ALGEBRAIC ALGORITHMS FOR MATCHING AND MATROID PROBLEMS

NICHOLAS J. A. HARVEY†

Abstract. We present new algebraic approaches for two well-known combinatorial problems: nonbipartite matching and matroid intersection. Our work yields new randomized algorithms that exceed or match the efficiency of existing algorithms. For nonbipartite matching, we obtain a simple, purely algebraic algorithm with running time $O(n^\omega)$ where $n$ is the number of vertices and $\omega$ is the matrix multiplication exponent. This resolves the central open problem of Mucha and Sankowski (2004). For matroid intersection, our algorithm has running time $O(nr^{\omega-1})$ for matroids with $n$ elements and rank $r$ that satisfy some natural conditions.

Key words. nonbipartite matching, matroid intersection, algebraic algorithms, fast matrix multiplication

1. Introduction. The nonbipartite matching problem—finding a largest set of disjoint edges in a graph—is a fundamental problem that has played a pivotal role in the development of graph theory, combinatorial optimization, and computer science [50]. For example, Edmonds' seminal work on matchings [14, 15] inspired the definition of the class P and launched the field of polyhedral combinatorics. The matching theory book [38] gives an extensive treatment of this subject and uses matchings as a touchstone to develop much of the theory of combinatorial optimization.

The matroid intersection problem—finding a largest common independent set in two given matroids—is another fundamental optimization problem, originating in the pioneering work of Edmonds [17, 19]. This work led to significant developments concerning integral polyhedra [49], submodular functions [21], and convex analysis [44]. Algorithmically, matroid intersection is a powerful tool that has been used in various areas such as approximation algorithms [4, 31, 26], mixed matrix theory [43], and network coding [30].

1.1. Matching algorithms. The literature for nonbipartite matching algorithms is quite lengthy. Table 1 provides a brief summary; further discussion can be found in [49, section 24.4]. As one can see, there was little progress from 1975 until 2004, when an exciting development of Mucha and Sankowski [42] gave a randomized algorithm to construct a maximum matching in time $O(n^\omega)$, where $\omega < 2.38$ is the exponent indicating the time to multiply two $n \times n$ matrices [8]. A nice exposition of their algorithm is in Mucha's thesis [41].

Unfortunately, most of the algorithms mentioned above are quite complicated; the algorithms of Edmonds and Rabin–Vazirani are perhaps the only exceptions. For example, the Micali–Vazirani algorithm was not formally proven correct until much later [53]. The Mucha–Sankowski algorithm relies on a nontrivial structural decomposition

of graphs called the “canonical partition” and uses sophisticated dynamic connectivity data structures to maintain this decomposition online. Mucha writes [41, section 6]:

[The nonbipartite] algorithm is quite complicated and heavily relies on graph-theoretic results and techniques. It would be nice to have a strictly algebraic, and possibly simpler, matching algorithm for general graphs.

Interestingly, for the special case of bipartite graphs, Mucha and Sankowski give a simple algorithm that amounts to performing Gaussian elimination lazily. Unfortunately, this technique seems to break down for general graphs, leading to the conjecture that there is no \( O(n^\omega) \) matching algorithm for nonbipartite graphs that uses only lazy computation techniques [41, section 3.4].

1.2. Matroid intersection algorithms. The discussion of matroids in this section is necessarily informal since we defer the formal definition of matroids until section 4. Generally speaking, algorithms involving matroids fall into two classes.

- **Oracle algorithms.** These algorithms access the matroid via an oracle which answers queries about its structure.
- **Linear matroid algorithms.** These algorithms assume that a matroid is given as input to the algorithm as an explicit matrix which represents the matroid.

Linear matroid algorithms only apply to a subclass of matroids known as **linear matroids**, but most useful matroids indeed lie in this class.

Tables 2 and 3 provide a brief summary of the existing algorithms for matroid intersection. It should be noted that the Gabow–Xu algorithm achieves the running time of \( O(nr^{1.62}) \) by using the \( O(n^2.38) \) matrix multiplication algorithm of Coppersmith and Winograd [8]. However, this bound seems somewhat unnatural: for square matrices their running time is \( O(n^{2.62}) \), although one would hope for a running time of \( O(n^{2.38}) \).

1.3. Our results. In this paper, we present new algebraic approaches for the problems mentioned above.

\(^1\)Edmonds [16] gives an efficient algorithm for the matroid partition problem. As was shown in Edmonds [17, 18], this implies an efficient algorithm for the matroid intersection problem.

Nonbipartite matching. We present a purely algebraic, randomized algorithm for constructing a maximum matching in \(O(n^\omega)\) time. The algorithm is conceptually simple—it uses lazy updates and does not require sophisticated data structures or subroutines other than a black-box algorithm for matrix multiplication/inversion. Therefore our work resolves the central open question of Mucha and Sankowski [42] and refutes the conjecture [41] that no such lazy algorithm exists.

Our algorithm is based on a simple divide-and-conquer approach. The key insight is, adding an edge to the matching involves modifying two symmetric entries of a certain matrix. (See section 3 for further details.) These entries may be quite far apart in the matrix, so a lazy updating scheme that only updates “nearby” matrix entries will fail. We overcome this difficulty by traversing the matrix in a novel manner such that symmetric locations are nearby in our traversal, even if they are far apart in the matrix.

Matroid intersection. We present a linear matroid algorithm for the matroid intersection problem that uses only \(O(nr^{\omega-1})\) time. Whereas most existing matroid algorithms use augmenting path techniques, ours uses an algebraic approach. Several previous matroid algorithms also use algebraic techniques [2, 37, 45]. This approach requires that the given matroids are linear and additionally requires that the two matroids can be represented as matrices over the same field. These assumptions will be discussed further in section 4.

2. Preliminaries.

2.1. Notation. The set of integers \(\{1, \ldots, n\}\) is denoted by \([n]\). If \(J\) is a set, \(J + i\) denotes \(J \cup \{i\}\). The notation \(X \cup Y\) denotes the union of sets \(X\) and \(Y\) and asserts that this is a disjoint union, i.e., \(X \cap Y = \emptyset\).

If \(M\) is a matrix, a submatrix containing rows \(S\) and columns \(T\) is denoted \(M[S,T]\). A submatrix containing all rows (resp., columns) is denoted \(M[*,*]\) (resp., \(M[*,s]\)). A submatrix \(M[S,T]\) is sometimes written as \(M_{S,T}\) when this enhances legibility. The \(i\)th row (resp., column) of \(M\) is denoted \(M_{i,*}\) (resp., \(M_{*,i}\)). The entry of \(M\) in row \(i\) and column \(j\) is denoted \(M_{i,j}\).

2.2. Assumptions and conventions. We assume a randomized computational model, in which algorithms have access to a stream of independent, unbiased coin flips. All algorithms presented in this paper are randomized, even if this is not stated explicitly. Furthermore, our computational model assumes that arithmetic operations all require a single time step, even if we work with an extension field of the given field.
A Monte Carlo algorithm is an algorithm whose output may be incorrect with some (bounded) probability but whose running time is not a random variable. A Las Vegas algorithm is one whose output is always correct but whose running time is a random variable with bounded expectation.

The value $\omega$ is a real number defined as the infimum of all values $c$ such that multiplying two $n \times n$ matrices requires $O(n^c)$ time. We say that matrix multiplication requires $O(n^\omega)$ time although, strictly speaking, this is not accurate. Nevertheless, this inaccuracy justifies the following notational convention: we will implicitly ignore polylog($n$) factors in expressions of the form $O(n^\omega)$.

2.3. Facts from linear algebra. We will use the following basic facts from linear algebra. Some proofs can be found in Appendix A.1.

Let $F$ be a field, let $F[x_1, \ldots, x_m]$ be the ring of polynomials over $F$ in indeterminates $\{x_1, \ldots, x_m\}$, and let $F(x_1, \ldots, x_m)$ be the field of rational functions over $F$ in these indeterminates. A matrix with entries in $F[x_1, \ldots, x_m]$ or $F(x_1, \ldots, x_m)$ will be called a matrix of indeterminates. A matrix $M$ of indeterminates is said to be nonsingular if its determinant is not the zero function. In this case, $M^{-1}$ exists and it is a matrix whose entries are in $F(x_1, \ldots, x_m)$. The entries of $M^{-1}$ are given by

$$
(M^{-1})_{i,j} = (-1)^{i+j} \cdot \det M_{\text{del}(j,i)} / \det M,
$$

where $M_{\text{del}(j,i)}$ denotes the submatrix obtained by deleting row $j$ and column $i$. Given a matrix of indeterminates, our algorithms will typically substitute values in $F$ for the indeterminates. So for much of the discussion below, it suffices to consider ordinary numeric matrices over $F$.

The following useful fact is fundamental to many of our results.

**Fact 2.1 (Sherman–Morrison–Woodbury formula).** Let $M$ be an $n \times n$ matrix, $U$ be an $n \times k$ matrix, and $V$ be a $k \times n$ matrix. Suppose that $M$ is nonsingular. Then

- $M + UV^T$ is nonsingular iff $I + V^T M^{-1} U$ is nonsingular,
- if $M + UV^T$ is nonsingular, then

$$
(M + UV^T)^{-1} = M^{-1} - M^{-1} U (I + V^T M^{-1} U)^{-1} V^T M^{-1}.
$$

The subsequent sections will not use Fact 2.1 directly, but rather the following convenient corollary.

**Corollary 2.2.** Let $M$ be a nonsingular matrix and let $N$ be its inverse. Let $\tilde{M}$ be a matrix which is identical to $M$ except that $\tilde{M}_{S,S} \neq M_{S,S}$. Then $\tilde{M}$ is nonsingular iff

$$
\det (I + (\tilde{M}_{S,S} - M_{S,S}) \cdot N_{S,S}) \neq 0.
$$

If $\tilde{M}$ is nonsingular, then

$$
\tilde{M}^{-1} = N - N_{S,S} (I + (\tilde{M}_{S,S} - M_{S,S}) N_{S,S})^{-1} (\tilde{M}_{S,S} - M_{S,S}) N_{S,S}.
$$

**Fact 2.3 (Schur complement).** Let $M$ be a square matrix of the form

$$
M = S_1 \begin{pmatrix} S_2 & S \end{pmatrix} S_2^{-1} \begin{pmatrix} W & X \\ Y & Z \end{pmatrix}.
$$
where Z is square. If Z is nonsingular, the matrix $C := W - XZ^{-1}Y$ is known as the Schur complement of Z in $M$. The Schur complement satisfies many useful properties, two of which are the following:

- Let $C_{A,B}$ be a maximum rank square submatrix of $C$; i.e., $|A| = |B| = \text{rank} C$ and $C_{A,B}$ is nonsingular. Then $M_{A \cup S_2, B \cup S_2}$ is a maximum rank square submatrix of $M$.

A matrix $M$ is called skew-symmetric if $M = -M^T$. Note that the diagonal entries of a skew-symmetric matrix are necessarily zero.

**Fact 2.4.** Let $M$ be an $n \times n$ skew-symmetric matrix. If $M$ is nonsingular, then $M^{-1}$ is also skew-symmetric.

**Algorithms.** We conclude this section by considering the algorithmic efficiency of operations on matrices with entries in a field $\mathbb{F}$. As mentioned above, we assume that two $n \times n$ matrices can be multiplied in $O(n^\omega)$ time. This same time bound suffices for the following operations.

- **Determinant.** Given an $n \times n$ matrix $M$, compute $\det M$.
- **Rank.** Given an $n \times n$ matrix $M$, compute $\text{rank} M$.
- **Inversion.** Given a nonsingular $n \times n$ matrix $M$, compute $M^{-1}$.
- **Max-rank submatrix.** Given an $n \times n$ matrix $M$, compute sets $A$ and $B$ such that $M[A, B]$ is nonsingular and $|A| = |B| = \text{rank} M$.

Consider now the problem of rectangular matrix multiplication. For example, one could multiply an $r \times n$ matrix $A$ by an $n \times r$ matrix $B$, where $r < n$. This can be accomplished by partitioning $A$ and $B$ into blocks of size $r \times r$, multiplying the $i$th block of $A$ by the $i$th block of $B$ via an $O(r^\omega)$ time algorithm, then finally adding these results together. Since $\lceil n/r \rceil$ multiplications are performed, the total time required is $O(n^\omega)$.

This basic technique will frequently be used in the subsequent sections. More sophisticated rectangular matrix multiplication algorithms [7] do exist, but they will not be considered herein.

### 3. Nonbipartite matching

#### 3.1. Preliminaries

Let $G = (V, E)$ be a graph with $|V| = n$, and let $\mathcal{M}$ be the set of all perfect matchings of $G$. A lot of information about $\mathcal{M}$ is contained in the Tutte matrix $T$ of $G$. This is defined as follows. For each edge $\{u, v\} \in E$, associate an indeterminate $t_{\{u,v\}}$. Then $T$ is an $n \times n$ matrix where $T_{u,v}$ is $\pm t_{\{u,v\}}$ if $\{u, v\} \in E$ and 0 otherwise. The signs are chosen such that $T$ is skew-symmetric.

We now describe an important polynomial associated with the Tutte matrix. The Pfaffian of $T$ is defined as

$$\text{Pf}(T) := \sum_{\mu \in \mathcal{M}} \text{sgn}(\mu) \cdot \prod_{\{u,v\} \in \mathcal{M}} T_{u,v},$$

where $\text{sgn}(\mu) \in \{-1, 1\}$ is a sign whose precise definition is not needed for our purposes. Tutte showed many nice properties of $T$, one of which is the following fact.

**Fact 3.1.** (see Tutte [52]) $G$ has a perfect matching iff $T$ is nonsingular.

**Proof.** This follows from the (previously known) fact that $\det(T) = \text{Pf}(T)^2$. See, e.g., Godsil [25].

This is a useful characterization, but it does not directly imply an efficient algorithm to test if $G$ has a perfect matching. The issue is that $\text{Pf}(T)$ has a monomial
for every perfect matching of $G$, of which there may be exponentially many. In this case $\det T$ also has exponential size, and so computing it symbolically is inefficient.

Fortunately, Lovász [37] showed that the rank of $T$ is preserved with high probability after randomly substituting nonzero values from a sufficiently large field for the indeterminates. Let us argue the full-rank case more formally. Suppose that $G$ has a perfect matching. Then, over any field, $\det T$ is a nonzero polynomial of degree $n/2$. It follows that $\det T$ is a nonzero polynomial of degree $n$, again over any field. The Schwartz–Zippel lemma [40, Theorem 7.2] shows that if we evaluate this polynomial at a random point in $\mathbb{F}_q^{|E|}$ (i.e., pick each $t_{\{u,v\}} \in \mathbb{F}_q$ independently and uniformly), then the evaluation is zero with probability at most $n/q$. Therefore the rank is preserved with probability at least $1 - n/q$. If we choose $q \geq 2n$, the rank is preserved with probability at least $1/2$. We may obtain any desired failure probability $\lambda$ by performing $\log \lambda$ independent trials.

After this numeric substitution, the rank of the resulting matrix can be computed in $O(n^\omega)$ time. If the resulting matrix has full rank, then $G$ definitely has a perfect matching. Otherwise, we assume that $G$ does not have a perfect matching. This discussion shows that there is an efficient, randomized algorithm to test if a graph has a perfect matching (with failure probability at most $n/q$). The remainder of this section considers the problem of constructing a perfect matching, if one exists.

### 3.2. A self-reducibility algorithm

Since Lovász’s approach allows one to efficiently test if a graph has a perfect matching, one can use a self-reducibility argument to actually construct a perfect matching. Such an argument was explicitly stated by Rabin and Vazirani [47]. The algorithm deletes as many edges as possible subject to the constraint that the remaining graph has a perfect matching. Thus, at the termination of the algorithm, the remaining edges necessarily form a perfect matching.

The first step is to construct $T$, then to randomly substitute values for the indeterminates from a field of size $q$, where $q$ will be chosen below. If $T$ does not have full rank, then the algorithm halts and announces that the graph has no perfect matching. Otherwise, it examines the edges of the graph one by one. For each edge $\{r,s\}$, we temporarily delete it and test if the resulting graph still has a perfect matching. If so, we permanently delete the edge; if not, we restore the edge.

When temporarily deleting an edge, how do we test if the resulting graph has a perfect matching? This is done again by Lovász’s approach. We simply set $T_{r,s} = T_{s,r} = 0$, then test whether $T$ still has full rank. The Schwartz–Zippel lemma again shows that this test fails with probability at most $n/q$, even without choosing new random numbers.

Since there are fewer than $n^2$ edges, a union bound shows that the failure probability is less than $n^3/q$. If the random values are chosen from a field of size at least $n^3/\delta$, then the overall failure probability is at most $\delta$. The time for each rank computation is $O(n^\omega)$, so the total time required by this algorithm is $O(n^{\omega+2})$. As mentioned earlier, we may set $\delta = 1/2$ and obtain any desired failure probability $\lambda$ by performing $\log \lambda$ independent trials.

### 3.3. An algorithm using rank-2 updates

The self-reducibility algorithm can be improved to run in $O(n^4)$ time. To do so, we need an improved method to test if an edge can be deleted while maintaining the property that the graph has a perfect matching. This is done by applying Corollary 2.2 to the matching problem as follows.
Suppose that we have computed the inverse of the Tutte matrix \( N := T^{-1} \). Let \( \tilde{G} \) denote the graph where edge \( \{r, s\} \) has been deleted. We wish to decide if \( \tilde{G} \) still has a perfect matching. This can be decided (probabilistically) as follows. Let \( \tilde{T} \) be the matrix which is identical to \( T \) except that \( \tilde{T}_{S, S} = 0 \), where \( S = \{r, s\} \). We will test if \( \tilde{T} \) is nonsingular. By Corollary 2.2 and Fact 2.4, this holds iff the following determinant is nonzero:

\[
\det\left(\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \begin{pmatrix} 0 & T_{r,s} \\ -T_{r,s} & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & N_{r,s} \\ -N_{r,s} & 0 \end{pmatrix}\right) = \det\left(1 + T_{r,s} N_{r,s} \quad 1 + T_{r,s} N_{r,s}\right). 
\]

Thus \( \tilde{T} \) is nonsingular iff \((1 + T_{r,s} N_{r,s})^2 \neq 0\). So, to decide if edge \( \{r, s\} \) can be deleted, we simply test if \( N_{r,s} = -1/T_{r,s} \). The probability that this test fails (i.e., if \( \tilde{G} \) has a perfect matching but \( \tilde{T} \) is singular) is at most \( n/q \), again by the Schwartz–Zippel lemma.

After deleting an edge \( \{r, s\} \) the matrix \( N \) must be updated accordingly. By Corollary 2.2, we must set

\[
N := N + N_{s,S} \begin{pmatrix} 1 + T_{r,s} N_{r,s} \\ 1 + T_{r,s} N_{r,s} \end{pmatrix}^{-1} T_{S,S} N_{S,s}.
\]

This computation takes only \( O(n^2) \) time, since it is a rank-2 update.

The algorithm examines each edge, decides if it can be deleted, and, if so, performs the update described above. The main computational work of the algorithm is the updates. There are \( O(n^2) \) edges, so the total time required is \( O(n^3) \). As in section 3.2, if the random values are chosen from a field of size at least \( n^3/\delta \), then the overall failure probability is at most \( \delta \).

### 3.4. A recursive algorithm.

In this section, we describe an improvement of the previous algorithm which requires only \( O(n^2) \) time. The key idea is to examine the edges of the graph in a particular order, with the purpose of minimizing the cost of updating \( N \). The ordering is based on a recursive partitioning of the graph which arises from the following observation.

**Claim 3.2.** Let \( R \) and \( S \) be disjoint subsets of \( V \). Define the following subsets of edges:

\[
E[R] = \{ \{u, v\} : u, v \in R, \ and \ \{u, v\} \in E \}, \\
E[R, S] = \{ \{u, v\} : u \in R, v \in S, \ and \ \{u, v\} \in E \}.
\]

Suppose that \( R = R_1 \cup R_2 \) and \( S = S_1 \cup S_2 \). Then

\[
E[S] = E[S_1] \cup E[S_2] \cup E[S_1, S_2], \\
E[R, S] = E[R_1, S_1] \cup E[R_1, S_2] \cup E[R_2, S_1] \cup E[R_2, S_2].
\]

The pseudocode in Algorithm 1 examines all edges of the graph by employing the recursive partitioning of Claim 3.2. At each base of the recursion, the algorithm examines a single edge \( \{r, s\} \) and decides if it can be deleted, via the same approach as the previous section: by testing if \( N_{r,s} = -1/T_{r,s} \). As long as we can ensure that \( N_{r,s} = (T^{-1})_{r,s} \) in each base of the recursion then the algorithm is correct: the matrix \( T \) remains nonsingular throughout the algorithm and, at the end, \( N \) has exactly one nonzero entry per row and column (with failure probability \( n^3/\delta \)).

Algorithm 1 ensures that \( N_{r,s} = (T^{-1})_{r,s} \) in each base case by updating \( N \) whenever an edge is deleted. However, the algorithm does not update \( N \) all at once, as (3.1) indicates one should do. Instead, it only updates portions of \( N \) that are needed to satisfy the following two invariants.

\[\text{Corollary 2.2, we must set}\]

\[N := N + N_{s,S} \begin{pmatrix} 1 + T_{r,s} N_{r,s} \\ 1 + T_{r,s} N_{r,s} \end{pmatrix}^{-1} T_{S,S} N_{S,s}.
\]
Algorithm 1. \texttt{FindPerfectMatching} constructs a perfect matching of the graph \( G \). The probability of failure is at most \( \delta \) if the field \( \mathbb{F} \) has cardinality at least \( |V|^3/\delta \). \texttt{DeleteEdgesWithin} deletes any edge \( \{r,s\} \) with both \( r,s \in S \), subject to the constraint that the graph still has a perfect matching. \texttt{DeleteEdgesCrossing} deletes any edge \( \{r,s\} \) with \( r \in R \) and \( s \in S \), subject to the constraint that the graph still has a perfect matching. Updating \( N \) requires \( O(|S|^\omega) \) time; details are given below.

\begin{verbatim}
\textbf{FindPerfectMatching}(G = (V,E))
\hspace{1em} Let \( T \) be the Tutte matrix for \( G \)
\hspace{1em} Replace the variables in \( T \) with random values from field \( \mathbb{F} \)
\hspace{1em} If \( T \) is singular, return "no perfect matching"
\hspace{1em} Compute \( N := T^{-1} \)
\hspace{2em} \textbf{DeleteEdgesWithin}(V)
\hspace{2em} Return the set of remaining edges

\textbf{DeleteEdgesWithin}(S)
\hspace{2em} If \( |S| = 1 \) then return
\hspace{2em} Divide \( S \) in half: \( S = S_1 \cup S_2 \)
\hspace{2em} For \( i \in \{1,2\} \)
\hspace{3em} \textbf{DeleteEdgesWithin}(S_i)
\hspace{3em} Update \( N[S,S] \)
\hspace{2em} \textbf{DeleteEdgesCrossing}(S_1, S_2)

\textbf{DeleteEdgesCrossing}(R, S)
\hspace{2em} If \( |R| = 1 \) then
\hspace{3em} Let \( r \in R \) and \( s \in S \)
\hspace{3em} If \( T_{r,s} \neq 0 \) and \( N_{r,s} \neq -1/T_{r,s} \) then
\hspace{4em} \( \triangleright \) Edge \( \{r,s\} \) can be deleted
\hspace{4em} Set \( T_{r,s} = T_{s,r} = 0 \)
\hspace{4em} Update \( N[R \cup S, R \cup S] \)
\hspace{2em} Else
\hspace{3em} Divide \( R \) and \( S \) each in half: \( R = R_1 \cup R_2 \) and \( S = S_1 \cup S_2 \)
\hspace{3em} For \( i \in \{1,2\} \) and for \( j \in \{1,2\} \)
\hspace{4em} \textbf{DeleteEdgesCrossing}(R_i, S_j)
\hspace{4em} Update \( N[R \cup S, R \cup S] \)
\end{verbatim}

1. \texttt{DeleteEdgesWithin}(S) initially has \( N[S,S] = T^{-1}[S,S] \). It restores this property after each recursive call to \texttt{DeleteEdgesWithin}(S_i) and after calling \texttt{DeleteEdgesCrossing}(S_1, S_2).
2. \texttt{DeleteEdgesCrossing}(R, S) initially has \( N[R \cup S, R \cup S] = T^{-1}[R \cup S, R \cup S] \).
   It restores this property after deleting an edge, and after each recursive call to \texttt{DeleteEdgesCrossing}(R_i, S_j).

To explain why invariant 1 holds, consider executing \texttt{DeleteEdgesWithin}(S). We must consider what happens whenever the Tutte matrix is changed, i.e., whenever an edge is deleted. This can happen when calling \texttt{DeleteEdgesWithin}(S_i) or \texttt{DeleteEdgesCrossing}(S_1, S_2).

First, suppose the algorithm has just recursed on \texttt{DeleteEdgesWithin}(S_1). Let \( T \) denote the Tutte matrix before the recursion and let \( \tilde{T} \) denote the Tutte matrix after the recursion (i.e., incorporating any edge deletions that occurred during the recursion). Note that \( T \) and \( \tilde{T} \) differ only in that \( \Delta := \tilde{T}[S_1,S_1] - T[S_1,S_1] \) may be nonzero. Since the algorithm ensures that the Tutte matrix is always nonsingular,
Corollary 2.2 shows that
\[ \hat{T}^{-1} = T^{-1} - (T^{-1})_{s,S_1} \cdot (I + \Delta \cdot (T^{-1})_{s_1,S_1})^{-1} \cdot \Delta \cdot (T^{-1})_{s_1,s}. \]

Restricting to the set \( S \), we have
\[ (\hat{T}^{-1})_{s,S} = (T^{-1})_{s,S} - (T^{-1})_{s,S_1} \cdot (I + \Delta \cdot (T^{-1})_{s_1,S_1})^{-1} \cdot \Delta \cdot (T^{-1})_{s_1,S}. \]

Let \( N \) refer to that matrix’s value before the recursion. To restore invariant 1, we must compute the following new value for \( N[S,S] \):
\[ N_{s,S} = N_{s,S_1} \cdot (I + \Delta \cdot N_{s_1,S_1})^{-1} \cdot \Delta \cdot N_{s_1,S}. \]

The matrix multiplications and inversions in this computation all involve matrices of size at most \(|S| \times |S|\), so \( O(|S|^2) \) time suffices.

Next, suppose that the algorithm has just called \( \text{DELETEEDGESCROSSING}(S_1, S_2) \) at the end of \( \text{DELETEEDGESWITHIN}(S) \). Invariant 2 ensures that
\[ N[S,S] = N[S_1 \cup S_2, S_1 \cup S_2] = T^{-1}[S_1 \cup S_2, S_1 \cup S_2] = T^{-1}[S,S] \]
at the end of \( \text{DELETEEDGESCROSSING}(S_1, S_2) \), and thus invariant 1 holds at the end of \( \text{DELETEEDGESWITHIN}(S) \).

Similar arguments show how to compute updates such that invariant 2 holds. After deleting an edge \( \{r,s\} \), it suffices to perform the following update:
\[ N_{r,s} := N_{r,s} \cdot (1 - T_{r,s} N_{r,s})/(1 + T_{r,s} N_{r,s}), \]
\[ N_{s,r} := -N_{r,s}. \]

After recursively calling \( \text{DELETEEDGESCROSSING}(R_i, S_j) \), we perform an update as follows. Let \( T \) denote the Tutte matrix before the recursion, let \( \hat{T} \) denote the Tutte matrix after the recursion, and let \( \Delta := (\hat{T} - T)_{R_i \cup S_j, R_i \cup S_j} \). Then we set
\[ N_{R_i \cup S_j, R_i \cup S_j} = N_{R_i \cup S_j, R_i \cup S_j} \cdot \Delta \cdot N_{R_i \cup S_j, R_i \cup S_j}. \]

This shows that the algorithm satisfies the stated invariants.

**Analysis.** Let \( f(n) \) and \( g(n) \), respectively, denote the running time of the functions \( \text{DELETEEDGESWITHIN}(S) \) and \( \text{DELETEEDGESCROSSING}(R,S) \), where \( n = |R| = |S| \). As argued above, updating \( N \) requires only \( O(|S|^2) \) time, so we have
\[ f(n) = 2 \cdot f(n/2) + g(n) + O(n^2), \]
\[ g(n) = 4 \cdot g(n/2) + O(n^2). \]

By a standard analysis of divide-and-conquer recurrence relations [9], the solutions of these recurrences are \( g(n) = O(n^2) \) and \( f(n) = O(n^2) \).

As argued in section 3.3, each test to decide whether an edge can be deleted fails with probability at most \( n/q \), and therefore the overall failure probability is at most \( n^2/q \). Therefore setting \( q \geq n^3/\delta \) ensures that the algorithm fails with probability at most \( \delta \).
3.5. Extensions.

**Maximum matching.** Algorithm 1 is a Monte Carlo algorithm for finding a perfect matching in a nonbipartite graph. If the graph does not have a perfect matching, then $T$ is singular and the algorithm reports a failure. An alternative solution would be to find a maximum cardinality matching. This can be done by existing techniques [47, 41], without increasing the asymptotic running time. Let $T_{R,S}$ be a maximum rank square submatrix of $T$; i.e., $|R| = |S| = \text{rank} T$ and $T_{R,S}$ is nonsingular. Since $T$ is skew-symmetric, it follows that $T_{S,S}$ is also nonsingular [47, p. 560]. Furthermore, a perfect matching for the subgraph induced by $S$ gives a maximum cardinality matching in $G$.

This suggests the following algorithm. Randomly substitute values for the indeterminates in $T$ from $F_q$. The submatrix $T_{R,S}$ remains nonsingular with probability at least $n/q$. Find a maximum rank submatrix of $T$; without loss of generality, it is $T_{R,S}$. This can be done in $O(n^\omega)$ time. Now apply Algorithm 1 to obtain a matching containing all vertices in $S$. This matching is a maximum cardinality matching of the original graph.

**Las Vegas.** The algorithms presented above are Monte Carlo. They can be made Las Vegas by constructing an optimum dual solution—the Edmonds–Gallai decomposition [49, p. 423]. Karloff [33] showed that this can be done by algebraic techniques, and Cheriyan [5] gave a randomized algorithm using only $O(n^\omega)$ time. If the dual solution agrees with the constructed matching, then this certifies that the matching indeed has maximum cardinality. We may choose the field size $q$ so that both the primal algorithm and dual algorithm succeed with constant probability. Thus, the expected number of trials before this occurs is a constant, and hence the algorithm requires $O(n^\omega)$ time in expectation.

4. Matroid intersection. This section is organized as follows. First, in section 4.1, we define matroids and some relevant terminology. Section 4.2 gives an overview of our algorithmic approach. Section 4.3 fills in some details by introducing some tools from linear algebra. Section 4.4 shows how these tools can be used to give an efficient algorithm for matroids of large rank. That algorithm is then used as a subroutine in the algorithm of section 4.5, which requires only $O(nr^{\omega-1})$ time for matroids on $n$ elements with rank $r$. Some proofs can be found in the appendix.

4.1. Definitions. Matroids were first introduced by Whitney [55] and others in the 1930s. Many excellent texts contain an introduction to the subject [6, 36, 43, 46, 49, 54]. We review some of the important definitions and facts below.

A **matroid** is a combinatorial object defined on a finite ground set $S$. The cardinality of $S$ is typically denoted by $n$. There are several important ancillary objects related to matroids, any one of which can be used to define them. Below we list those objects that play a role in this paper, and we use “base families” as the central definition.

**Base family.** This nonempty family $\mathcal{B} \subseteq 2^S$ satisfies the axiom:

Let $B_1, B_2 \in \mathcal{B}$. For each $x \in B_1 \setminus B_2$, there exists $y \in B_2 \setminus B_1$ such that $B_1 - x + y \in \mathcal{B}$.

A matroid can be defined as a pair $M = (S, \mathcal{B})$, where $\mathcal{B}$ is a base family over $S$. A member of $\mathcal{B}$ is called a base. It follows from the axiom above that all bases are equicardinal. This cardinality is called the **rank of the matroid** $M$, typically denoted by $r$. 
Independent set family. This family \( I \subseteq 2^S \) is defined as
\[
I = \{ I : I \subseteq B \text{ for some } B \in \mathcal{B} \}.
\]
A member of \( I \) is called an independent set. Any subset of an independent set is clearly also independent, and a maximum-cardinality independent set is clearly a base. The independent set family can also be characterized as a nonempty family \( I \subseteq 2^S \) satisfying
\[
\begin{align*}
&\bullet \ A \subseteq B \text{ and } B \in I \implies A \in I; \\
&\bullet \ A \in I \text{ and } B \in I \text{ and } |A| < |B| \implies \exists b \in B \setminus A \text{ such that } A + b \in I.
\end{align*}
\]
Rank function. This function, \( r : 2^S \to \mathbb{N} \), is defined as
\[
r(T) = \max_{I \in \mathcal{I}, I \subseteq T} |I| \quad \forall T \subseteq S.
\]

A maximizer of this expression is called a base for \( T \) in \( \mathcal{M} \). A set \( I \) is independent iff \( r(I) = |I| \).

Since all of the objects listed above can be used to characterize matroids, we sometimes write \( \mathcal{M} = (S, \mathcal{I}) \), or \( \mathcal{M} = (S, \mathcal{I}, \mathcal{B}) \), etc. To emphasize the matroid associated with one of these objects, we often write \( \mathcal{B}_\mathcal{M} \), \( r_\mathcal{M} \), etc.

A linear representation over \( \mathbb{F} \) of a matroid \( \mathcal{M} = (S, \mathcal{I}) \) is a matrix \( Q \) over \( \mathbb{F} \) with columns indexed by \( S \), satisfying the condition that \( Q[*] \) has full column-rank iff \( I \in \mathcal{I} \). There do exist matroids which do not have a linear representation over any field. However, many interesting matroids can be represented over some field; such matroids are called linear matroids.

One important operation on matroids is contraction. Let \( \mathcal{M} = (S, \mathcal{B}) \) be a matroid. Given a set \( T \subseteq S \), the contraction of \( \mathcal{M} \) by \( T \), denoted by \( \mathcal{M}/T \), is defined as follows. Its ground set is \( S \setminus T \). Next, fix a base \( B_T \) for \( T \) in \( \mathcal{M} \); i.e., \( B_T \subseteq T \) and \( r_\mathcal{M}(B_T) = r_\mathcal{M}(T) \). The independent sets of \( \mathcal{M}/T \) are, for any \( I \subseteq S \setminus T \),
\[
I \in \mathcal{I}_{\mathcal{M}/T} \iff I \cup B_T \in \mathcal{I}_\mathcal{M}.
\]

One may easily see that the base family of \( \mathcal{M}/T \) is
\[
\mathcal{B}_{\mathcal{M}/T} = \{ B \subseteq S \setminus T : B \cup B_T \in \mathcal{B}_\mathcal{M} \}.
\]
The rank function of \( \mathcal{M}/T \) satisfies
\[
(4.1) \quad r_{\mathcal{M}/T}(X) = r_\mathcal{M}(X \cup T) - r_\mathcal{M}(T).
\]

The following fact is well known. A proof is given in Appendix A.2.

Fact 4.1. Let \( Q \) be a linear representation of a matroid \( \mathcal{M} = (S, \mathcal{B}) \). Let \( T \subseteq S \) be arbitrary, and let \( Q[A, B] \) be a maximum-rank square submatrix of \( Q[*] \). Then
\[
Q[\overline{A}, T] = Q[\overline{A}, B] \cdot Q[A, B]^{-1} \cdot Q[A, T]
\]
is a linear representation of \( \mathcal{M}/T \).

Matroid intersection. Suppose two matroids \( \mathcal{M}_1 = (S, \mathcal{B}_1) \) and \( \mathcal{M}_2 = (S, \mathcal{B}_2) \) are given. A set \( B \subseteq S \) is called a common base if \( B \in \mathcal{B}_1 \cap \mathcal{B}_2 \). A common independent set (or an intersection) is a set \( I \in \mathcal{I}_1 \cap \mathcal{I}_2 \). The matroid intersection problem is to construct a common base of \( \mathcal{M}_1 \) and \( \mathcal{M}_2 \). The decision version of the problem is to decide whether a common base exists. The optimization version of the problem
is to construct an intersection of $\mathbf{M}_1$ and $\mathbf{M}_2$ with maximum cardinality. Edmonds [17] proved the following important min-max relation which gives a succinct certificate of correctness for the matroid intersection problem.

**Fact 4.2 (matroid intersection theorem).** Let $\mathbf{M}_1 = (S, \mathcal{I}_1, r_1)$ and $\mathbf{M}_2 = (S, \mathcal{I}_2, r_2)$ be given. Then

$$\max_{I \in \mathcal{I}_1 \cap \mathcal{I}_2} |I| = \min_{A \subseteq S} \left( r_1(A) + r_2(S \setminus A) \right).$$

**Assumptions.** In general, specifying a matroid requires space that is exponential in the size of the ground set; see [34] and [54, section 16.6]. In this case, many matroid problems trivially have an algorithm whose running time is polynomial in the input length. This observation motivates the use of the oracle model for matroid algorithms. However, most of the matroids arising in practice actually can be stored in space that is polynomial in the size of the ground set. The broadest such class is the class of linear matroids, mentioned above.

The algebraic approach used in this paper works only for linear matroids, as do some existing algorithms [2, 3, 37, 45]. One additional assumption is needed, as in this previous work. We assume that the given pair of matroids are represented as matrices over the same field. Although there exist matroids for which this assumption cannot be satisfied (e.g., the Fano and non-Fano matroids), this assumption is valid for the vast majority of matroids arising in applications. For example, the regular matroids are those that are representable over all fields; this class includes the graphic, cographic, and partition matroids. Many classes of matroids are representable over all but finitely many fields; these include the uniform, matching, and transversal matroids, as well as deltoids and gammoids [49]. Our results apply to any two matroids from the union of these classes.

4.2. Overview of algorithms. We now give a high-level overview of the algorithms. First, some notation and terminology are needed. Let $\mathbf{M}_1 = (S, \mathcal{B}_1)$ and $\mathbf{M}_2 = (S, \mathcal{B}_2)$. Our algorithms will typically assume that $\mathbf{M}_1$ and $\mathbf{M}_2$ have a common base; the goal is to construct one. Any subset of a common base is called an extensible set. If $J$ is extensible, $i \in S \setminus J$, and $J + i$ is also extensible, then $i$ is called allowed (relative to $J$).

The general idea of our algorithm is to build a common base incrementally. For example, suppose that $\{b_1, \ldots, b_r\}$ is an arbitrary common base. Then

- $\emptyset$ is extensible,
- $b_1$ is allowed relative to $\emptyset$,
- $b_2$ is allowed relative to $\{b_1\}$,
- $b_3$ is allowed relative to $\{b_1, b_2\}$, etc.

So building a common base is straightforward, so long as we can test whether an element is allowed, relative to the current set $J$. This strategy is illustrated in Algorithm 2. The following section provides linear algebraic tools that we will later use to test whether an element is allowed.

4.3. Formulation using linear algebra. Suppose that each $\mathbf{M}_i = (S, \mathcal{B}_i)$ is a linear matroid representable over a common field $\mathbb{F}$. Let $r_i : S \rightarrow \mathbb{N}$ be the rank function of $\mathbf{M}_i$. Let $Q_1$ be an $r \times n$ matrix whose columns represent $\mathbf{M}_1$ over $\mathbb{F}$ and let $Q_2$ be an $n \times r$ matrix whose rows represent $\mathbf{M}_2$ over $\mathbb{F}$.
Algorithm 2. A general overview of our algorithm for constructing a common base of two matroids $M_1$ and $M_2$.

\textbf{MatroidIntersection($M_1$, $M_2$)}

Set $J = \emptyset$

For each $i \in S$, do

\textit{Invariant:} $J$ is extensible

Test if $i$ is allowed (relative to $J$)

If so, set $J := J + i$

For each $J \subseteq S$, we define a diagonal matrix $T(J)$ as

$$T(J)_{i,i} := \begin{cases} 0 & \text{if } i \in J, \\ t_i & \text{if } i \notin J, \end{cases}$$

where each $t_i$ is an indeterminate. Next, define the matrix

$$Z(J) := \begin{pmatrix} Q_1 \\ Q_2 T(J) \end{pmatrix}.$$  \hfill (4.3)

For simplicity, we will let $T = T(\emptyset)$ and $Z = Z(\emptyset)$. Let $\lambda(J)$ denote the maximum cardinality of an intersection in the contracted matroids $M_1/J$ and $M_2/J$, which were defined in section 4.1.

\textbf{Theorem 4.3.} For any $J \subseteq S$, we have $\rank(Z(J)) = n + r_1(J) + r_2(J) - |J| + \lambda(J)$.

\textit{Proof.} See Appendix A.3. \hfill \Box

For the special case $J = \emptyset$, this result was stated by Geelen [24] and follows from the connection between matroid intersection and the Cauchy–Binet formula, as noted by Tomizawa and Iri [51]. See also Murota [43, Remark 2.3.37]. Building on Theorem 4.3, we obtain the following result which forms the foundation of our algorithms. Let us now assume that both $M_1$ and $M_2$ have rank $r$. That is, $r = r_1(S) = r_2(S)$.

\textbf{Theorem 4.4.} Suppose that $\lambda(\emptyset) = r$, i.e., $M_1$ and $M_2$ have a common base. For any $J \subseteq S$ (not necessarily an intersection), $Z(J)$ is nonsingular iff $J$ is an intersection and is extensible.

\textit{Proof.} See Appendix A.4. \hfill \Box

The preceding theorems lead to the following lemma which characterizes allowed elements. Here, we identify the elements of $S$ with the rows and columns of the submatrix $T(J)$ in $Z(J)$.

\textbf{Lemma 4.5.} Suppose that $J \subseteq S$ is an extensible set and that $i \in S \setminus J$. The element $i$ is allowed iff $(Z(J)^{-1})_{i,i} \neq t_i^{-1}$.

\textit{Proof.} By Theorem 4.4, our hypotheses imply that $Z(J)$ is nonsingular. Then element $i$ is allowed iff $Z(J + i)$ is nonsingular, again by Theorem 4.4. Note that $Z(J + i)$ is identical to $Z(J)$ except that $Z(J + i)_{i,i} = 0$. Corollary 2.2 implies that $Z(J + i)$ is nonsingular iff

$$\det \left( 1 - Z(J)_{i,i} \cdot (Z(J)^{-1})_{i,i} \right) \neq 0.$$  

Definition (4.3) shows that $Z(J)_{i,i} = t_i$, so the proof is complete. \hfill \Box
The structure of the matrix \( Z \) will play a key role in our algorithms below. Let \( Y \) denote the Schur complement of \( T \) in \( Z \), i.e., \( Y = -Q_1 \cdot T^{-1} \cdot Q_2 \). One may verify (by multiplying with \( Z \)) that

\[
Z^{-1} = \begin{pmatrix}
Y^{-1} & -Y^{-1} \cdot Q_1 \cdot T^{-1} \\
-T^{-1} \cdot Q_2 \cdot Y^{-1} & T^{-1} + T^{-1} \cdot Q_2 \cdot Y^{-1} \cdot Q_1 \cdot T^{-1}
\end{pmatrix}.
\]

Our algorithms cannot directly work with the matrix \( Z(J) \) since its entries contain indeterminates. A similar issue was encountered in section 3: for example, \( \det Z \) is a polynomial which may have exponential size. This issue is again resolved through randomization. Suppose that \( Z(J) \) is nonsingular over \( \mathbb{F} \), i.e., \( \det Z(J) \) is a nonzero polynomial with coefficients in \( \mathbb{F} \). Suppose that \( \mathbb{F} = \mathbb{F}_{p^c} \) is finite and let \( c' \geq c \). Evaluate \( \det Z(J) \) at a random point over the extension field \( \mathbb{F}_{p^{c'}} \) by picking each \( t_i \in \mathbb{F}_{p^{c'}} \) uniformly at random. This evaluation is zero with probability at most \( n/q \), where \( q = p^c \), as shown by the Schwartz–Zippel lemma [40]. This probability can be made arbitrarily small by choosing \( q \) as large as desired. If \( \mathbb{F} \) is infinite, then we simply need to choose each \( t_i \) uniformly at random from a subset of \( \mathbb{F} \) of size \( q \).

4.4. An algorithm for matroids of large rank. This section presents an algorithm which behaves as follows. It is given two matrices \( Q_1 \) and \( Q_2 \) over \( \mathbb{F} \) representing matroids \( M_1 \) and \( M_2 \), as in the previous section. The algorithm will decide whether the two matroids have a common base and, if so, construct one. The algorithm requires time \( O(n^5) \) and is intended for the case \( r = \Theta(n) \).

The algorithm maintains an extensible set \( J \), initially empty, and it computes \( Z(J)^{-1} \) to help decide which elements are allowed. As elements are added to \( J \), the matrix \( Z(J)^{-1} \) must be updated accordingly. A recursive scheme is used to do this, as in the matching algorithm of section 3. Pseudocode is shown in Algorithm 3.

First let us argue the correctness of the algorithm. The base cases of the algorithm examine each element of the ground set in increasing order. For each element \( i \), the algorithm decides whether \( i \) is allowed relative to \( J \) using Lemma 4.5: if so, \( i \) is added to \( J \). Thus the behavior of Algorithm 3 is identical to Algorithm 2, and its correctness follows.

The algorithm decides whether \( i \) is allowed by testing whether \( (Z(J)^{-1})_{i,i} \neq t_i \). (Note that invariant 2 ensures that \( N_{i,i} = (Z(J)^{-1})_{i,i} \)) Lemma 4.5 shows that this test is correct when the \( t_i \)'s are indeterminates. When the \( t_i \)'s are random numbers, the probability that this test fails (i.e., \( i \) is allowed but \( (Z(J)^{-1})_{i,i} = t_i \)) is at most \( n/q \), again by the Schwartz–Zippel lemma. By a union bound over all elements, the probability of failure is at most \( \delta \) so long as \( q \geq n^2/\delta \).

We now complete the description of the algorithm by explaining how to compute the matrix \( M = (Z(J \cup J_1)^{-1})_{S_2,S_2} \) during the recursive step. First, note that \( N_{S_2,S_2} = (Z(J)^{-1})_{S_2,S_2} \). Next, note that \( Z(J \cup J_1) \) is identical to \( Z(J) \) except that \( Z(J \cup J_1)_{J_1,J_1} = 0 \). It follows from Corollary 2.2 that

\[
Z(J \cup J_1)^{-1} = Z(J)^{-1} + (Z(J)^{-1})_{S,J_1} (I - Z(J)_{J_1,J_1} (Z(J)^{-1})_{J_1,J_1})^{-1} Z(J)_{J_1,J_1} (Z(J)^{-1})_{J_1,J_1}.
\]

Thus

\[
(Z(J \cup J_1)^{-1})_{S_2,S_2} = N_{S_2,S_2} + N_{S_2,J_1} (I - Z_{J_1,J_1} N_{J_1,J_1})^{-1} Z_{J_1,J_1} N_{J_1,S_2}.
\]

The matrix \( M \) is computed according to this equation, which requires time at most \( O(|S|^5) \) since all matrices have size at most \( |S| \times |S| \).
Algorithm 3. *A recursive algorithm to compute a common base of two matroids $M_1 = (S, E_1)$ and $M_2 = (S, E_2)$, where $n = |S|$ and the rank $r = \Theta(n)$.*

**MATROIDINTERSECTION($M_1, M_2$)**

Let $S = \{1, \ldots, n\}$ be the ground set of $M_1$ and $M_2$.
Construct $Z$ and assign random values to the indeterminates $t_1, \ldots, t_n$.
Compute $N := (Z^{-1})_{S,S}$.
$J = \text{BUILDINTERSECTION}(S, \emptyset, N)$
Return $J$.

**BUILDINTERSECTION($S = \{a, \ldots, b\}$, $J$, $N$)**

*Invariant 1:* $J$ is an extensible set.

*Invariant 2:* $N = (Z(J)^{-1})_{S,S}$

If $|S| \geq 2$ then
  Partition $S$ into $S_1 = \{a, \ldots, \lfloor \frac{a+b}{2} \rfloor \}$ and $S_2 = \{\lfloor \frac{a+b}{2} \rfloor + 1, \ldots, b\}$
  $J_1 = \text{BUILDINTERSECTION}(S_1, J, N_{S_1,S_1})$
  Compute $M := (Z(J \cup J_1)^{-1})_{S_2,S_2}$, as described below
  $J_2 = \text{BUILDINTERSECTION}(S_2, J \cup J_1, M)$
  Return $J_1 \cup J_2$
Else
  This is a base case: $S$ consists of a single element $i = a = b$
  If $N_{i,i} \neq t_i^{-1}$ (i.e., element $i$ is allowed) then
    Return $\{i\}$
  Else
    Return $\emptyset$

We now argue that this algorithm requires $O(n^\omega)$ time. The work is dominated by the matrix computations. Computing the initial matrix $Z^{-1}$ clearly takes $O(n^\omega)$ time since $Z$ has size $(n+r) \times (n+r)$. As shown above, computing $M$ requires time $O(|S|^\omega)$. Thus the running time of BUILDINTERSECTION is given by the recurrence

$$f(n) = 2 \cdot f(n/2) + O(n^\omega),$$

which has solution $f(n) = O(n^\omega)$.

4.5. **An algorithm for matroids of any rank.** This section builds upon the algorithm of the previous section and obtains an algorithm with improved running time when $r = o(n)$. The high-level idea is as follows: partition the ground set $S$ into parts of size $r$, then execute the BUILDINTERSECTION subroutine from Algorithm 3 on each of those parts. For each part, executing BUILDINTERSECTION requires $O(r^\omega)$ time. Since there are $n/r$ parts, the total time required is $O(nr^{\omega-1})$. More detailed pseudocode is given in Algorithm 4.

Algorithm 4 is correct for the same reasons that Algorithm 3 is: each element $i$ is examined exactly once, and the algorithm decides if $i$ is allowed relative to the current set $J$. Indeed, all decisions made by Algorithm 4 are performed in the BUILDINTERSECTION subroutine, which was analyzed in the previous section. Correctness follows immediately, and again the failure probability is $\delta$ so long as $q \geq n^2/\delta$.

Let us now analyze the time required by Algorithm 4. First, let us consider the matrix $Y$, which is computed in order to later compute the matrix $N$. Since $T$ is diagonal, $Q_1 T^{-1}$ can be computed in $O(nr)$ time. Since $Q_1 T^{-1}$ has size $r \times n$ and $Q_2$ has size $n \times r$, their product can be computed in time $O(nr^{\omega-1})$.

Now let us consider the time for each loop iteration. Each call to the function
Algorithm 4. The algorithm to compute a common base of two matroids $M_1 = (S, B_1)$ and $M_2 = (S, B_2)$.

MATROIDINTERSECTION($M_1, M_2$)
- Construct $Z$ and assign random values to the indeterminates $t_1, \ldots, t_n$
- Compute $Y := -Q_1T^{-1}Q_2$ (used below for computing $N$)
- Partition $S = S_1 \cup \cdots \cup S_{n/r}$, where $|S_i| = r$
- Set $J := \emptyset$
- For $i = 1$ to $n/r$ do
  - Compute $N := (Z(J)^{-1})_{S_i, S_i}$
  - $J' = \text{BUILDINTERSECTION}(S_i, J, N)$
- Set $J := J \cup J'$
- Return $J$

BUILDINTERSECTION requires $O(r^\omega)$ time, as argued in the previous section. The following claim shows that computing the matrix $N$ also requires $O(r^\omega)$ time. Thus, the total time required by all loop iterations is $(n/r) \cdot O(r^\omega) = O(nr^\omega - 1)$. Thus Algorithm 4 requires $O(nr^\omega - 1)$ time in total.

**Claim 4.6.** In each loop iteration, the matrix $N$ can be computed in $O(r^\omega)$ time.

To prove this, we need another claim.

**Claim 4.7.** Suppose that the matrix $Y$ has already been computed. For any $A, B \subseteq S$ with $|A| \leq r$ and $|B| \leq r$, the submatrix $(Z^{-1})_{A,B}$ can be computed in $O(r^\omega)$ time.

**Proof.** As shown in (4.4), we have

$$(Z^{-1})_{S_i, S_i} = T^{-1} - T^{-1}Q_2Y^{-1}Q_1T^{-1}.$$ 

Thus,

$$(Z^{-1})_{A,B} = T^{-1}_{A,B} + (T^{-1}Q_2)_{A,*}(Y^{-1})_{*,B}(Q_1T^{-1})_{*,B}.$$ 

The submatrices $(T^{-1}Q_2)_{A,*}$ and $(Q_1T^{-1})_{*,B}$ can be computed in $O(r^2)$ time since $T$ is diagonal. The remaining matrices have size at most $r \times r$, so all computations require at most $O(r^\omega)$ time. 

**Proof of Claim 4.6.** Note that $Z(J)$ is identical to $Z$ except that $Z(J)_{J,J} = 0$. It follows from Corollary 2.2 that

$$Z(J)^{-1} = Z^{-1} + (Z^{-1})_{*,J}(I-Z_{J,J}(Z^{-1})_{J,J})^{-1}Z_{J,J}(Z^{-1})_{*,J}.$$ 

Thus,

$$Z(J)^{-1}_{S_i, S_i} = (Z^{-1})_{S_i, S_i} + (Z^{-1})_{S_i, J}(I-Z_{J,J}(Z^{-1})_{J,J})^{-1}Z_{J,J}(Z^{-1})_{J,S_i}.$$ 

By Claim 4.7, the submatrices $(Z^{-1})_{S_i, S_i}, (Z^{-1})_{S_i, J}, (Z^{-1})_{J,J}$, and $(Z^{-1})_{J,S_i}$ can all be computed in $O(r^\omega)$ time. Thus the matrix $N = (Z(J)^{-1})_{S_i, S_i}$ can be computed in $O(r^\omega)$ time, as shown in (4.5).
4.6. Extensions.

4.6.1. Maximum cardinality intersection. The algorithms presented in the previous sections construct a common base of the two given matroids, if one exists. If the matroids do not have a common base, then the matrix $Z$ is singular and the algorithm reports a failure. An alternative solution would be to find a maximum cardinality intersection rather than a common base. Algorithm 4 can be adapted for this purpose, while retaining the running time of $O(nr^{\omega-1})$. We will use the same approach used in section 3 to get a maximum matching algorithm: restrict attention to a maximum-rank submatrix of $Z$.

Suppose the two given matroids $M_1 = (S, B_1)$ and $M_2 = (S, B_2)$ do not have a common base. By Theorem 4.3, rank $Z = n + \lambda$, where $\lambda$ is the maximum cardinality of an intersection of the two given matroids. Since $T$ is nonsingular, Fact 2.3 shows that there exists a row-set $A$ and column-set $B$, both disjoint from $S$, such that $|A| = |B| = \text{rank } Z - n$ and $Z_{A \cup S, B \cup S}$ is nonsingular. The matrix $Z_{A \cup S, B \cup S}$ has the following form:

$$Z_{A \cup S, B \cup S} = \begin{pmatrix} A & S \\ Q_1[A,*] & T \end{pmatrix} \begin{pmatrix} B \\ S \end{pmatrix}$$

Now Algorithm 4 can be used to find a common base $J$ for the matroids $M_A$, corresponding to $Q_1[A,*]$, and $M_B$, corresponding to $Q_2[*B]$. Then $Q_1[A,J]$ has full column rank, which certainly implies that $Q_1[*J]$ does too, so $J \in I_1$. Similarly, $J \in I_2$. Since $|J| = |A| = \text{rank } Z - n = \lambda$,

then $|J|$ is a maximum cardinality intersection for $M_1$ and $M_2$.

To analyze the time required by this algorithm, it suffices to focus on the time required to construct the sets $A$ and $B$. Let $Y = -Q_1TQ_2$ be the Schur complement of $T$ in $Z$. By Fact 2.3, if $Y_{A,B}$ is a maximum-rank square submatrix of $Y$, then $A$ and $B$ give the desired sets. As remarked earlier, $Y$ can be computed in $O(nr^{\omega-1})$ time, and a maximum-rank square submatrix can be found in $O(r^{\omega})$ time. This shows that a maximum cardinality intersection can be constructed in $O(nr^{\omega-1})$ time.

4.6.2. A Las Vegas algorithm. The algorithms presented above are Monte Carlo. In this section, we show that they can be made Las Vegas by constructing an optimal dual solution, i.e., a minimizing set $A$ in Fact 4.2. This dual solution can also be constructed in $O(nr^{\omega-1})$ time. If an optimal dual solution is constructed, then this certifies that the output of the algorithm is correct. Since this event occurs with constant probability, the expected number of trials before this event occurs is only a constant.

To construct a dual solution, we turn to the classical combinatorial algorithms for matroid intersection, such as Lawler’s algorithm [36]. Expositions can also be found in Cook et al. [6] and Schrijver [49]. Given an intersection, this algorithm searches for augmenting paths in an auxiliary graph. If an augmenting path is found, then the algorithm constructs a larger intersection. If no such path exists, then the intersection has maximum cardinality and an optimal dual solution can be constructed.

The first step is to construct a (purportedly maximum) intersection $J$ using the algorithm of section 4.6.1. We then construct the auxiliary graph for $J$ and search for an augmenting path. If one is found, then $J$ is not optimal, due to the algorithm’s
unfortunate random choices; this happens with only constant probability. Otherwise, if there is no augmenting path, then we obtain an optimal dual solution. It remains to show that we can construct the auxiliary graph and search for an augmenting path in $O(nr^{\omega-1})$ time.

The auxiliary graph is defined as follows. We have two matroids $\mathbf{M}_1 = (S, I_1)$ and $\mathbf{M}_2 = (S, I_2)$, and an intersection $J \in I_1 \cap I_2$. The auxiliary graph is a directed, bipartite graph $G = (V, A)$ with bipartition $V = J \cup (S \setminus J)$. The arcs are $A = A_1 \cup A_2$, where

$$
A_1 := \{ (x, y) : y \in J, x \notin J, \text{ and } J - y + x \in I_1 \},
$$

$$
A_2 := \{ (y, x) : y \in J, x \notin J, \text{ and } J - y + x \in I_2 \}.
$$

There are two distinguished subsets $X_1, X_2 \subseteq S \setminus J$, defined as follows:

$$
X_1 := \{ x : x \notin J \text{ and } J + x \in I_1 \},
$$

$$
X_2 := \{ x : x \notin J \text{ and } J + x \in I_2 \}.
$$

It is possible that $X_1 \cap X_2 \neq \emptyset$. Any minimum-length path from $X_1$ to $X_2$ is an augmenting path. So $J$ is a maximum cardinality intersection iff $G$ has no directed path from $X_1$ to $X_2$. When this holds, the set $U$ of vertices which have a directed path to $X_2$ satisfies $|J| = r_1(U) + r_2(S \setminus U)$, so $U$ is an optimum dual solution. Schrijver [49, p. 706] gives proofs of these statements.

Since the auxiliary graph has only $n$ vertices and $O(nr)$ arcs, we can search for a path from $X_1$ to $X_2$ in $O(nr)$ time.

**Claim 4.8.** The auxiliary graph can be constructed in $O(nr^{\omega-1})$ time.

**Proof.** Since $J \in I_1$, the submatrix $Q_1[* ,J]$ has full column-rank. Let $Q_1[I, J]$ be a nonsingular square submatrix, and let $C$ be the Schur complement of $Q_1[I, J]$ in $Q_1$. Fact 4.1 implies that $C$ is a linear representation of $\mathbf{M}_1/J$, and thus $J + i \in I_1$ iff $C_{*,i} \neq 0$. Thus we will add $i$ to $X_1$ iff $C_{*,i}$ contains a nonzero entry.

As in the proof of Fact 4.1 in Appendix A.2, let us decompose

$$
Q_1 = I \begin{pmatrix} J & \mathcal{J} \\ \mathcal{I} & WX \end{pmatrix}
$$

and define

$$
M = \begin{pmatrix} W^{-1} & 0 \\ -YW^{-1} & I \end{pmatrix}.
$$

Then $M \cdot Q_1$ is a linear representation of $\mathbf{M}_1$. Consider the decomposition

$$
M \cdot Q_1 = I \begin{pmatrix} J & X_1 & \mathcal{J} \cup X_1 \\ I & W^{-1}X_{*,X_1} & W^{-1}X_{*,X_1} \\ 0 & C_{*,X_1} & 0 \end{pmatrix}.
$$

Clearly $Q_1[* ,J-i+j]$ has full column-rank iff $(M \cdot Q_1)[*,J-i+j]$ has full column-rank. For $j \in \mathcal{J} \cup X_1$, it is clear from (4.6) that the latter condition holds iff $(M \cdot Q_1)_{i,j} \neq 0$.

The arcs in $A_1$ are constructed as follows. For any $x \in X_1$, we have $J + x \in I_1$, which implies that $J + x - y \in I_1$, $\forall y \in J$. Thus $(x, y) \in A_1$, $\forall x \in X_1$ and $y \in J$. For any $x \in S \setminus (J \cup X_1)$, we have $(x, y) \in A_1$ iff $(M \cdot Q_1)_{i,j} \neq 0$, as argued above.

The computational cost of this procedure is dominated by the time to compute $M \cdot Q_1$, which clearly takes $O(nr^{\omega-1})$ time. A symmetric argument shows how to build $X_2$ and $A_2$. \[\square\]
5. Discussion. This paper leaves open several questions.

- A common generalization of nonbipartite matching and matroid intersection is the matroid matching problem [36, 38, 49]. It seems likely that our matching and matroid intersection algorithms can be combined and extended to solve this problem as well, when the given matroids are linear.
- As mentioned earlier, there exist fast algorithms for rectangular matrix multiplication [7]. Can these be used to obtain a faster algorithm for matroid intersection?
- Do Theorems 4.3 and 4.4 have other applications?

Another common generalization of nonbipartite matching and matroid intersection is the basic path-matching problem [12, 13, 11] (or independent even factor problem [11, 32]). The techniques presented herein can be extended to solve that problem, when the given matroids are linear. A sketch of the argument was given in a preliminary version of this paper [29]. For the sake of brevity, we omit further discussion of this topic.

Appendix. Additional proofs.

A.1. Facts from linear algebra. This section proves the basic facts that are given in section 2.

Proof of Fact 2.1. Note that
\[
\begin{pmatrix}
I & V^T \\
-U & M + UV^T
\end{pmatrix}
\begin{pmatrix}
I \\
I
\end{pmatrix} = \begin{pmatrix}
I & V^T M^{-1} \\
-I & I
\end{pmatrix} \begin{pmatrix}
I + V^T M^{-1} U \\
I
\end{pmatrix}.
\]
Taking determinants shows that \(\det(M + UV^T) = \det(I + V^T M^{-1} U) \cdot \det(M)\). This proves the first claim.

The second claim follows since
\[
\begin{align*}
(M^{-1} - M^{-1} (I + V^T M^{-1} U)^{-1} V^T M^{-1}) & \cdot (M + UV^T) \\
= I + M^{-1} U (I - (I + V^T M^{-1} U)^{-1} - (I + V^T M^{-1} U)^{-1} V^T M^{-1} U) V^T \\
= I + M^{-1} U (I + V^T M^{-1} U)^{-1} ((I + V^T M^{-1} U) - I - V^T M^{-1} U) V^T \\
= I,
\end{align*}
\]
as required. This proof of the second claim is well known and may be found in Golub and Van Loan [28, section 2.1.3].

Proof of Corollary 2.2. Let us write \(\tilde{M} = M + UV^T\), where
\[
\begin{align*}
M &= S \begin{pmatrix}
S \\
\overline{S}
\end{pmatrix} \begin{pmatrix}
M_{S,S} \\
M_{\overline{S},S}
\end{pmatrix}, & \tilde{M} &= S \begin{pmatrix}
\tilde{M}_{S,\overline{S}} \\
\tilde{M}_{\overline{S},S}
\end{pmatrix}, \\
U &= S \begin{pmatrix}
S \\
\overline{S}
\end{pmatrix} \begin{pmatrix}
I \\
0
\end{pmatrix}, & V^T &= S \begin{pmatrix}
S \\
\overline{S}
\end{pmatrix} \begin{pmatrix}
\tilde{M}_{S,\overline{S}} - M_{S,\overline{S}} \\
0
\end{pmatrix}.
\end{align*}
\]
Then Fact 2.1 shows that \(\tilde{M}\) is nonsingular iff \(I + V^T M^{-1} U\) is nonsingular. Using the definition of \(N, V,\) and \(U\), we get
\[
I + V^T NU = I + (\tilde{M}_{S,\overline{S}} - M_{S,\overline{S}}) N_{S,\overline{S}}.
\]
Furthermore, Fact 2.1 also shows that
\[
\tilde{M}^{-1} = N - N \left( I + V^T NU \right)^{-1} V^T N \\
= N - N_{*,S} \left( I + (\tilde{M}_{S,S} - M_{S,S}) N_{S,S} \right)^{-1} (\tilde{M}_{S,S} - M_{S,S}) N_{S,*},
\]
as required. \( \Box \)

Proof of Fact 2.3. Note that
\[
\left( W - XZ^{-1} Y \begin{array}{c} 0 \\ Z \end{array} \right) = \begin{pmatrix} I & -XZ^{-1} \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} W & X \\ Y & Z \end{pmatrix} \cdot \begin{pmatrix} I & 0 \\ -Z^{-1}Y & I \end{pmatrix}.
\]
Taking the determinant of both sides gives
\[
\det \left( W - XZ^{-1} Y \right) \cdot \det Z = \det M,
\]
since \( \det N_1 = \det N_2 = 1 \). This proves the first property.
Furthermore, since \( N_1 \) and \( N_2 \) have full rank, we have
\[
\text{rank} M = \text{rank} \left( W - XZ^{-1} Y \right) + \text{rank} Z = \text{rank} C + |S_2|.
\]
Now suppose that \( C_{A,B} \) is nonsingular with \( |A| = |B| = \text{rank} C \). Then we have
\[
\begin{pmatrix} C_{A,B} & 0 \\ 0 & Z \end{pmatrix} = \begin{pmatrix} I & -X_{A,*}Z^{-1} \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} W_{A,B} & X_{A,*} \\ Y_{*,B} & Z \end{pmatrix} \cdot \begin{pmatrix} I & 0 \\ -Z^{-1}Y_{*,B} & I \end{pmatrix},
\]
It follows from (A.2) and (A.3) that
\[
\text{rank} M = \text{rank} C + \text{rank} Z = \text{rank} C_{A,B} + \text{rank} Z = \text{rank} M_{A \cup S_2, B \cup S_2},
\]
which proves the second property. \( \Box \)

Proof of Fact 2.4. Suppose that \( M^{-1} \) exists. Then
\[
(M^{-1})_{i,j} = ((M^{-1})^T)_{j,i} = ((M^T)^{-1})_{j,i} = ((-M)^{-1})_{j,i} = -(M^{-1})_{j,i},
\]
as required. \( \Box \)

A.2. Proof of Fact 4.1. Let us write \( Q \) as
\[
Q = A \begin{bmatrix} B & B \\ A & (W & X) \end{bmatrix}.
\]
For any nonsingular matrix \( M \), the matrix \( M \cdot Q \) is also a linear representation of \( M \).
We choose
\[
M = \begin{pmatrix} W^{-1} & 0 \\ -YW^{-1} & I \end{pmatrix},
\]
so that
\[
M \cdot Q = \begin{pmatrix} I & W^{-1}X \\ 0 & Z - YW^{-1}X \end{pmatrix}.
\]
Note that $C := Z - YW^{-1}X$ is the Schur complement of $Q[A,B]$ in $Q$. Fact 2.3 shows that $C[A', B']$ is a maximum-rank square submatrix of $C$ if $Q[A \cup A', B \cup B']$ is a maximum-rank square submatrix of $Q$. In other words,

$$
\{ B' \subseteq S \setminus T : C[*, B'] \text{ has full column-rank} \}
= \{ B' \subseteq S \setminus T : Q[*, B \cup B'] \text{ has full column-rank} \},
= \{ B' \subseteq S \setminus T : B \cup B' \in \mathcal{B} \},
$$

where $\mathcal{B}$ is the base family of $\mathbf{M}$. This family of sets is precisely $\mathcal{B}_{\mathbf{M}/T}$, so $C[*, \mathcal{T}]$ is a linear representation of $\mathbf{M}/T$. Since

$$
C[*, \mathcal{T}] = Q[\mathcal{A}, \mathcal{T}] - Q[\mathcal{A}, B] \cdot Q[A, B]^{-1} \cdot Q[A, \mathcal{T}],
$$

the claim is proven.

**A.3. Proof of Theorem 4.3.** By applying elementary row and column operations (as in the proof of Fact 4.1 in Appendix A.2), we may transform $Z(J)$ into the form

$$
\hat{Z}(J) := \begin{pmatrix} Q_1^I & Q_1^JT \\ Q_2^I & Q_2^T \end{pmatrix},
$$

where $Q_1^I$ has full row-rank, $Q_2^I$ has full column-rank, $Q_1^T$ is a linear representation of $\mathbf{M}_1/J$, and $Q_2^T$ is a linear representation of $\mathbf{M}_2/J$. Then we have

$$
\text{rank } Z(J) = \text{rank } \hat{Z}(J) = r_1(J) + r_2(J) + \text{rank } \hat{Z}(J),
$$

where

$$
\hat{Z}(J) := \begin{pmatrix} Q_1^T \\ Q_2^T \end{pmatrix} (J)_{\mathcal{T}, \mathcal{T}}.
$$

By the previously known special case of Theorem 4.3 due to Tomizawa and Iri [51], we have

$$
\text{rank } \hat{Z}(J) = |J| + \lambda(J) = n - |J| + \lambda(J).
$$

Thus we have

$$
\text{rank } Z(J) = r_1(J) + r_2(J) + n - |J| + \lambda(J),
$$

as required.

**A.4. Proof of Theorem 4.4.**

**Claim A.1.** Let $J$ be an intersection of $\mathbf{M}_1$ and $\mathbf{M}_2$. $J$ is extensible iff $\lambda(\emptyset) = \lambda(J) + |J|$.

**Proof.** Suppose that $J$ is an extensible intersection. This means that there exists an intersection $I$ with $J \subseteq I$ and $|I| = \lambda(\emptyset)$. Since $J \in \mathcal{I}_1$, it is a base for itself in $\mathbf{M}_1$. Thus, (4.1) shows that $\hat{J} \in J_{\mathbf{M}_2/J}$ for both $i$, implying that $\lambda(J) \geq |I \setminus J| = \lambda(\emptyset) - |J|$.
To show the reverse inequality, let \( I \) be a maximum cardinality intersection of \( M_1/J \) and \( M_2/J \). So \(|I| = \lambda(J)\). Then \( I \cup J \) is an intersection of \( M_1 \) and \( M_2 \), showing that \( \lambda(\emptyset) \geq \lambda(J) + |J| \). This establishes the forward direction.

Now suppose that \( \lambda(J) = \lambda(\emptyset) - |J| \). Then there exists an intersection \( I \) of \( M_1/J \) and \( M_2/J \) with \(|I| = \lambda(\emptyset) - |J| \). Then \( I \cup J \) is an intersection of \( M_1 \) and \( M_2 \), of cardinality \(|I| + |J| = \lambda(\emptyset)\). This shows that \( J \) is contained in a maximum cardinality intersection of \( M_1 \) and \( M_2 \), and therefore is extensible.

**Claim A.2.** Assume that \( M_1 \) and \( M_2 \) have the same rank \( r \). For any set \( J \subseteq S \), we have \( \lambda(J) \leq r - \max_{i \in \{1,2\}} r_i(J) \).

**Proof.** Note that \( \lambda(J) \) is at most the rank of \( M_i/J \), which is \( r - r_i(J) \).

Suppose that \( J \) is an extensible intersection. This implies that \( r_1(J) = |J| \) and \( r_2(J) = |J| \), by Claim A.1. Theorem 4.3 then shows that

\[
\text{rank } Z(J) = n + r_1(J) + r_2(J) - |J| + \lambda(J) \\
= n + |J| + |J| - |J| + \lambda(\emptyset) - |J| \\
= n + r,
\]

and hence \( Z(J) \) is nonsingular as required.

We now argue the converse. Clearly \( r_2(J) \leq |J| \) and, by Claim A.2, we have \( \lambda(J) + r_1(J) \leq r \). Thus

\[
\text{rank } Z(J) = n + r_1(J) + r_2(J) - |J| + \lambda(J) \\
= n + \left( r_1(J) + \lambda(J) \right) + \left( r_2(J) - |J| \right) \\
\leq n + r.
\]

If \( Z(J) \) is nonsingular, then equality holds, so we have \( r_2(J) = |J| \) and \( r_1(J) + \lambda(J) = r \). By symmetry, we also have \( r_1(J) = |J| \), implying that \( J \) is an intersection. Altogether this shows that \(|J| + \lambda(J) = r\), implying that \( J \) is extensible.

**Acknowledgments.** Simplified proofs of Theorems 4.3 and 4.4 were contributed by an anonymous referee and Michel Goemans, respectively. Additionally, the author thanks the anonymous referees for suggesting numerous improvements to the text of the paper.
