Dol (Chapter IV) provided a chemoenzymatic method to access the putative Alg11 substrate. Thus, having the means to prepare the pentasaccharide intermediate using TRX-Alg2 presented the opportunity to examine the function of Alg11. Our goal with respect to Alg11 was to unambiguously define the function using the same methods described in Chapter IV, for the validation of Alg2 function. The sensitivity of this preparation to mutations in the conserved EX₇E motif (Figure V-2) was also examined, primarily to eliminate the possibility of mistakenly assigning background activity to Alg11 activity, but also to gain some preliminary insights into the postulated importance of selected conserved residues. TRX-Alg11 was isolated in a cell membrane fraction, based on the positive results afforded by this method in the case of TRX-Alg2. Future studies will include purification of this enzyme.

Results and Discussion

TRX-Alg11 cloning, expression, and cell membrane fraction preparation

TRX-Alg11, with a free C-terminus, was cloned, expressed, and isolated in the membrane fraction of *E. coli* (Figure V-3), repeating exactly the methods used for TRX-Alg2 as described in Chapter IV.

Figure V-3. Isolated TRX-Alg11 from *E. coli* expression. A) Gelcode stain (Pierce Co.) and B) Western blot analysis of the cell membrane fraction from cells overexpressing TRX-Alg11. The Western blot was probed with the α -Thio antibody (Invitrogen), which detects the TRX domain. Molecular weight markers are labeled to the left in kDa.

TRX-Alg11 forms $\text{Man}_5\text{GlcNAc}_2\text{-PP-Dol}$ from $\text{Man}_3\text{GlcNAc}_2\text{-PP-Dol}$

The products of the TRX-Alg2 reaction were used as starting material for assays with TRX-Alg11 in the presence of GDP-Man. The starting material was composed primarily of the pentasaccharide, $\text{Man}_3\text{GlcNAc}_2\text{-PP-Dol}$, but also contained minor amounts of trisaccharide and tetrasaccharide (Figure V-4A). Incubation of this mixture with TRX-Alg11 resulted in the disappearance of the pentasaccharide with a concomitant

appearance of a heptasaccharide (Figure V-4B). The apparent loss of material in the conversion of pentasaccharide to heptasaccharide is presumably due to the relatively poor organic-partitioning properties of the latter compared to the former.

Figure V-4. HPLC of TRX-Alg11 product. Fluorescence HPLC traces show A) TRX-Alg2 products (starting material for TRX-Alg11 reaction) and B) TRX-Alg11 products. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

The TRX-Alg11 product (Figure V-5A) was characterized by cleavage with an α 1,2-mannosidase to yield a pentasaccharide (Figure V-5B). These results, in addition to the MALDI-MS of the heptasaccharide product (expected $[M+Na]^+ = 1377.5$, found $[M+Na]^+ = 1377.5$) (Figure V-5C), are consistent with the expected structure, Man α 1,2-Man α 1,2-Man α 1,3-(Man α 1,6)-Man β 1,4-GlcNAc β 1,4-GlcNAc-2AB (Figure V-5D).

Figure V-5. Characterization of the TRX-Alg11 product. Fluorescence HPLC traces A) before and B) after treatment with an α 1,2-mannosidase (Prozyme, Inc) (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide). C) MALDI-MS of the hydrolyzed and labeled heptasaccharide product, $\text{Man}_5\text{GlcNAc}_2\text{-2AB}$. D) Structure of the TRX-Alg11 product based on MALDI and mannosidase characterization. (Black squares, GlcNAc; gray circles, Man; P, phosphate)

Thus, TRX-Alg11 was shown to catalyze the elongation of $\text{Man}_3\text{GlcNAc}_2\text{-PP-Dol}$ to $\text{Man}_5\text{GlcNAc}_2\text{-PP-Dol}$ with the appropriate linkages corresponding to those of the dolichol pathway heptasaccharide intermediate. The residual trisaccharide and tetrasaccharide intermediates remained unreacted, highlighting the specificity of TRX-

Alg11 and providing more convincing evidence that the pentasaccharide is the native substrate of Alg11. Similar to the use of TRX-Alg11 as a negative control for ManGlcNAc₂-PP-Dol elongation in Chapter IV, the fact that the cell membrane fraction containing TRX-Alg2 does not elongate beyond the pentasaccharide product (Chapter IV) argues against the possibility that background *E. coli* enzymes are capable of completing the heptasaccharide biosynthesis.

Mannosyltransferase activities of TRX-Alg11 mutants

Further evidence that the observed activity comes from TRX-Alg11 was sought by mutating the Glu residues in the EX₇E motif. The relative expression levels of the three mutants were evaluated by Western blot analysis (Figure V-6A)). For reasons that are unclear, the double mutant is consistently expressed (or isolated) at a significantly higher level compared to the single mutants. This characteristic, however, does not complicate the interpretation of the elongation assay results.

Figure V-6. Analysis of expression and activity of TRX-Alg11 mutants. A) Western blot analysis of equivalent amounts of cell membrane fraction from the overexpression of all TRX-Alg11 mutants to show relative expression levels, with α -Thio (Invitrogen) detection of the TRX domain. Fluorescence HPLC traces show the results of incubating $\text{Man}_3\text{GlcNAc}_2\text{-PP-Dol}$ with the TRX-Alg11 mutants B) E405A, C) E413A, or D) the double mutant E405A/E413A.

Mutation of the first Glu to yield the TRX-Alg11 E405A mutant resulted in only trace amounts of product formation (Figure V-6B). These trace products were subjected to α 1,2-mannosidase cleavage in order to identify them as the expected hexasaccharide

and heptasaccharide products, $\text{Man}_4\text{GlcNAc}_2\text{-PP-Dol}$ and $\text{Man}_5\text{GlcNAc}_2\text{-PP-Dol}$, respectively. The cleavage products are shown in Figure V-7.

Figure V-7. Characterization of the TRX-Alg11E405A products. α 1,2-Mannosidase treatment of the products of TRX-Alg11 E405A. Cleavage products of A) putative heptasaccharide and B) hexasaccharide.

In contrast, the TRX-Alg11 E413A mutant suffered no detectable loss in activity (Figure V-6C), which is consistent with another example in which the first Glu residue of the EX₇E motif in a retaining glycosyltransferase was found to be more critical for catalysis than the second.⁸ The complete loss of activity in the double mutant, TRX-Alg11 E405A/E413A (Figure V-6D), suggests that either the E413 is critical for the residual activity displayed by the E405A mutant, or perhaps this perturbation in local structure is enough to abolish the remaining activity. More importantly, in terms of the current goal of defining the precise function of Alg11, the sensitivity of the observed

activity to point mutations in TRX-Alg11, and particularly the complete loss of activity in the double mutant, despite robust expression, argues against any involvement of enzymes in the *E. coli* cell membrane fraction background.

Specificity of TRX-Alg2 and TRX-Alg11

In the interest of unambiguously assigning the function of Alg2 and Alg11 from these studies, it was necessary to show that each is specific for the proposed substrate. To demonstrate that Alg2 and Alg11 are capable of distinguishing the correct substrate from preceding intermediates in the pathway, and to support the results presented here as biologically relevant, different combinations of Alg1 from *S. cerevisiae* expression (Chapter III), TRX-Alg2 (Chapter IV), and TRX-Alg11 were incubated with the Alg1 substrate, GlcNAc₂-PP-Dol. In the absence of Alg1, there was no evidence of elongation of GlcNAc₂-PP-Dol, demonstrating that neither TRX-Alg2 nor TRX-Alg11 accepts this intermediate (Figure V-8A). In the absence of TRX-Alg2, ManGlcNAc₂-PP-Dol accumulates, showing that TRX-Alg11 also does not accept the trisaccharide intermediate (Figure V-8B). The complete elongation to Man₅GlcNAc₂-PP-Dol in the presence of Alg1, TRX-Alg2, and TRX-Alg11 confirmed that all components were active (Figure V-8C).

Figure V-8. Specificity of TRX-Alg2 and TRX-Alg11. Fluorescence HPLC traces of GlcNAc₂-PP-Dol elongation with different permutations of Alg1, TRX-Alg2, and TRX-Alg11. A) TRX-Alg2 + TRX-Alg11 B) Alg1 + TRX-Alg11 C) Alg1 + TRX-Alg2 + TRX-Alg11. *uncharacterized impurity has the retention time of peracetylated GlcNAc₂-2AB. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

The specificity of Alg11 for the isoprenoid carrier was also addressed. As shown in Chapter IV, Alg1 and TRX-Alg2 were each able to accept the undecaprenyl-PP (Und-PP) derivative of their native substrates, though with reduced turnover under comparable conditions. This experiment was repeated with TRX-Alg11 as an additional component, and the formation of the heptasaccharide intermediate demonstrated the ability of TRX-Alg11 to accept Man₅GlcNAc₂-PP-Und as a substrate (Figure V-9). Interestingly, every

intermediate, with the exception of the hexasaccharide, is observed to accumulate to some extent in this series of transformations.

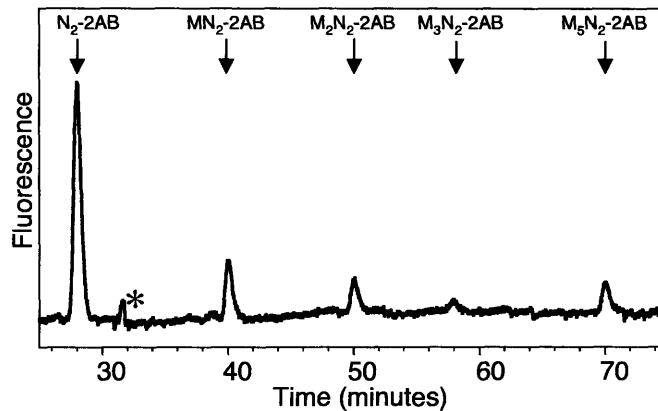

Figure V-9. TRX-Alg11 accepts Und-PP-linked substrate. Fluorescence HPLC of GlcNAc₂-PP-Und elongation with Alg1, TRX-Alg2, and TRX-Alg11. *uncharacterized impurity has the retention time of peracetylated GlcNAc₂-2AB. (M, Man; N, GlcNAc; 2AB, 2-aminobenzamide)

Conclusion

The results presented in this chapter demonstrate the dual function of Alg11, which complements the recent evidence for the dual function of Alg9,⁶ as well as that of Alg2. These assignments complete the identification of the entire ensemble of glycosyltransferases that comprise the dolichol pathway. These findings explain the absence of candidates for any remaining cytosolic mannosyltransferases, despite numerous genetic screens and bioinformatics searches. Similar examples of this paradox, in which too few candidate glycosyltransferases are available to account for all of the

steps in a biosynthetic pathway, have recently been found in *Streptomyces cyanogenus* and in *Campylobacter jejuni*.^{9, 10} In *S. cyanogenus*, Landomycin A biosynthesis involves the assembly of a hexasaccharide moiety by two monofunctional and two bifunctional glycosyltransferases.⁹ The Pgl pathway of *N*-linked protein glycosylation in *C. jejuni* has many similarities to the dolichol pathway, including assembly of a polyisoprenoid pyrophosphate-linked oligosaccharide as the donor for transfer to protein.¹¹ The α 1,4-*N*-acetylgalactosaminyltransferase, PglH, acts iteratively to transfer three GalNAc residues to the growing oligosaccharide chain.¹⁰ In these two examples, as in the case of Alg11, the enzymes are transferring the same sugar in the same configuration. Thus, it does not seem likely that more than one active site would be necessary. This hypothesis is supported by the results from the TRX-Alg11 double mutant, showing that a complete loss of detectable turnover can be achieved by point mutations within the confines of a 9-residue stretch of sequence. Due to the lower degree of membrane association compared to Alg2, Alg11 is a promising candidate for efficient expression and purification, which would facilitate more quantitative studies.

Experimental procedures

Cloning of pBAD-*ALG11*-DEST49

Genomic DNA was extracted from the *S. cerevisiae* strain PRY46 using the Yeast DNA Extraction Reagent (Y-DER) (Pierce, Inc.). *ALG11* was amplified from the yeast genomic DNA by PCR using Vent polymerase with the forward primer 5'-CAC CAT GGG CAG TGC TTG GAC A-3' and reverse primer 5'-TCA GCC CCT TTC CTC CTC-3' to yield a construct with a stop codon. This gene was then cloned into the pENTR/SD/D-TOPO vector, from which it was transferred to the pBAD-DEST49 destination vector by homologous recombination using the Gateway[®] Cloning Technology (Invitrogen) for *E. coli* expression of TRX-Alg11.

All mutants were prepared in the entry vector (pENTR/SD/D-TOPO) containing the *ALG11* gene by site-directed mutagenesis using the QuikChange Kit (Stratagene) using the following primers. Wild-type and mutant plasmids were all verified by DNA sequencing at the MIT Biopolymers laboratory. The *ALG11* double mutant was prepared by incorporating both mutations simultaneously into the wild-type background. Underlined codons denote sites of mutation.

TRX-Alg11 Expression and elongation assays

Using the construct, pBAD-*ALG11*-DEST49, expression of TRX-Alg11 and preparation of the cell membrane fraction were carried out exactly as described in Chapter IV.

The pentasaccharide substrate for TRX-Alg11 was prepared by scaling up the elongation reaction containing ManGlcNAc₂-PP-Dol, GDP-Man, and TRX-Alg2 that was described in Chapter IV. Wild-type TRX-Alg11 reactions contained 135 µg of total protein. Mutant TRX-Alg11 reactions were carried out with equivalent amounts of cell membrane fraction, and relative amounts of TRX-Alg11 in each are indicated by the Western blot analysis (Figure V-6A). In the extraction steps, the organic layer was washed with CHCl₃: MeOH: 100 mM KCl (3:48:47).

Glycan analysis by hydrolysis, labeling, HPLC, and MALDI were carried out as described in Chapter III, and the α1,2-mannosidase reactions were performed according to the manufacturer's instructions (Prozyme, Inc.).

GlcNAc₂-PP-Dol and GlcNAc₂-PP-Und elongation assays

These assays were carried out as described for TRX-Alg2 assays (Chapter IV). The enzymes, used as indicated for individual assays, were used in the following amounts: 0.1 µg of Alg1 (from expression in *S. cerevisiae*, Chapter III), 195 µg of total protein from a cell membrane fraction preparation containing wild-type TRX-Alg2, and

50 µg of total protein from a cell membrane fraction preparation containing wild-type TRX-Alg11.

Chapter VI: Peptidyl inhibitors of Oligosaccharyl Transferase and Peptide: *N*-Glycanase

in the Imperiali group had provided insight into the conformational requirements of the nascent polypeptide at the site of glycosylation. Specifically, using conformationally-constrained substrates, NMR studies suggested that an Asx-type turn was crucial for glycosylation to occur (Figure VI-2).⁷ In contrast, examination of X-ray structures of native glycoproteins revealed a preference for β -turns at sites of glycosylation.⁸ These results suggested the possibility of a conformational switch of the peptide structure upon glycosylation. Indeed, both fluorescence resonance energy transfer (FRET)⁹ and NMR¹⁰ studies have shown that peptides representing natively glycosylated sequences adopt an extended Asx-turn motif in the unglycosylated form, while adopting a tighter β -turn structure in the presence of a β -linked chitobiosyl moiety on the asparagine residue.

Taking into account the potential requirement of an Asx-turn motif for catalysis, a mechanism was proposed that involves protonation of the Asn side chain carbonyl with concomitant deprotonation of the amide nitrogen by an active site base, leading to tautomerization and generation of a more nucleophilic species that is capable of reacting with the activated saccharide donor (Figure VI-1)¹¹. Other proposed mechanisms involve either deprotonation of the Asn side chain amide nitrogen by an active-site base to generate a negatively-charged species,¹² or deprotonation of the hydroxyamino acid side chain by an active-site base to facilitate deprotonation of the amide-nitrogen of the Asn side chain by the consequent alkoxide.¹³ The latter mechanism is inconsistent with the need for an Asx turn, as the carbonyl of the Asn side chain would be directed away from the core of the turn. Neither of these mechanisms involve tautomerization of the carboxamide, but rather invoke negatively-charged intermediates. The observation that

replacement of the Asn residue with an Asp residue abrogates binding argues against such an intermediate.¹¹

Figure VI-1. Proposed mechanism of OT-catalyzed glycosylation.

As part of an effort to understand the mechanism of asparagine activation, a number of peptides with modified asparagine surrogates have been prepared.^{11, 14, 15} The tripeptide Bz-Dab-Leu-Thr-NHMe (where Dab = 1,4-diaminobutyric acid) was identified as a competitive inhibitor of OT with an inhibition constant (K_i) of 1 mM in porcine liver microsomes, using the corresponding asparagine tripeptide as substrate.¹¹ Building upon the discovery that the Asx turn may be important for catalysis, side-chain to main-chain cyclization was carried out to constrain the tripeptide inhibitor to an Asx turn, leading to an improvement of the inhibition constant by an order of magnitude ($K_i = 100 \mu\text{M}$), and at the same time highlighting the need for an Asx turn for catalysis.¹⁶ Extension of the tripeptide at the C-terminus using the dipeptide Val-Thr greatly improved potency of the inhibitor,^{16, 17} as predicted by the examination of the statistical frequency of amino acids at these sites in native glycoproteins.¹⁸ The preference of the enzyme for these residues was later confirmed by evaluating a range of different amino acid combinations at these sites *in vitro*; none of the dipeptides tested were preferred over Val-Thr.¹⁷ Taking into account all of these improvements, and including a *p*-nitrophenylalanine residue for

quantitation of peptide concentration, a potent ($K_i = 37$ nM in yeast) and specific inhibitor, **1** (Figure VI-2), was developed.¹⁶

Figure VI-2. Cyclized hexapeptide optimized for OT inhibition ($K_i = 37$ nM in yeast).

A variety of approaches were envisioned for building upon this progress, including improving potency through the design of neoglycoconjugates and optimization of the Xaa residue of the Asn-Xaa-Ser/Thr consensus sequence, as well as probing the nature of binding and catalysis through isosteric modifications to existing inhibitors. The synthesis of neoglycoconjugates has received considerable attention recently with the development of C- and S-glycoside analogs as well as targets prepared by chemoselective ligation techniques.^{19, 20} With the goal of evaluating this class of molecules as product analog inhibitors of OT, a series of neoglycoconjugates was designed based on the use of alanine- β -hydroxylamine ($\text{A}\beta\text{x}$),²¹ alanine β -hydrazide ($\text{A}\beta\text{z}$),²¹ and Dab¹¹ as asparagine surrogates (Figure VI-3). These residues have been chosen because they react chemoselectively with reducing sugars, without the need for protecting groups or activating agents, to afford *N*-linked neoglycoconjugates in highly convergent synthetic routes. Also explored was an isosteric C-glycoside that allowed the importance of heteroatoms to be probed.

Figure VI-3. Structures of A) Asn, B) Aβx, C) Aβz, and D) Dab side chains.

In addition to the pursuit of more potent inhibitors, there has also been interest in understanding the mechanisms of catalysis and inhibition. Because the γ -amine of Dab is much more likely to be protonated at physiological pH than that of the asparagine side chain, it has been proposed that it is the positive charge that confers the inhibitory activity, by engaging in a salt bridge with a negatively-charged active site residue, and that this interaction compensates for the loss of the Asx-turn stabilization.^{11, 14} In other cases of asparagine-mimetic peptides, such as the β -hydroxyasparagine mimetic, in which the amide group is substituted with a hydroxamate group, inhibition may be accompanied by the inhibitor acting as a weak substrate.¹⁴ Our goal was to probe such questions by expanding the available pool of asparagine-surrogate containing peptides modeled after the consensus site for *N*-linked glycosylation.

OT is tolerant of a variety of substitutions at the central amino acid of the tripeptide consensus sequence Asn-Xaa-Ser/Thr, with proline being the exception. Main-chain to Xaa side-chain cyclization, for example, was not only tolerated, but improved affinity, and in another study, benzophenone was successfully introduced at this position as a photoactivated cross-linking reagent for potential identification of the peptide-binding residues.^{22, 23} A more comprehensive study was carried out in which the central residue of

a glycosylation sequon of the rabies virus glycoprotein was varied by site-directed mutagenesis, and glycosylation efficiency was measured.²⁴ These results suggested that OT is sensitive to the identity of this residue, with effects ranging from inefficient to full glycosylation. As expected, replacement with proline resulted in a complete loss of glycosylation. Additionally, particularly detrimental changes included Trp, Leu, and Asp. These effects, however, may be due to structural perturbations due to other contacts within the protein substrate beyond the sequon, and not simply OT preferences; therefore these results may not be general for all sequons. The use of short peptidyl inhibitors may provide an improved method for probing the discrete preference of OT for the residue at this site, including both natural and non-natural amino acids in an effort to optimize binding affinity.

Having a series of neoglycoconjugate product-based inhibitors of OT at hand enabled an additional study involving an enzyme that uses the product of OT as a substrate. Specifically, the cytoplasmic enzyme, peptide:*N*-glycanase, or PNGase, catalyzes the hydrolysis of the β -aspartylglycosamine bond in the degradative pathway of misfolded glycoproteins (Scheme VI-2).²⁵ Interestingly, the bond broken by PNGase is different from the bond formed by the OT-catalyzed reaction. Nascent glycoproteins fold in the ER with the help of an intricate quality-control system that includes lectin-based chaperones and a glucosyltransferase that senses misfolded proteins.²⁶ When glycoproteins fail to become properly folded, they are exported from the ER and degraded by PNGase.

Scheme VI-2. PNGase-catalyzed hydrolysis of *N*-linked glycans catalyzed by PNGase.

PNGase was discovered in *Saccharomyces cerevisiae* (*PNG1*) by the isolation of a temperature-sensitive mutant, *png1-1*, and glycanase function was validated following cloning and heterologous expression of the gene in *E. coli*.²⁷ This soluble and well-behaved protein is a valuable target for the development of novel inhibitors, as the perturbation of its function could provide insight into the regulation of quality control in protein folding. Short glycopeptides are ideal substrates for the screening of putative inhibitors of PNGase due to their ease of synthesis, provided a minimal saccharide unit is used, as well as the facility for developing an assay based on the separation of substrates from products by HPLC. The K_m value of the fetuin-derived glycopeptide Leu-Asn(NeuAc₃Gal₃Man₃GlcNAc₅)-Asp-Ser-Arg for PNGase from mouse fibroblasts was found to be 114 μ M, and this substrate, as well as the asialo form, has been used extensively for PNGase characterization.²⁷⁻³¹ Previous studies had also shown that in the case of the bacterial PNGase F and the plant seed PNGase A, the minimum glycan requirement for hydrolysis was a chitobiosyl unit, which was removed with the same relative rate as the native glycan from a fetuin-derived glycopeptide.²⁸ These minimal

binding determinants suggested that synthetically tractable substrate analogs may provide a starting point for development of specific and potent inhibitors.

PNGase has been shown to be weakly inhibited by a variety of glycan structures, including the minimal GlcNAc₂, which is a millimolar inhibitor of bacterial, plant, and animal PNGases.²⁸ Additionally, a known caspase inhibitor, carbobenzyloxy-Val-Ala-Asp- α -fluoromethylketone (Z-VAD-fmk), was found to be a potent, specific, and cell-permeable inhibitor of yeast and mammalian PNGase, having an *in vivo* apparent IC₅₀ value of 7 μ M.³² However, it has been pointed out that ER stress, which is linked to PNGase function, can also be associated with caspase activation; thus, results from PNGase inhibition studies that involve the use of a caspase inhibitor should be interpreted carefully.³³ The development of more specific inhibitors would therefore be useful for *in vivo* studies of PNGase function.

Results and Discussion

Effects of conformational preferences in neoglycoconjugate binding to OT

The substrate peptide Bz-Asn-Ala-Thr-Val-Thr-Nph-NH₂ (**2**) (Table VI-1) was synthesized by standard solid-phase peptide synthesis methods, and the K_m for yeast OT was determined to be 0.31 μ M. Comparison of **2** to the corresponding Asn(GlcNAc)-containing peptide (**2a**) (Table VI-1), which has a K_i value of 100 μ M for yeast OT, reveals a loss in binding affinity of over two orders of magnitude when the saccharide is included. Such a drastic change in binding affinity is consistent with the observations that glycosylated peptides tend to favor β -turns,¹⁰ and that the Asx turn is a necessary

motif for binding and catalysis.⁷ This situation may suggest a mechanism for favorable product release, which is needed to ensure that the rate of glycosylation keeps up with the rate of protein synthesis.

Table VI-1. Structures and kinetic data for neoglycoconjugates and precursors.

Isosteric molecules mimic the geometries and spatial locations of natural compounds. As such they represent new compounds that can be used to probe the effects of certain atoms or electronic effects on biological activity. A series of neoglycoconjugates containing amide isosteres were then prepared and the inhibitory activity of each was compared to each non-glycosylated analogue. This study was carried out in collaboration with Drs. Maria de L. Ufret and Stephane Peluso, and the details of the synthesis and kinetic evaluation can be found in Peluso, et al.^{21, 34} These

results are summarized in Table VI-1. Glycoconjugates in which the amide was replaced with more flexible linkers such as hydrazide (**3a**), hydroxylamine (**4a-b**), or amine (**5a**) groups did not suffer the same loss in affinity that was observed for the native amide bond glycoconjugate (**2a**). In the case of neoglycoconjugate **4a**, significant improvement in inhibitory activity was even achieved compared to the parent peptide **4**.³⁴

Previous studies have shown that *N*- δ -alkylation of the Dab side chain with a bulky, aromatic naphthyl group improves on already potent inhibitory activity.³⁵ This effect is in stark contrast with modification of the native asparagine side chain of OT substrates, where a GlcNAc residue drastically reduces binding to the enzyme relative to the unsubstituted form. Considering this observation, and in light of the results described, a hypothesis was proposed that amide bond cis-trans isomerization of a substituted asparagine side chain about the C-N bond might result in a steric clash, disrupting the Asx turn and favoring product release (Figure VI-4).

Figure VI-4. Proposed model of Asn amide bond cis-trans isomerization.

A constrained version of the hexapeptide containing a Dab(GlcNAc) surrogate, c[Hex-Dab-Cys]-Thr-Val-Thr-Nph-NH₂ (**8**) (Figure VI-6), was prepared by reductive amination for a more direct comparison with the cyclized C-glycoside peptide. In this case, a K_i value of 0.026 μM was found for **8**.

Figure VI-6. Structure and inhibition constant of cyclized Dab-GlcNAc conjugate (**8**).

These results indicate that incorporation of a more flexible, isosteric, all-carbon linker and preservation of the closed form of the sugar confers no improvement over any of the neoglycoconjugates described here. The linear (**5a**) and cyclized (**8**) Dab(GlcNAc) peptides are two orders of magnitude more potent than the linear (**6**) and cyclized (**7**) C-glycoside counterparts, respectively. A direct comparison is precluded by the fact that the saccharide moiety of the Dab(GlcNAc) side chain is locked into the open-ring form, although an even lower inhibition constant may be expected for the Dab(GlcNAc) inhibitors if the saccharide were locked into the closed-ring (pyranose) form. These

results highlight the dramatic effect that the positive charge of the Dab side-chain amine has on inhibition, especially considering that the binding of the C-glycoside is so similar to that of the hydrazide and hydroxylamine neoglycoconjugates, which bear the δ -nitrogen, but are more likely to be neutral under physiological conditions.

Role of side-chain charge in OT inhibition by asparagine-mimetic peptides

In order to test the hypothesis that the positive charge on the Dab side chain is critical in conferring potent inhibitory activity, design of an isosteric side chain that is neutral was envisioned. The functionality chosen was a hydrazine side chain, which is isosteric with Dab, but perturbs the pK_a of the terminal amine such that it is a neutral species under physiological conditions (Figure VI-7).

Figure VI-7. Comparison of pK_a values for Dab and hydrazine side chains.

The β -hydrazine analogue would also enable the future synthesis of neoglycoconjugates bearing a stable hydrazone linkage³⁷ through chemoselective ligation.²¹ Such a conjugate would be an improvement over the less stable amine linkage of Dab glycoconjugates, which must be reduced in order to create a stable linkage to the saccharide moiety. The necessary building block for such a surrogate is an amino acid with a β -hydrazine side chain bearing protecting groups on each of the three nitrogens.

The β -hydrazine amino acid (**9**) was prepared by a four-step synthesis starting from L-serine (**10**) (Scheme VI-3). Identical protecting groups could be installed at the two nitrogen atoms of hydrazine, but the α -amine required an orthogonal protecting group. Therefore, the first step was to protect the α -amine of L-serine with Alloc.²¹ This reaction was done under Schotten-Bauman conditions with allylchloroformate and 4 N NaOH to afford **11**. Following this step, Alloc-serine (**11**) was cyclized by a Mitsunobu-type reaction to provide the β -lactone (**12**),³⁸ and the 4-membered lactone was then opened with *t*-butylcarbazate to give *N*¹-Alloc, *N*³-Boc protected β -hydrazino amino acid (**13a**).³⁹ Selective attack of the ring methylene carbon can be achieved by using specific solvent polarity and order of addition.³⁸ However, a minor product (**13b**) can also be formed from opening of the β -lactone at the carbonyl. Unfortunately these compounds are difficult to distinguish by ¹H and ¹³C NMR spectra, and therefore further characterization was necessary to ensure that **13a** was the major product.

Scheme VI-3: Synthesis of the β-hydrazine amino acid^a

^aReagents and conditions: (i) allylchloroformate, 4 N NaOH, added simultaneously at 0°C under Schotten-Bauman conditions, then warmed to room temperature over 1 hr, 43% yield; (ii) 1) PPh₃, 2) DEAD, 3) **11**, -75°C to room temperature over 2 hr in THF, 29%; (iii) *t*-butylcarbazate, anhydrous CH₃CN, room temperature, 20 hr, 39% yield major product; (iv) Boc anhydride, DIEA, H₂O: dioxane (2:1), room temperature, 18 hr, 64% yield.

In order to confirm the presence of the free carboxylic acid, a common coupling reagent in solid phase peptide synthesis, HBTU, was reacted with the major product **13a**. This coupling reagent would not react with **13b**, but would only activate **13a**. Indeed, a new product was formed, suggesting that the activation had occurred. Further evidence

was later provided when the isolated major product was successfully incorporated into a peptide.

Finally, Boc-anhydride was used to protect the proximal amine of the hydrazine. The resulting amino acid (**9**) was analyzed for racemization using Marfey's reagent (1-fluoro-2,3-dinitrophenyl-5-L-alanine amide), from which only one product from the HPLC separation was found to have the mass of the adduct. Compound **9** was thus used as a building block for the synthesis of **14** (Figure VI-8), using standard solid-phase peptide synthesis techniques. The only exception involved the presence of an Alloc protecting group instead of the standard Fmoc protecting group on the main chain amine of the building block. The procedure for removal of the Alloc group was used as described in "Experimental Procedures" for deprotection.

Figure VI-8. Structure and K_i value of the hydrazinopeptide inhibitor **14**

Evaluation of the inhibitory activity against yeast OT revealed a K_i of $30 \mu\text{M}$, which is three orders of magnitude lower in potency compared to the corresponding Dab-

containing hexapeptide inhibitor (**5a**) (Table VI-1). Thus, as postulated, charge does seem to have an important role in binding.

Comparison of Asn amide *N*-hydroxylation to *N*-amination in OT inhibition

To further investigate the inhibition of OT by the hydrazide asparagine surrogate peptide (**3**) (Table VI-1), an analog was designed for comparison that bears a hydroxamate side chain in place of the hydrazine, effectively exchanging the primary amine of the hydrazide with a primary alcohol (Figure VI-9A). A tripeptide version of the hydroxamate analog had previously been shown to be a weak substrate of OT,¹⁴ and therefore one goal with the hydrazide and hydroxamate inhibitors was to evaluate them as OT substrates. Hydroxamate peptide **15** (Figure VI-9B) was prepared by first building the benzoyl-capped hexapeptide with Fmoc-Asp(OAlloc)-OH installed as a precursor to the hydroxamate residue. Selective deprotection of the Alloc group followed by the coupling of hydroxylamine with PyAOP and DIEA yielded the final peptide **15**.

Figure VI-9. A) Structures of hydrazide and hydroxamate side-chain functionalities. B) Structure and inhibition constant of hydroxamate surrogate peptide **15**.

Evaluation of the inhibitory activity of **15** revealed a K_i value of 2.6 μM , which is strikingly similar to that of the hydrazide analog (**3**) (2.5 μM). The substrate capabilities of these two inhibitors were found by using a modification of the radioactive assay described in the previous section. The substrate peptide, Bz-Asn-Ala-Thr-Val-Thr-Nph-NH₂ (**2**) (Table VI-1) was also included for comparison. Following incubation with OT, peptides were separated from (³H)GlcNAc-GlcNAc-PP-Dol by aqueous/organic extractions and analyzed by HPLC, using the radiolabel to detect the glycopeptide products and the UV absorbance at 228 nm to monitor elution of the parent peptides (Figure VI-10). The UV trace is not sensitive enough to detect the low turnover of peptide to glycopeptide, and therefore fractions were collected and subjected to scintillation counting. The shift in retention time of the glycopeptide product relative to the starting material peak in the UV trace is consistent with the addition of the polar saccharide. Minor impurities observed in the UV trace were expected due to the yeast microsomes used in the assay. The results of these assays reveal that both peptides **3** and **15** exhibit weak substrate capability.

Figure VI-10. UV (top) and radioactive (bottom) HPLC traces of OT substrate assays.

A) natural substrate (**2**), B) hydrazide inhibitor (**3**), and C) hydroxamate inhibitor (**15**) as substrates.

Optimization of the central residue of the Asn-Xaa-Ser/Thr consensus sequence

Alanine is a commonly used residue in the central position of the tripeptide consensus sequence, Asn-Xaa-Ser/Thr, of many inhibitors and substrates. A study was carried out to ascertain whether minor modifications to this side chain would have any impact on the binding affinity of OT inhibitors. Bz-Dab-Val-Thr-Val-Thr-Nph-NH₂ (**16**) and Bz-Dab-Nva-Thr-Val-Thr-Nph-NH₂ (**17**) (Nva = norvaline) (Figure VI-11) were synthesized by standard solid phase peptide synthesis using Fmoc-protected amino acids and were evaluated as inhibitors of OT. Compared to the analogous hexapeptide **5a** bearing an alanine residue at the central position, which has a K_i of 62 nM (Table VI-1),³⁴ both of these modified peptides have similarly improved potency, with K_i values of 14 nM and 11 nM for **17** and **18**, respectively. The tolerance of OT for a variety of residues

at this position suggests that there is considerable space available for binding, and thus filling this space with larger aliphatic groups may increase binding energy.

Figure VI-11. Structures and inhibition constants of peptides **16** and **17**.

Activity and inhibitor assays of PNGase1

The product of OT is also the substrate of the deglycosylating enzyme, PNGase, and therefore product-based OT inhibitors such as the neoglycoconjugates described here can also be valuable tools for the study of PNGase. Also facilitating this study was the availability of the fluorescein-labeled interferon fragment glycopeptide (Figure VI-12) that had been prepared to test the substrate specificity of Alg1 (Chapter III), and here could be used as a substrate for screening PNGase inhibitors. The fluorophore enables a sensitive HPLC assay based on the shift in retention time upon deglycosylation.

Figure VI-12. Synthetic glycopeptidyl Png1 substrate.

Hexapeptide neoglycoconjugates **18**, **19**, and **20** (Figure VI-13), prepared by reductive amination with GlcNAc or GlcNAc₂, were synthesized as OT inhibitors by Dr. Stephane Peluso using standard solid-phase peptide synthesis in conjunction with chemoselective ligation methods described elsewhere.²¹ These product-mimetic OT inhibitors were postulated to be excellent candidates for substrate-mimetic inhibitors of PNGase, considering the presence of both the peptide and glycan binding determinants, as well as the fact that they are coupled via non-hydrolyzable linkers.

Figure VI-13. Structures of neoglycoconjugate Png1 inhibitors (18-20).

PNG1 from *S. cerevisiae* had been cloned into a bacterial expression vector²⁷ and was provided by the laboratory of Professor William Lennarz. This enzyme was overexpressed and purified to homogeneity by Talon™ affinity chromatography, with a yield of approximately 6 mg per liter of cell culture. The purified enzyme is stable at 4 °C for several months. This preparation was used in hydrolysis assays with the GlcNAc₂-linked interferon fragment peptide (Figure VI-12). Reaction progress was monitored by analytical C₁₈ HPLC with UV detection, which showed a change in retention time of approximately 2 minutes upon deglycosylation. Percent conversion was measured by dividing the area under the product peak by the sum of the areas under the starting material and product peaks. Mass spectrometry (ESI-MS) was employed to confirm the identity of the starting material and product peaks. The K_m of the

fluorescein-labeled glycopeptide used in this study for Png1 is not known, because the range of concentrations necessary to determine that value would be undetectable in this preliminary assay.

Incubation of the fluorescein-labeled glycopeptide (100 μ M) in the presence of 3.3 pM Png1 resulted in 15% conversion to the cleaved product after 12 hours at 30 °C. Using these same conditions, but preincubating the enzyme with **18**, **19**, or **20** (10 μ M) for 30 minutes resulted in a drop in percent conversion to 5%, 9%, and 3%, respectively. From these preliminary data, it appears that all of these neoglycoconjugates have the ability to bind and inhibit Png1.

In order to obtain quantitative data on these inhibitors, the use of a fluorescence detector is necessary. Because fluorescein fluorescence is pH-sensitive, and the acidic conditions used in HPLC (0.1% TFA) are enough to significantly quench the fluorescence, a new substrate was designed. Rhodamine was chosen as the fluorophore, which is not sensitive to lower pH, and is commercially available as the *N*-hydroxysuccinimide ester, making it amenable to solid-phase peptide synthesis. The peptide substrate chosen was based on a fetuin-derived glycopeptide Leu-Asn(NeuAc₃Gal₃Man₃GlcNAc₅)-Asp-Ser-Arg. Peptide **21** (Figure VI-14) was synthesized by standard solid-phase peptide synthesis, using the same Asn-GlcNAc₂ building block described in Chapter III. Prior to cleavage from the solid support, rhodamine-NHS was coupled to the aminohexanoic acid spacer. This peptide, in the absence of the spacer and rhodamine, was previously shown to be hydrolyzed by both bacterial and plant seed PNGase with the same relative rate as the native fetuin-derived glycopeptide.²⁸ Given this precedent in conjunction with the demonstration that yeast

Png1 accepts the GlcNAc₂-interferon fragment glycopeptide, GlcNAc₂-fetGPI was postulated to be an excellent substrate for PNG1 inhibition assays. Also, since PNGase is meant to act on a wide variety of peptide sequences, and a 6-carbon spacer has been included, the rhodamine is not suspected to greatly affect binding and amidase activity. The availability of this substrate will enable future quantitative evaluation of neoglycoconjugates as inhibitors of Png1.

Figure VI-14. Structure of the rhodamine-labeled fetuin-based Png1 substrate.

Conclusion

Appending saccharide moieties to asparagine-mimetic side chains in order to make product-based inhibitors did not dramatically improve potency in general, although this study did lead to insights into the possible involvement of cis-trans isomerization in

product release. In the OT inhibitors described, flexible non-amide linkers can tolerate functionalization of the side chain without significant changes in binding affinity. This result is in contrast to the native Asn side chain, which drastically loses binding affinity upon addition of a GlcNAc moiety to the amide nitrogen. However, these findings are reminiscent of the discrepancy between the tolerance of OT for a naphthyl moiety on a Dab side chain and the sensitivity of OT binding to even minor functionalization of the Asn side chain.

As had been previously hypothesized, the positive charge of the side-chain amine on Dab appears to play an important role in the binding affinity of OT inhibitors. This effect was demonstrated in the comparison of amine and hydrazine side chains as asparagine mimics, and in the comparison of the C-glycoside to the Dab-glycoside.

It has been postulated that weak substrate behavior may be the source of inhibitory activity for OT substrate mimics bearing either a hydroxamate and hydrazide side chain in place of the asparagine amine. Indeed, both analogues were found to be low micromolar inhibitors as well as substrates of OT. The reduced substrate behavior of these modified asparagine analogs may be due to impairment of the deprotonation of the amide nitrogen, or, considering the cis/trans isomerization model, reduced binding affinity resulting from disruption of the Asx turn by an additional substituent directed toward the interior of the turn.

Improvements to the binding affinity of Dab-containing inhibitors with modifications to the central site of the consensus sequence suggests that there is much more opportunity for optimization of inhibition by varying the substitution of this site.

Neoglycoconjugates were also found to be inhibitors of the deglycosylating enzyme, Png1. Future directions may include a more quantitative description of this inhibitory activity, as well as improvements to potency and bioavailability. Such molecules could be extremely valuable in probing the intricate pathways of protein folding quality control and degradation.

Taken together, these results show that isosteric surrogates of natural substrates and products can be useful tools for understanding catalysis, inhibition, and product release. Seemingly minor changes in substrates and inhibitors can have dramatic consequences, and have led to a more thorough understanding of the active site of OT, which still remains elusive due to the complicated nature of this enzyme complex.

Acknowledgements

A portion of this chapter has been published,³⁴ and was carried out in collaboration with Drs. Stephane Peluso and Maria de L. Ufret. Inhibitors used for the Png1 studies were synthesized by Dr. Stephane Peluso. The C-glycoside building block was synthesized and generously provided by the laboratory of Prof. Alessandro Dondoni (University of Ferrara, Italy). The *PNG1* clone was generously provided by the laboratory of Prof. William Lennarz (SUNY Stonybrook).

Experimental procedures

General procedure for solid phase peptide synthesis

All peptides were prepared manually using a glass reaction vessel fitted with a sintered glass frit. Fmoc-PAL-PEG-PS resin was washed and swollen in CH_2Cl_2 (2 x 10 mL/g resin x 15 min) and dimethylformamide (DMF) (1 x 10 mL/g resin x 15 min). *N*- α -Fmoc was removed by treatment with piperidine : DMF 1:5 (3 x 10 mL/g resin x 5 min), followed by washing with DMF (5 x 10 mL/g resin x 1 min). The number of equivalents was determined by quantification of Fmoc release. This was accomplished by measuring the UV absorbance at 300 nm of the pooled deprotection rinses and DMF washes. Coupling reactions were performed using 1.5 equivalents of *N*- α -Fmoc protected amino acids activated *in situ* with 1.5 equivalents of PyBOP and 3 equivalents of diisopropylethylamine (DIEA) in DMF (10 mL/g resin) for 1 hour.

General procedure for *O*-Allyl removal on solid support

For the removal of the Allyl protecting group from the aspartic acid side chain, the resin was treated with 25 equivalents of PhSiH_3 in CH_2Cl_2 (1 mL/g resin) under nitrogen for 2 min, followed by the addition of 0.25 equivalents of $(\text{PPh}_3)_4\text{Pd}(0)$ in CH_2Cl_2 (1 mL/g resin). The reaction proceeded for 30 min under nitrogen and then was washed with CH_2Cl_2 (2 x 5 mL x 1 min). This procedure was repeated twice more, then followed by washing with CH_2Cl_2 (2 x 10 mL/g resin x 1 min).

General procedure for N-terminal capping

Capping was accomplished by reacting the resin with 10 equivalents of benzoic anhydride and 10 equivalents of pyridine in DMF (2.5 mL/g resin) for 1 hour. Resin was then washed with DMF (5 x 10mL/g resin x 1 min) and CH₂Cl₂ (2 x 10mL/g resin x 1 min).

General procedure for side chain to main chain cyclization

Following the coupling of the last amino acid and removal of Fmoc, 10 equivalents of 6-bromohexanoic acid and 10 equivalents of PyBOP were added to the resin in DMF. The coupling was initiated by the addition of 20 equivalents of diisopropylethylamine, followed by orbital shaking for 12 hours under nitrogen. The monomethoxytrityl (Mmt) protecting group was removed from cysteine by treatment of the resin with 1% trifluoroacetic acid in CH₂Cl₂ (5 X 1 min). DMF was added to the resin (1 mL/1 g resin) and degassed. 5 equivalents of freshly distilled 1,1,3,3-tetramethylguanidine was added and the reaction shaken orbitally under nitrogen. After 12 hours, the resin was washed with DMF (5 X 1 min) and CH₂Cl₂ (2 X 1 min).

General procedure for peptide release and deprotection

Cleavage of peptides from resin with concomitant removal of side chain protecting groups was performed using 10 mL/g resin of trifluoroacetic acid (TFA):

CH₂Cl₂: triisopropylsilane: H₂O (90:5:2.5:2.5). The cleavage reaction was allowed to proceed for 1 hour. The mixture was filtered through a pasteur pipet equipped with a glass wool plug, and resin was rinsed with TFA (2 x 1 mL). Filtrate was concentrated under a stream of nitrogen to 1 mL, then triturated with 14 mL of diethyl ether. The white solid obtained was isolated by centrifugation, washed twice with ether, and allowed to dry. Dab-containing peptides were redissolved in acetonitrile: H₂O (1:1), and all others in acetonitrile: DMSO: acetic acid (5:3:2). All peptides were purified by preparative HPLC.

Bz-AsnAlaThrValThrNph-NH₂ (2)

2

The immobilized peptide was assembled according to the general procedures described above.

HPLC : $t_R=19.9\text{min}$ (7-100% CH₃CN/0.1%TFA in 30 min)

Bz-C-glycoside-Ala-Thr-Val-Thr-Nph-NH₂ (6)

Fmoc-Ala-Thr-Val-Thr-Nph-PALPEG-PS was prepared as described, and 150 mg of resin-bound peptide was used for incorporation of the C-glycoside. The exact amount of peptide was determined to be 0.017 mmol by quantifying the amount of Fmoc released upon deprotection as described above. Following deprotection, 11 mg of the C-glycoside was dissolved in 0.5 mL of DMF, and the purity was confirmed by TLC, which was developed with chloroform: methanol: water (65: 25: 4) and stained with PMA. PyAOP (18 mg) was dissolved in 0.5 mL of DMF and added to the resin in addition to the Fmoc-protected C-glycoside in DMF. A 10- μ L portion of collidine was added and the reaction proceeded with shaking overnight at room temperature. N-terminal benzyl capping and cleavage from the resin with concomitant deprotection of side chain protecting groups were as described.

Prior to HPLC purification, deprotection of the peracetylated GlcNAc was performed. To a solution of methanol/0.3% (final) NaOMe (2.7 mL), 0.3 mL of cleaved peptide in DMSO was added dropwise with constant stirring in a 10-mL pear-shaped flask. The reaction was allowed to stir at room temperature overnight. The reaction

mixture was brought to pH 4 with glacial acetic acid (10%), and solvent was removed on a rotary evaporator.

HPLC : $t_R=20.7$ min (7-100% CH₃CN/0.1%TFA in 30 min)

LRMS calcd for **6** [C₄₅H₆₅N₉O₁₆ + H]⁺ requires m/z 988.5. Found 988.3 (ESI+)

(cyc)-C-glycoside-Cys-Thr-Val-Thr-Nph-NH₂ (7)

Synthesis was as described for linear C-glycoside, with the exceptions that the Ala is replaced by a Cys(MMT), and the peptide is capped with 6-bromohexanoic acid and cyclized as described above.

HPLC : $t_R= 20.0$ min (C₁₈, 7-100% CH₃CN/0.1%TFA in 30 min)

LRMS calcd for **7** [C₄₄H₆₉N₉O₁₆S + H]⁺ requires m/z 1012.5. Found 1012.5 (ESI+)

mixture was removed from the ice bath and allowed to warm to room temperature with continuous stirring. An hour after removing from the ice bath, the reaction mixture was diluted with H₂O (50 mL), and washed with diethyl ether (3 x 50 mL). The aqueous layer was adjusted to pH=3 with 5N HCl, then washed with ethyl acetate (5 x 50 mL). Pooled organic layers were dried over sodium sulfate, filtered, and dried under vacuum for 24 hours, removing residual ethyl acetate to yield 820 mg (2.9 mmol) of compound **11** as a clear oil (43% yield). ¹H NMR (400 MHz, CDCl₃): δ 3.88 (d, *J*=8.8 Hz, 1H) CHH-OH, 4.06 (d, *J*=10.1 Hz, 1H) CHH-OH, 4.40 (m, 1H) αH, 4.59 (m, 2H) CH₂=CH-CH₂-O-, 5.22 (d, *J*=10.3 Hz, 1H) CHH=, 5.32 (d, *J*=17.2 Hz, 1H) CHH=, 5.90 (m, 1H) CH₂=CH-. R_f = 0.52 in CHCl₃:MeOH:H₂O (65:25:4)

***N*-Alloc-serine-β-lactone (12)**

PPh₃ (2.1g, 7.9 mmol) was dissolved in anhydrous THF (50 mL) at -70 °C under nitrogen in a tri-neck round bottom flask. DEAD (1.2 mL, 7.9 mmol) was added over 10 minutes. The solution was then stirred for an additional 10 minutes. One septum on the flask was quickly replaced with a dropping funnel containing *N*-Alloc-serine (1.5 g, 7.9 mmol) in anhydrous THF (25 mL). This solution was added to the reaction mixture over 30 minutes at -70 °C. The reaction was stirred for 20 minutes more at -70° C, then brought to room temperature slowly over 1 hour with stirring. The reaction mixture was concentrated on a rotary evaporator and purified by flash chromatography (5-cm

diameter, 130 g silica). 1 L of hexane: ethyl acetate (85:15) was used to pack the column and rinse impurities. The product was eluted with 1 L of hexane: ethyl acetate (7:3) followed by 500 mL of hexane: ethyl acetate (65:35). Compound **12** was recovered as a white solid in 29% yield. ¹H NMR (400 MHz, CDCl₃): δ 4.45 (d, *J*=6 Hz, 2H) -CH₂-, 4.57 (d, *J*=5.6 Hz, 2H) CH₂=CH-CH₂-, 5.10 (m, 1H) ring CH, d (5.22 (d, *J*=10.4, 1H) CHH=, 5.29 (d, *J*=17.2 Hz, 1H) CHH=, 5.88 (m, 1H) CH₂=CH-.
*R*_f=0.31 in hexane: ethyl acetate (65:35)

***N*¹-Alloc-Ala[βHz(*N*³-Boc)]-OH (**13a**)**

To a solution of *t*-butylcarbazate (2.2 g, 17 mmol) in anhydrous acetonitrile (20 mL) was cannulated a solution of *N*-Alloc-serine-β-lactone (**12**) (120 mg, 0.67 mmol) in anhydrous acetonitrile (10 mL) over 30 minutes. After stirring under nitrogen for 14 hours at room temperature, the reaction was complete. The reaction mixture was concentrated on a rotary evaporator to a clear oil, to which 20 mL of ethyl acetate were added. This solution was extracted with 0.1 N HCl (4 x 10 mL). The ethyl acetate layer was dried over sodium sulfate, filtered, and concentrated on a rotary evaporator. The product was purified by flash chromatography (2-cm diameter, 40 g silica). The column was packed in ethyl acetate: hexane (9:1). After loading the crude product, 200 mL of this solvent system was used to remove impurities, then the product was eluted with CH₂Cl₂: MeOH: AcOH (10:1:0.1). After concentrating the product-containing fractions,

the product was washed 3X with toluene, then allowed to dry under vacuum overnight to yield compound **13a** as a white solid in 39% yield.

^1H NMR (400 MHz, CDCl_3): δ 1.44 (s, 9H) $-\text{C}(\text{CH}_3)_3$, 3.23 (m, 1H) βH_1 , 3.32 (m, 1H) βH_2 , 4.44 (m, 1H) αH , 4.57 (d, $J=5.4$ Hz, 2H) $\text{CH}_2=\text{CH}-\text{CH}_2-$, 5.21 (d, $J=10.4$ Hz, 1H) $\text{CHH}=\text{}$, 5.31 (d, $J=17.2$ Hz, 1H) $\text{CHH}=\text{}$, 5.87 (m, 1H) $\text{CH}_2=\text{CH}$.

$R_f = 0.31$ in $\text{CH}_2\text{Cl}_2:\text{MeOH}:\text{AcOH}$ (10:1:0.1)

N^1 -Alloc-Ala[$\beta\text{Hz}(N^{2,3}$ -bisBoc)]-OH (**9**)

To a solution of N^1 -Alloc-Ala[$\beta\text{Hz}(N^3$ -Boc)]-OH (**13a**) (0.080 g, 0.26 mmol) in 2:1 H_2O : dioxane (1 mL) was added Boc_2O (0.011 g, 0.52 mmol) and diisopropyl ethylamine (DIEA) (140 μL , 0.78 mmol). The reaction mixture was stirred at room temperature for 36 hours. The reaction mixture was diluted with ethyl acetate (2 mL) and washed with 0.1 N HCl (4 x 2 mL). The organic layer was dried over sodium sulfate, filtered, and concentrated on a rotary evaporator to a clear oil. The crude product was purified by flash chromatography (2 cm diameter, 40 g silica). Impurities were eluted with 9:1 chloroform: methanol (300 mL), the pure product was eluted with 100:5:1 CH_2Cl_2 : MeOH: AcOH. Product-containing fractions were concentrated on a rotary evaporator, then washed three times with toluene and dried under vacuum to afford a clear oil in 64% yield.

^1H NMR (400 MHz, CDCl_3): δ 1.46 (s, 9H) $-\text{C}(\text{CH}_3)_3$, 1.49 (s, 9H) $-\text{C}(\text{CH}_3)_3$, 3.71 (m, 1H) βH_1 , 3.87 (m, 1H) βH_2 , 4.44 (m, 1H) αH , 4.57 (m, 2H) $\text{CH}_2=\text{CH}-\text{CH}_2-$, 5.21 (m, $J=8.2$ Hz, 1H) $\text{CHH}=\text{}$, 5.31 (d, $J=17.1$ Hz, 1H) $\text{CHH}=\text{}$, 5.91 (m, 1H) $\text{CH}_2=\text{CH}-$.

$R_f = 0.53$ in CH_2Cl_2 : MeOH: AcOH (10:1:0.1)

Marfey's test for racemization

In order to react Marfey's reagent (1-fluoro-2,3-dinitrophenyl-5-L-alanine amide) with the amino acid, the Alloc protecting group needed to be removed from the main-chain amine. To a solution of N^1 -Alloc-Ala[$\beta\text{Hz}(N^{2,3}$ -Bisboc)]-OH (1 mg, 0.0025 mmol) in CH_2Cl_2 (100 μL) was added phenylsilane (7.7 μL , 0.063 mmol), followed by a solution of $(\text{PPh}_3)_4\text{Pd}(0)$ (0.6 mg, 0.0005 mmol) in dichloromethane (100 μL). The reaction mixture was stirred at room temperature for 20 minutes, then dried under a stream of nitrogen to remove CH_2Cl_2 and under vacuum for 1 hour to remove phenylsilane.

To a solution of the deprotected amino acid in 50 μL of H_2O was added 100 μL of Marfey's reagent (10 mg/mL), followed by 20 μL of NaHCO_3 (1 M). The reaction mixture was left at 37°C for 1 hour, then was quenched with 20 μL of 1 N HCl. For HPLC analysis, the reaction mixture was diluted with 810 μL of acetonitrile, then filtered through a 0.45- μm syringe filter. The filtrate was passed through a sep-pack, doubling the volume of the sample, then filtered once more. A 20- μL aliquot of sample was injected onto a Waters C_{18} analytical HPLC column and eluted with a linear gradient of 0-70% or 30-70% $\text{CH}_3\text{CN}/0.1\%$ TFA over 30 minutes while monitoring the absorbance at both 254 nm and 280 nm. ESI-MS was performed on each of three peaks, which had retention times of 21.8, 25.5, and 26.6 min, respectively, for the 0-70% gradient, and 6.8,

15.8, and 20.0 min, respectively, for the 30-70% gradient. No signal was seen for the first peak, which is likely Marfey's reagent. This molecule may not ionize very easily. The second peak, with a mass of $[M+H^+ = 279.1$ and $M+H^++Na^+ = 301.1]$, did not have an absorbance at 280 nm, and therefore was not an adduct of Marfey's reagent. The third peak from the HPLC had a mass of $[M+H^++Na^+ = 594.2]$, which corresponds to the dipeptide adduct formed in the reaction.

Bz-Ala(β H_z)-Ala-Thr-Val-Thr-Nph-NH₂ (14)

A 200-mg portion of Fmoc-Ala-Thr-Val-Thr-Nph-PAL-PEG-PS (see above for general procedure for peptide synthesis) was transferred to a fritted glass reaction vessel and the Fmoc group was removed with 20% piperidine in DMF (3 x 5 mL x 5 minutes). Following deprotection, resin was rinsed with DMF (5 x 5 mL x 1 minute) and CH₂Cl₂ (2 x 5 mL x 1 minute). Resin was transferred from the reaction flask to a 10-mL pear-shaped vial containing 16 mg of dry *N*¹-Alloc-Ala[β H_z(*N*^{2,3}-Bisboc)]-OH. DMF (2 mL), PyAOP (41 mg, 0.080 mmol), and collidine (21 μ L, 0.16 mmol) were added, and the coupling reaction was allowed to shake overnight at room temperature. Contents of the vial were then transferred back to the fritted glass reaction vessel, reagents were drained, and the resin was rinsed with DMF (5 x 5 mL x 1 min) and CH₂Cl₂ (2 x 5mL x 1 min).

Alloc group removal, capping, cleavage and purification were done as described in general procedures.

Bz-Ala(β -hydroxylamide)-AlaThrValThrNph-NH₂ (15**)**

The immobilized peptide, Ala-Thr-Val-Thr-Nph-PAL-PEG-PS, was assembled according to the general procedures described above. Activation of *N*- α -Fmoc-Asp(OAll) was performed *in situ* with 2 equivalents of PyAOP and 4 equivalents of collidine to prevent epimerization. Following the coupling of this residue to the resin, removal of Fmoc from this residue was completed using 20% piperidine in DMF containing 0.1 M dinitrophenol (3 x 5 mL/g resin x 20 min), then washed with CH_2Cl_2 , DMF, and methanol until yellow color disappeared. The hydroxylamide functionality was prepared by deprotection of O-Allyl protected Asp residue as described above, followed by coupling of hydroxylamine (activated *in situ* with 1.5 equivalents of PyAOP and 3 equivalents of DIEA) for 1 hour in DMF (10 mL/g resin).

HPLC : t_R = 18.0 min (7-100% $CH_3CN/0.1\%$ TFA in 30 min)

LRMS calcd for **15** [$C_{36}H_{49}N_9O_{13} + H$]⁺ requires m/z 816.8. Found 816.2 (ESI+)

Bz-DabValThrValThrNph-NH₂ (16)

Rho-Ahx-Leu-Asn(GlcNAc₂)-Asp-Ser-Arg-NH₂ (21)

Preparation of this substrate began with the previously described de-allylation of 44 mg of the Fmoc-Asn(GlcNAc₂-TBS₃)-OAll building block (Chapter III), which had been prepared previously for a putative Alg1 substrate. The peptide NH₂-Ahx-Asn(GlcNAc₂)-Asp-Ser-Arg-PAL-PEG-PS (where Ahx = aminohexanoic acid) was prepared by standard SPPS methods, incorporating the deprotected Asn(GlcNAc₂) building block. One equivalent of the succinimidyl ester of the rhodamine derivative carboxy-X-rhodamine (ROX) was coupled in DMF overnight in the presence of eight equivalents of DIPEA. Peptide **22** was cleaved from the resin in a cocktail consisting of 95% TFA, 2.5% H₂O, and 2.5% triisopropylsilane at room temperature for 1 hour. HPLC purification and ESI-MS analysis followed.

HPLC : t_R=21.5 min (7-100% CH₃CN/0.1%TFA in 30 min)

LRMS calcd for **22** [C₇₈H₁₀₉N₁₅O₂₄]⁺ requires *m/z* 1639.8. [C₇₈H₁₀₉N₁₅O₂₄ + H]²⁺ requires *m/z* 819.9. Found 820.1 (ESI+).

OT Activity Assays

Dolichylpyrophosphate-linked (^3H)GlcNAc-GlcNAc-PP-Dol was prepared using porcine liver microsomes as described.⁴⁰ A 50,000-dpm aliquot of the dolichylpyrophosphate-linked substrate was resuspended in 10 μl of dimethylsulfoxide (DMSO) and vortexed to resuspend the sugar. Assay buffer was prepared by adding 30 μL of 1 M MnCl_2 to 1.5 mL of the following buffer: 140 mM sucrose, 50 mM Hepes pH 7.5, 1.2% Triton X-100, and 0.5 mg/ml PC. Assay buffer was added to the sugar substrate to achieve a final volume of 200 μL after addition of enzyme and peptide substrate. OT-containing solubilized microsomes, prepared from *S. cerevisiae* as previously described,⁴¹ were then added and vortexed at a low setting. Finally, the reaction was initiated by the addition of 10 μl of Bz-NLT-NHMe (5 mM), followed by vortexing at a low setting and then shaking at 180 rpm. Four 7-mL scintillation vials, each containing 1 mL of chloroform:methanol (3:2) and 200 μL of 4 mM MgCl_2 , were used to quench 40- μL aliquots from the reaction at exactly two minute intervals until eight minutes had passed. The vials were vortexed at a low setting simultaneously with quenching. Once all four time points had been taken, and the organic and aqueous layers were separated and clear, the aqueous layer from each vial was extracted and transferred to four separate 7-mL scintillation vials. A 600- μL aliquot of theoretical upper layer, or TUP (2.75% chloroform, 44% methanol, 53.25% aqueous magnesium chloride (1.55 mM)), was then added to each of the organic layers and vortexed at a low setting. Once the organic and aqueous layers had separated, the aqueous layer was removed from each vial and added to the previously removed aqueous layer. The TUP extraction was repeated once again, pooling the aqueous layers for each time point separately. Aliquots

of 5-mL of Eco-Lite scintillation cocktail (ICN Biomedicals, Inc.) were added to each of the pooled aqueous layers, then the vials were capped and vortexed at high speed to clarify solutions. The solutions were counted by a scintillation counter for five minutes per vial. Disintegrations per minute (dpm) were plotted as a function of time.

K_m of Bz-Asn-Ala-Thr-Val-Thr-Nph-NH₂

OT assays were performed as described above, except that instead of Bz-NLT-NHMe, Bz-Asn-Ala-Thr-Val-Thr-Nph-NH₂ was used as the disaccharide acceptor. The K_m of the tripeptide substrate, 0.25 μ M, is similar to that of the hexapeptide containing asparagine that is used for comparison in this study, which has a K_m of 0.31 μ M. The following concentrations were assayed: 5 nM, 50 nM, 125 nM, 250 nM, 500nM, 1 μ M, 2 μ M, 3 μ M, and 4 μ M. From the slope of the dpm vs. time plots, velocity (nmol/sec) was calculated. Velocity vs. substrate concentration were plotted to confirm saturation, and a Hanes plot ($[S]/V$ vs. $[S]$) was used to determine the K_m , with a linear regression of 0.99447. From the Hanes plot, the x-intercept is equal to $(-K_m)$.

OT Inhibition assays

Inhibition assays proceeded as described in the preceding section with the following changes: A 10- μ L aliquot of inhibitor in DMSO was used in place of the 10- μ L DMSO aliquot added first to the dried sugar substrate. (³H)GlcNAc-GlcNAc-PP-Dol of approximate specific activity 20 Ci/mmol was used as well as a final concentration of 0.1 mM Bz-AsnLeuThrNH₂. Reaction mixtures contained 10 μ L of DMSO or inhibitor, 140

μL of assay buffer, 40 μL of solubilized OT microsomes, and to initiate the reaction after a 30 minute incubation with orbital shaking on ice, 10 μL of 2 mM Bz-NLT-NH₂.

The disintegrations per minute (dpm) were plotted as a function of time for the control and 3 different inhibitor concentrations. The percentage of inhibition was determined from this plot in order to estimate the IC₅₀. Three concentrations were then selected to give between 30% and 70% inhibition. All experiments were run a minimum of three times. In each case, the approximate K_i was determined using the following equation.⁴²

$$K_i = \frac{[I] \times (1-i)}{i + \left(\frac{[S]}{K_M} \times i \right)}$$

HPLC Assay for inhibitors as substrates

Peptides to be assayed were prepared as 2 mM solutions in DMSO. A 10- μL aliquot of 2 mM peptide was then added to 100,000 dpm (9 Ci/mmol) of dried (³H)GlcNAc-GlcNAc-PP-Dol and vortexed at high speed. To this mixture was added 140 μL of standard OT assay buffer and vortexed again. To initiate the reaction, 50 μL of solubilized OT microsomes were added with gentle mixing. After fifteen hours of incubation at room temperature with orbital shaking, the reactions were quenched by adding the entire amount to 5 mL of chloroform: methanol (3:2) containing 1 mL of 2.5 mM MgCl₂ and vortexing to mix the layers. Once the organic and aqueous layers separated, the aqueous layer was transferred to a separate vial. The organic phase was extracted twice with 4-mL aliquots of TUP without salt [chloroform: methanol: water (2.75 : 44 : 53.25 v/v)], and combined with the original aqueous layer. Pooled aqueous

layers were left to dry overnight under a stream of nitrogen. Once dry, the peptide was redissolved in 880 μ L of water : DMSO (10:1) and filtered through a 0.45 micron syringe filter. The entire sample was then injected onto a Waters analytical C₁₈ HPLC column equilibrated with 20% acetonitrile, 80% water, 0.1% trifluoroacetic acid (TFA) at a rate of 1 mL/minute. Following injection, this solvent ratio was maintained for 5 minutes, then a gradient of 20-80% acetonitrile/0.1%TFA was completed over 20 minutes. Fractions of 1 mL were collected every minute for the first ten minutes, then 0.5-mL fractions were collected every thirty seconds for ten minutes, and finally 1-mL fractions were collected for the last five minutes. Aliquots of 5 mL of Eco-Lite were added to each fraction and counted on a Beckman LS-5000TD scintillation counter to give the amount of (³H)-GlcNAc incorporation into the peptide.

Png1 expression and purification

The laboratory of Professor W. Lennarz provided the PNG1 gene from *S. cerevisiae* cloned into an expression vector (pET-28b) for *E. coli* expression of this construct with a C-terminal His tag. Cells from a glycerol stock were used to grow a 50-mL overnight culture in LB containing 34 μ g/mL chloramphenicol. Following overnight growth, the 50-mL culture was added to 950 mL of LB-chloramphenicol, and grown to an O.D. of 0.79. Protein expression was then induced with the addition of IPTG to 1 mM and growth was continued for 4 hours. Cells were harvested by centrifugation at 3,000 rpm for 30 minutes at 4 °C and stored in four equal-sized batches at -80 °C.

Purification began by thawing one aliquot of cells (from 250 mL of expression culture) on ice, then resuspending them in 25 mL of lysis buffer (20 mM Tris-HCl, pH

7.5, 1% Triton X-100, and 1 mM PMSF). All steps were carried out at 4 °C. Cell lysis was achieved by three 10-second pulses of sonication, separated by 10-second cooling periods. The cells were kept on ice during the entire process. The resulting lysate was clarified by centrifugation at 8,000 rpm for 45 minutes. Supernatant was added to 2 mL of Talon™ resin pre-equilibrated in binding buffer (20 mM Tris-HCl, pH 7.5, 100 mM NaCl). This mixture was shaken at 4 °C for 2 hr to allow binding of His-tagged protein, then poured into a column with a plugged outlet. The plug was then removed and the flow-through was collected. Resin-bound protein was washed twice with 20 mL of binding buffer containing 10 mM imidazole, and eluted with 12 mL of binding buffer containing 100 mM imidazole, collecting 2-mL elution fractions. Fractions were stored at -20 °C. Png1-containing fractions were thawed, brought to 10 mM DTT, combined, and concentrated to 3 mL with concomitant buffer-exchange into B88 buffer (20 mM HEPES-KOH, pH 6.8, 5 mM potassium acetate, 150 mM magnesium acetate, 250 mM D-sorbitol, 10 mM DTT) using a Millipore Ultrafree-15 centrifugal filter device by centrifuging at 3,000 rpm, 4 °C. Protein was quantified using the BioRad protein assay, according to the manufacturer's instructions. A standard curve was plotted with A_{595} vs. [BSA](mg/mL) using only the values for the BSA standards. The equation from fitting the data to a line was $y=0.029+0.5985x$ $R=0.99933$. From this equation, the concentration of Png1 was determined to be 0.53 mg/mL. Prior to assays, the enzyme was diluted to 14 µg/mL in B88 buffer.

Png1 assays

An aliquot of diluted Png1 (either 14 ng or 140 ng) was added to a solution of the FITC-labeled glycopeptide substrate (450 pmol) in 40 mM Mes-NaOH, pH 6.6, 10 mM DTT for a final volume of 100 μ L. Reaction mixtures were heated to 30 $^{\circ}$ C and incubated overnight. HPLC analysis was performed by removing 30 μ L of reaction mixture, adding 70 μ L of water and 100 μ L of acetonitrile, centrifuging to remove any insoluble material, and injecting the supernatant onto a Waters C₁₈ analytical HPLC column. Products were eluted with a gradient of 20-60% acetonitrile/0.1% TFA in water /0.1% TFA. For identification, peaks were collected, dried on a Speed-vac, redissolved in methanol: water (50: 50) containing 1% acetic acid, and analyzed by ESI-MS.

In the first round of inhibitor assays, 1 nmol of inhibitor **19**, **20**, or **21** was added to PNGase1 (14 ng) in Mes-NaOH buffer (above) for a final volume of 19.3 μ L and incubated at 30 $^{\circ}$ C for 30 minutes. The reaction was then initiated by the addition of fluorescein-labeled glycopeptide substrate (0.4 nmol), bringing the final volume to 20 μ L. Incubation was continued for 12 hours before the reactions were quenched with the addition of TFA to 1%, and the products were analyzed as described above. The second round of inhibition assays was completed in the same manner as the first with the exception that 2 nmol of substrate, 0.2 nmol of inhibitor, and 140 ng of enzyme were used. Percent conversion was measured by dividing the area under the product peak by the sum of the areas under the starting material and product peaks.

ACADEMIC BACKGROUND

- | | |
|------|--|
| 2006 | Ph.D. Biological Chemistry
Massachusetts Institute of Technology, Cambridge, MA |
| 1999 | B.S. Chemistry
Purdue University, West Lafayette, IN |

PROFESSIONAL BACKGROUND

- | | |
|-----------|--|
| 2000-2006 | Research Assistant, Department of Chemistry
Advisor: Professor Barbara Imperiali
Massachusetts Institute of Technology |
| 2003 | Two-month Industrial Internship
Advisor: Dr. Francine Perler
New England Biolabs, Inc. |
| 1997-1999 | Research Assistant, Department of Chemistry
Advisor: Professor Jean Chmielewski
Purdue University |
| 1997 | Research Assistant, Department of Chemistry
Advisor: Professor Bruce Morimoto
Purdue University |
