RESEARCH OBJECTIVES

The research on noise in electron devices has two objectives:

(i) The study of specific devices, such as the parametric amplifier and the maser, to determine the physical sources of noise and the limitations they impose on the noise performance of the amplifier.

The parametric amplifier with coherent input signals at both the signal and idler frequency, and the degenerate parametric amplifier are the impetus for the second objective.

(ii) The determination of a measure of the optimum noise performance of multiterminal linear amplifiers. The optimum noise performance of a linear twoport amplifier is known to be expressible in terms of its minimum noise measure, a quantity that is characteristic of the amplifier. The optimum noise performance of a multiterminal pair amplifier excited by a multiterminal pair source is at present under study for the purpose of developing an analogous measure for the optimum noise performance of such an amplifier.

A. SOLUTIONS TO THE PROBLEM OF THE OPTIMUM NOISE PERFORMANCE OF MULTITERMINAL AMPLIFIERS

In a previous report we showed that under certain restrictions the stationary values of signal-to-noise ratio which can be obtained for a specified value of exchangeable signal power at a single-output terminal pair by imbedding an n-terminal pair source and an m-terminal pair amplifier in an n + m + 1 terminal pair lossless network are governed by two coupled matrix equations – Eqs. 1 and 2.

\[
\begin{align*}
E_n x_2 + 2\lambda(Z_a + Z^\dagger) x_2 &= 0 \\
E_s x_1 + \mu \left[ E_n x_2 + 2\lambda(Z + Z^\dagger) \right] &= 0
\end{align*}
\]  

By a simpler derivation, it has been established that Eqs. 1 and 2 are valid regardless of the nature of the matrices characterizing the source and amplifier networks; however, for simplicity we shall assume here that \(E_s E_n\) is positive definite, \(Z + Z^\dagger\) is positive definite, and \(Z_a + Z^\dagger_a\) is indefinite.

Components of the vectors \(x_1\) and \(x_2\) may be interpreted as complex voltage ratios. For instance, with all voltage sources in the source and amplifier short-circuited

(XII. NOISE IN ELECTRON DEVICES)

except the source represented by $E_{s_1}$, which is the open-circuit signal voltage at the first terminal pair of the source network, the open-circuit voltage at the output terminal pair is $x_{11}E_{s_1}$, where $x_{11}$ is the first component of the vector $x_1$. Similarly, the components of $x_2$ relate the open-circuit noise voltage at the output terminal pairs to the open-circuit voltages of the amplifier. Imbedding the source and amplifier networks in a given $n + m + 1$ terminal pair lossless network enables us to define a unique pair of vectors $x_1$ and $x_2$. The reverse is not true; it can be shown that there are an infinite number of lossless networks corresponding to a particular pair of vectors $x_1$ and $x_2$.

For Eq. 1 there are $n$ eigenvalues $\lambda_i$ and eigenvectors $x^{(i)}_2$. We may express the eigenvalue $\lambda_1$ in terms of its eigenvectors as

$$\lambda_1 = -\frac{x^{(i)\dagger}_2 E_{na} E^{\dagger}_{na} x^{(i)}_2}{2x^{(i)\dagger}_2 (Z_a + Z_a^\dagger) x^{(i)}_2}.$$  \hspace{1cm} (3)

For convenience later, we shall label the smallest positive eigenvalue as $\lambda_1$ and the remaining positive eigenvalues in ascending order, and we shall label the smallest negative eigenvalues $\lambda_m$ and the remaining negative eigenvalues in descending order.

Equation 2, on the other hand, has $n$ solutions for each of the $m$ eigenvalues $\lambda_i$ of Eq. 1; this gives us a total of $n \times m$ sets of solutions to Eqs. 1 and 2. Using a double-subscript notation for these eigenvalues and eigenvectors, we may express the eigenvalue $\mu_{ij}$ in terms of $\lambda_i$ and the eigenvector $x^{(ij)}_1$ as

$$\frac{1}{\mu_{ij}} = \frac{x^{(ij)\dagger}_1 E_{sn} E^{\dagger}_{sn} x^{(ij)}_1 + 2\lambda_i x^{(ij)\dagger}_1 (Z + Z^\dagger) x^{(ij)}_1}{x^{(ij)\dagger}_1 E_{sn} E^{\dagger}_{sn} x^{(ij)}_1}.$$  \hspace{1cm} (4)

Here, we number our eigenvalues for a given $\lambda_i$ by the order of the value of their reciprocals; the minimum value of $1/\mu_i$ (which may be negative) is $1/\mu_{i1}$ and the maximum is $1/\mu_{in}$.

We would now like to relate the quantities of interest, namely the signal-to-noise ratio at the output and the exchangeable signal power at the output, to the eigenvalues derived from Eqs. 1 and 2. For the optimal imbedding network corresponding to a set of values $\lambda_i$ and $\mu_{ij}$ we write the signal-to-noise ratio as

$$\sigma_{ij} = \frac{x^{(ij)\dagger}_1 E_{sn} E^{\dagger}_{sn} x^{(ij)}_1}{x^{(ij)\dagger}_1 E_{sn} E^{\dagger}_{sn} x^{(ij)}_1 + x^{(ij)\dagger}_1 E_{na} E^{\dagger}_{na} x^{(ij)}_2},$$  \hspace{1cm} (5)

and the exchangeable signal power as
We now see why these quantities do not appear directly as eigenvalues. In Eq. 3 we see that $\lambda_1$ is independent of the magnitude of $x_2^{(i)}$; similarly, $\mu_{ij}$ in Eq. 4 is independent of the magnitude of $x_1^{(i)}$. On the other hand, both of the quantities defined in Eqs. 5 and 6 are dependent on the relative magnitude of $x_2^{(i)}$ and $x_1^{(i)}$. We can explicitly demonstrate the consequences of this by considering the particular realization of the optimal network that places this fact in evidence.

Consider an imbedding of the $m$-terminal pair amplifier in an arbitrary $m + 1$ terminal pair lossless network. We know that we can always pick this network in such a manner that the mean-square voltage and the real part of the impedance at the output terminal pair are $x_2^{(i)^\dagger} E_{na} E_{na}^{\dagger} x_2^{(i)}$ and $1/2 x_2^{(i)^\dagger} (Z_a + Z_a^{\dagger}) x_2^{(i)}$, respectively, where $x_2^{(i)}$ is a vector that is proportional to $x_2^{(i)}$. Similarly, we can losslessly reduce the source network to a one-terminal pair network with mean-square signal voltage.

Fig. XII-1. Realization of the optimal network.
x^{(ij)\dagger}_{1} E_{s} E_{s}^{\dagger} x^{(ij)}_{1}, \text{ mean-square noise voltage } x^{(ij)\dagger}_{1} E_{n} E_{n}^{\dagger} x^{(ij)}_{1}, \text{ and impedance } 
1/2 x^{(ij)\dagger}_{1} (Z+Z^{\dagger}) x^{(ij)}_{1}. \text{ Combining these two reduced networks as shown in Fig. XII-1, we see that the signal-to-noise ratio and the exchangeable signal power at the output are given by Eqs. 5 and 6, respectively, where } x^{(i)}_{2} = n x^{(i)'}_{1}. \text{ This network is optimal in the sense of Eqs. 1 and 2 for any value of } n. \text{ We see that varying the transformer ratio is equivalent to varying the ratio of } |x^{(i)}_{2}| \text{ to } |x^{(i)}_{1}|. \text{ Physically, then, when we vary } n \text{ or } |x^{(i)}_{2}|/|x^{(i)}_{1}|, \text{ we are changing the amount of our use of the amplifier, since we are changing the exchangeable signal power at the output and, thereby, also changing the signal-to-noise ratio at the output. This interpretation is actually completely general and independent of the particular imbedding network that we are using. However, in general, variation of the ratio of } |x^{(i)}_{2}| \text{ to } |x^{(i)}_{1}| \text{ can correspond to some complex variation of the imbedding network because of the multiple feedback loops that may exist between the source and amplifier networks. Figure XII-1, then, just gives a convenient way of visualizing the effects of varying the ratio of } |x^{(i)}_{2}| \text{ to } |x^{(i)}_{1}|. \text{ We see then that setting the ratio of } |x^{(i)}_{2}| \text{ to } |x^{(i)}_{1}| \text{ equal to zero or, equivalently, setting } n=0 \text{ is the same as throwing away the amplifier. The values of } \sigma_{ij} \text{ and } p_{ij} \text{ for this limit are just the signal-to-noise ratio and the exchangeable power of the source network alone. We designate these two quantities as }

\sigma_{ij, s} = \frac{x^{(ij)\dagger}_{1} E_{s} E_{s}^{\dagger} x^{(ij)}_{1}}{x^{(ij)\dagger}_{1} E_{n} E_{n}^{\dagger} x^{(ij)}_{1}}, \quad (7)

p_{ij, s} = \frac{x^{(ij)\dagger}_{1} E_{s} E_{s}^{\dagger} x^{(ij)}_{1}}{2 x^{(ij)\dagger}_{1} (Z+Z^{\dagger}) x^{(ij)}_{1}},

\text{respectively.}

It follows that for a given pair of eigenvalues } \lambda_{i} \text{ and } \mu_{ij}, \text{ we may vary } \sigma_{ij} \text{ and } p_{ij} \text{ by varying the ratio of the magnitudes of the eigenvectors, that is, by varying only the transformer ratio in Fig. XII-1. Such a variation enables us to plot the stationary values of signal-to-noise ratio as a function of the exchangeable signal power at the output corresponding to this particular solution to Eqs. 1 and 2. For this purpose we need the relation }

1/\sigma_{ij} = 1/\mu_{ij} - \lambda_{i}/p_{ij}, \quad (9)

\text{which may be verified by using Eqs. 3-6. From Eq. 9 we see that it is more convenient to plot characteristic curves of } 1/\sigma_{ij} \text{ as a function of } 1/p_{ij}. \text{ In the } 1/\sigma_{ij} - 1/p_{ij} \text{ plane these characteristic curves are straight lines with slopes } -\lambda_{i} \text{ and intercepts } 1/\mu_{ij} \text{ with the } 1/\sigma_{ij} \text{ axis. Thus a set of eigenvalues } \lambda_{i} \text{ and } \mu_{ij} \text{ merely determine a}
characteristic line in the $1/\sigma_{ij} - 1/p_{ij}$ plane; moreover, we see that for the stated problem there are $n \times m$ such lines.

It must be pointed out, however, that only one-half of a characteristic line is realizable. Comparing Eqs. 5 and 7, we see that

$$\frac{1}{\sigma_{ij}} \geq \frac{1}{\sigma_{ij}, s},$$

(10)

and, using Eqs. 4, 7, 8, and 10 in Eq. 9, we find that either

$$\lambda_i > 0 \text{ and } 1/p_{ij} \leq 1/p_{ij}, s$$

or

$$\lambda_i < 0 \text{ and } 1/p_{ij} \geq 1/p_{ij}, s.$$  

(11)

The equality signs in Eqs. 10 and 11 will hold only when $|x_2^{(l)}|/|x_1^{(ij)}|$ is zero, that is, the realizable one-half of the characteristic line ends at the point determined by the source — the point whose coordinates are $1/\sigma_{ij}, s$ and $1/p_{ij}, s$. Hence, in the $1/\sigma_{ij} - 1/p_{ij}$ plane we can realize only the one-half of the characteristic line that is above and to the left of the source point for negative $\lambda_i$, and above and to the right of the source point for positive $\lambda_i$. We can only achieve a signal-to-noise ratio equal to $\mu_{ij}$ at infinite exchangeable signal power if $1/p_{ij} = 0$ satisfies one of the inequalities of Eq. 11.

In displaying the solution to the optimization problem in the $1/\sigma_{ij} - 1/p_{ij}$ plane, we shall show only those solutions for a given $\lambda_i$ which correspond to $1/\mu_{11}$, the minimum value of $1/\mu_i$, and $1/\mu_{in}$, the maximum value of $1/\mu_i$. We would like to find where the end points of these characteristic curves lie in the $1/\sigma_{ij} - 1/p_{ij}$ plane. If we consider how these end points change as $\lambda_i$ changes, we find that they generate a closed curve. This is illustrated in Fig. XII-2, in which several of these characteristic curves are shown as they must appear for positive $\lambda_i$'s and minimum $1/\mu_i$. With reference to Fig. XII-1, when we vary $\lambda_i$ we are changing amplifiers and then reoptimizing the source for use with this new amplifier and thereby obtaining a new source point.

![Fig. XII-2. Characteristic curves for $\lambda_i > 0$, $1/\mu_{11}$](image)
The closed curve generated is tangent to each of the characteristic lines. Physically, this curve represents the boundary of the region of values of the noise-to-signal ratio and the reciprocal of the exchangeable signal power that may be obtained at the output by imbedding only the source network, and not the amplifier, in an arbitrary lossless imbedding network.

In Fig. XII-3 we show a typical plot of characteristic curves for a positive definite source and an amplifier having both positive and negative eigenvalues. We have shown only those characteristics corresponding to extremal values of $1/\mu_1$ for four values of $\lambda_1$ — the two smallest positive eigenvalues and the two smallest negative eigenvalues. (All solutions corresponding to intermediate eigenvalues of $1/\mu_1$ would give rise to characteristic curves that terminate at points inside the source region.) All of these characteristics may be interpreted. The line characterized by $\lambda_1$ and $\mu_1\lambda_{ij}$ is the true optimum-performance curve. It is the curve of the maximum signal-to-noise ratio as a function of exchangeable signal power for exchangeable signal power greater than $P_\alpha$. The line characterized by $\lambda_1$ and $\mu_{1n}$ represents the worst way of increasing exchangeable signal power with the best reduction of the amplifier. The line characterized by $\lambda_2$ and $\mu_{21}$ is just a locus of points of stationary signal-to-noise ratio for fixed exchangeable signal powers. This same statement applies to all of the curves shown. The line characterized by $\lambda_m$ and $\mu_{m1}$ represents the best way of reducing the
exchangeable signal power below $p_\beta$. Since $\lambda_m$ is negative here, we are using the amplifier as a positive resistor; for that matter, we are using the least noisy positive resistor appearing in the cannonic form of the amplifier.
