Conspectus

Organic semiconductors (OSCs) have recently received significant attention for their potential use in photovoltaic, LED and FET devices. Part of the appeal of OSCs is their robustness to material disorder (e.g. packing defects), making them more flexible and easier to process than their inorganic counterparts. In addition to their technological applications, OSCs provide an attractive laboratory for examining the chemistry of heterogeneous systems. In particular, because OSCs are both electrically and optically active, one has access to a wealth of electrical and spectroscopic probes that are sensitive to a variety of localized electronic states in these materials. In this tutorial, we review the basic concepts involved in first-principles modeling of the electronic properties of disordered OSCs. There are three theoretical ingredients in the computational recipe. First, Marcus theory of nonadiabatic electron transfer (ET) provides a direct link between energy and kinetics. Second, constrained density functional theory (CDFT) forms the basis for an ab initio model of the diabatic charge states required in ET. Finally, quantum mechanical/molecular mechanical (QM/MM) techniques allow us to incorporate the influence of the heterogeneous environment on the diabatic states. As an illustration,

∗To whom correspondence should be addressed
we apply these ideas to the small molecule OSC tris(8-hydroxyquinolinato)aluminum (Alq₃). In films, Alq₃ can possess a large degree of short-range order, placing it in the middle of the order-disorder spectrum - with pure crystals on one end and totally amorphous structures on the other. We show that the QM/MM recipe reproduces the transport gap, charge carrier hopping integrals, optical spectra and reorganization energies of Alq₃ in quantitative agreement with available experiments. However, none of these quantities can be specified accurately by a single number. Instead, each property is characterized by a distribution that reflects the influence of the heterogeneous environment on the electronic states involved. For example, the hopping integral between a given pair of Alq₃ molecules can vary by as much as a factor of five on the nanosecond timescale, while the integrals for two different pairs can easily differ by a factor of 100. In order to make accurate predictions of mesoscopic properties such as carrier mobilities based on these calculations, one must account for the dynamic range of the microscopic inputs, rather than just their average values. We thus find that many of the computational tools required to characterize these materials are now in hand. As we continue to improve this computational toolbox, one envisions a future scenario in which, given some information about OSC deposition, one could simulate device operation on the atomic scale to obtain data that not only aids in the interpretation of experimental results but also guides the design of more efficient devices.

1 Introduction

The study of organic electronics presents a new landscape upon which chemists, materials scientists, and others are working to supplement conventional inorganic semiconductor devices with a palette of small molecule and polymeric materials.¹ These are typically π-conjugated systems with low-lying excited states and the ability to transport both holes and electrons.² While work remains to be done, significant progress has been made on device applications such as organic light-emitting diodes (OLEDs), photovoltaics (OPVs), and field-effect transistors (OFETs).³

Although monocrystalline organic materials can be produced, most applications are limited by
cost to polycrystalline or amorphous structures. Thus disorder greatly affects carrier mobilities and generation-recombination behavior of OSC devices. In addition, because there are no intermolecular covalent bonds, weak van der Waals (vdW) forces dominate interactions in the solid creating localized (Frenkel type) excitons while strong electron-phonon interactions lead to polaron formation and hopping-type transport. The conceptual simplicity of bands in traditional semiconductors is thus replaced by a complex disordered system where electron interactions and electron-phonon coupling determine the energy landscape.

In this picture, the key quantities are the energies and couplings between the different localized electronic states, and an array of computational tools exist that give us access this information. Individual chromophores can be described with semi-empirical, density functional theory (DFT), or wavefunction-based methods. To describe short-range disorder in the solid, simulated annealing can generate dimer structures for which the electronic coupling between pairs of molecules can be computed, leading to an estimate of carrier mobility. To crudely address electrostatic effects of the environment, polarizable continuum models (PCMs) can also be invoked.

Figure 1: Illustration of QM/MM method. Left: Disordered Alq supercell, generated using MM simulation techniques. Center: Selection of QM region within the MM environment. Right: Electronic structure calculation of desired electronic state.

QM/MM studies can shed more light on the impact of the environment on the energy landscape. By explicitly including intermolecular interactions in the QM/MM potential, the effect of
neighboring molecules on optical and transport properties can be better described. Even for an
amorphous material with nanometer-scale disorder, the localized nature of the electronic states
means that the QM region need only include one or two monomers (See Figure 1). This makes
QM/MM calculations vastly faster than a full DFT calculation on the same system.

Recently, we and others\textsuperscript{8,11} have begun a systematic study of organic materials with QM/MM
methods. This review is a tutorial intended to illustrate the fundamental principles involved in this
new class of simulations. We begin by introducing the relevant theoretical ingredients - the Marcus
picture of ET, identifying diabatic states using CDFT, and the integration with QM/MM techniques.
To illustrate how the techniques interface with one another, we focus on Alq\textsubscript{3}, a well-studied
molecule\textsuperscript{8,9,12–14} that is the prototypical OLED material. We apply the QM/MM methodology to
Alq\textsubscript{3} and compute a range of electronic properties: transport gap, electron- and hole- transfer rates,
spectral densities and charge carrier recombination rates. At every stage, we observe the crucial
influence of the environment, and particularly disorder, on the distribution of electronic states. We
conclude by summarizing the strengths and weaknesses of this approach for studying OSCs and
detail future work necessary for broader applications.

2 Theory

2.1 Marcus Theory of Electron Transfer

In the condensed phase, ET occurs as the static and dynamic polarization of the environment
stabilizes (or destabilizes) charged species. For nonadiabatic reactions (see Figure 2) the landscape
is described by two parameters: the reorganization energy, $\lambda$, which describes the relaxation of the
entire system as a result of the new electronic state, and $\Delta G$, the free energy change attending ET.
The intramolecular ET rate, $k_{ET}$, can be approximately written as\textsuperscript{15}

$$k_{ET} = \frac{2\pi}{\hbar} \left| V_{RP} \right|^2 \frac{1}{\sqrt{4\pi \lambda k_B T}} \exp \left( -\frac{(\lambda + \Delta G)^2}{4\lambda k_B T} \right) .$$

(1)
Here, the prefactor involves the electronic coupling element, $V_{RP}$, between the (diabatic) reactant and product states of ET.

In solid state systems, the reactant and product states are the *polarons* that determine charge transport.\textsuperscript{16} $\lambda$ leads to polaron trapping via two mechanisms: the relaxation of the “inner sphere” molecules undergoing ET ($\lambda_i$), and the polarization of the “outer sphere” molecules in the environment ($\lambda_o$). Meanwhile, charge hopping is generated by the tunneling matrix element $V_{RP} \equiv \langle P | \hat{H} | R \rangle$, where $| R \rangle (| P \rangle)$ is the reactant (product) state, and $\hat{H}$ is the electronic Hamiltonian. $V_{RP}$ is often assumed constant along the reaction coordinate (Condon approximation). While this turns out to be a good approximation for Alq\textsubscript{3} (there is very little correlation between $\Delta G$ and $V_{RP}$) in general we avoid this approximation and instead compute $V_{RP}$ at each instantaneous configuration.

We note that Marcus theory is typically an *ensemble* theory. A given reaction is characterized by a single value of $\Delta G$, $\lambda$, and $V_{RP}$ (Figure 2a). Meanwhile, organic solids tend to be disordered, nonequilibrium systems. As a result, an OSC has many relevant values of $\Delta G$, $\lambda$, and $V_{RP}$ (Figure 2b) leading to a distribution of ET rates via Eq. 1. In order to translate the tangle of energy landscapes in Figure 2b into a single rate, one must resolve the individual timescales of relaxation versus charge hopping. In what follows, we will not unravel this particular Gordian knot but instead focus on quantifying the underlying distributions.

### 2.2 Constrained DFT as a Route to Diabatic States

In order to connect the Marcus picture to a physical system, a prescription for diabatic electronic states must be chosen. In this vein, empirical valence bond,\textsuperscript{10} semiempirical molecular orbital,\textsuperscript{4} CDFT\textsuperscript{17,18} and CI-based\textsuperscript{19} approaches have all proven useful. In what follows, we em-
ploy CDFT to define diabatic electronic states and compute relevant ET parameters. We choose this route because CDFT provides a compromise between computational cost and accuracy: the calculations are fast enough for realistic systems but also reliable enough for chemical accuracy in many properties.

Within CDFT, a diabatic ET state such as $D^+A^-$ is defined to be the lowest energy state such that the partial charges on the atoms that compose the acceptor ($A$) sum to $-1$. If the overall system is neutral, the donor ($D$) atom charges will then sum to $+1$, reflecting the hole left behind by the transferred electron. Other diabatic states, such as $A^-A$ or $D^+D$ are defined analogously. The constraint is enforced by applying a local chemical potential bias, $V$, between donor and acceptor. By varying the strength of this potential, one can control the charge on the acceptor. In CDFT, $V$ is determined *self-consistently* with the charge density to determine the lowest energy state that satisfies the charge constraint exactly.\(^\text{20}\) The charge-constrained states thus obtained form the foundation for a seamless connection between DFT and ET theory.\(^\text{17,21}\)

For a rigid system like an organic crystal, the entropic contributions to the Marcus parameters ($\Delta G$, $\lambda$) are expected to be small, so the task reduces to computing enthalpies. These enthalpies can be computed from a combination of geometry optimizations and energy evaluations. Adopting a notation of $(X|Y)$ for the energy of state $X$ at the optimized geometry of $Y$, we can compute the driving force and reorganization of $R \rightarrow P$ from (see Figure 2)

\[
\Delta G \equiv \frac{1}{2} \left[ (R|R) + (R|P) - (P|P) - (P|R) \right],
\]

\[
\lambda \equiv -\frac{1}{2} \left[ (R|R) - (R|P) + (P|P) - (P|R) \right].
\]

These expressions make the standard linear response assumption that both free energy surfaces are perfect parabolas with the same curvature.\(^\text{15}\) Finally, we compute $V_{RP}$ in CDFT from a combination of the overlap between electronic states and the matrix elements of the chemical potential between them:\(^\text{22}\)

\[
V_{RP} = \langle \Psi_R | \hat{H} | \Psi_P \rangle = \frac{F_R + F_P}{2} \langle \Psi_R | \Psi_P \rangle - \frac{1}{2} \langle \Psi_R | V_R + V_P | \Psi_P \rangle,
\]
where $F_R, V_R (F_P, V_P)$ are the free energy and constraining chemical potential of the reactant (product) state. Recent applications have shown that CDFT can provide accurate predictions of $\Delta G$, $\lambda$, and $V_{RP}$ when used within this framework.\textsuperscript{17,18,21}

### 2.3 QM/MM Modeling of Disordered Systems

QM/MM techniques have a long history of application to systems where a small active site is surrounded by a much larger environment. The simulation cell is thus divided into classical (MM) and quantum (QM) regions, which interact via the Hamiltonian.\textsuperscript{10} The important quantum phenomena are contained within the molecules of the QM region, while the surrounding MM region provides essential corrections (e.g. local electric fields) from the heterogeneous environment.

The total energy of the QM/MM simulation is given by:

$$ E = E_{QM}(r_Q) + E_{MM}(r_M) + E_{QM/MM}(r_Q, r_M). $$  \hspace{1cm} (5)

Here, $E_{QM}$ and $E_{MM}$ are the energies of the QM and MM regions, which depend on the coordinates of the QM ($r_Q$) and MM ($r_M$) nuclei respectively. $E_{QM/MM}$ represents the interaction energy between the regions and consists of electrostatic interactions plus an empirical vdW repulsion:

$$ E_{QM/MM} = -\int \sum_{i \in M} \frac{q_i}{|r_i - r'|} \rho(r') \, dr' + \sum_{i \in M, j \in Q} \frac{q_i Z_j}{|r_i - r_j|} + \sum_{i \in M, j \in Q} V_{vdW}(r_i, r_j). $$  \hspace{1cm} (6)

In addition to simple electrostatic effects, the QM/MM treatment must account for the fact that the OSC environment is polarizable. We do this by introducing fictitious “Drude” charges, $q_i^d$, which are harmonically bound to MM atoms:\textsuperscript{23}

$$ E_{Drude} = \sum_i \frac{1}{2} k_i^d |d_i - r_i|^2 + \sum_{i,j} \frac{q_i^d q_j^d}{|d_i - r_j|} + \sum_{i,j} \frac{q_i^d q_j^d}{|d_i - d_j|}. $$  \hspace{1cm} (7)

Electronic polarization is modeled by allowing the Drude particles to respond instantaneously to local electric fields, so that for any given nuclear configuration $\{r\}$, $E_{Drude}$ is minimized with
respect to the positions of the Drude particles. The positions of the Drude particles must be determined self-consistently with the QM charge density, because the electric field experienced by the Drude particles depends on the QM charges and vice versa. For Alq$_3$, the empirical parameters contained in the FF terms above were fitted to reproduce available experimental and *ab initio* data as detailed in the supporting information.

### 2.4 Simulation Procedure

We begin our QM/MM calculations by obtaining thermally sampled configurations of the OSC material. A pure MM trajectory with a large number of molecules is simulated at constant temperature, from which we extract a large number of snapshots at fixed time intervals for QM/MM calculations.

Each snapshot contains a disordered supercell of many molecules (Figure 1, left pane). Because electronic states in OSCs are largely localized, molecules distant from the active region mostly contribute long-range effects that are well described by MM. We invoke QM/MM by selecting a small subset of the snapshot (Figure 1, center pane), which by physical intuition we assume to contain the interesting quantum effects. The quantum region is intentionally chosen as small as possible to minimize the spurrious charge delocalization problems that plague DFT.\(^{17}\) Finally, the QM molecules are embedded in the MM simulation and treated using a full QM electronic structure calculation (Figure 1, right pane); the interaction with the MM system is replaced by the QM/MM Hamiltonian (Eq. 5). The MM atomic charges appear as external point charges in the QM calculation, which affect the QM electronic density.

At the boundary between the regions, QM electron density can localize unphysically around nearby MM point charges (i.e. the system transfers charge to the environment). We can repair this by replacing MM point charges with Gaussians, \(\rho(r) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(r-r_0)^2}{2\sigma^2}}\). In this work, we choose the blurring parameter \(\sigma = 3.5 \ \text{Å}\), approximately half the radius of Alq$_3$. Finally, forces on QM and MM atoms alike are given by differentiating the QM/MM Hamiltonian with respect to the nuclear coordinates. When an optimized structure is desired (e.g. when computing \(\lambda\)) these forces are
used to minimize the energy of the entire system.

3 Computational Details

3.1 Alq$_3$ as a Model Material

Alq$_3$ is an octahedral coordination complex in which three 8-hydroxyquinoline ligands are bound to a central aluminum atom. Numerous experimental and theoretical studies are available in the literature, making this material an ideal candidate for illustrating the methodology. Alq$_3$ is known to exist in several different crystalline phases; the experimentally determined unit cell of $\beta$-Alq$_3$ is used here as our initial structure because it most closely resembles that of the amorphous film. We constructed a triclinic supercell of 6x6x6 Alq$_3$ unit cells (Z=2) containing 432 molecules. For consistency with our QM method, our simulation cell used the equilibrium monomer geometry from a gas-phase B3LYP/3-21G geometry optimization, placed in maximal coincidence with the experimental molecular coordinates (RMSD < 0.1 Å).

3.2 MM Sampling and QM/MM Methodology

We performed non-polarizable MM sampling in GROMACS 4.0 using the NVT ensemble at 300 K. Full periodic boundary conditions were applied, and bond lengths were held to DFT-optimized values using the LINCS algorithm. The entire simulation length was 5.0ns, intended to sample typical thermal fluctuations in this material. 500ps was allowed for thermal equilibration, after which snapshots were extracted at 20ps intervals to minimize shot-to-shot correlation. QM/MM calculations were performed with the CHARMM-Q-Chem interface. Where noted, the QM/MM calculations account for electronic polarizability of the MM system through the presence of the Drude particles.
3.3 Electronic Structure Calculations

Electronic structure calculations were all performed using the 3-21G basis set at the B3LYP level of theory. To investigate the basis set dependence of each property, we performed selected calculations using the larger cc-pVDZ and aug-cc-pVDZ basis sets. Unless specifically noted, we find negligible basis set dependence (<5% change) for all of the properties discussed in the text.

We determine most excitation energies using time-dependent DFT (TDDFT), with the exception of CT states, which are obtained with CDFT. Becke weights are used to define electron populations in the CDFT framework with charge and spin constrained together.

4 Charge Transport Properties

The motion of charge carriers in OSCs is governed by several material properties. First, the transport gap (also called the band gap) measures the energy difference between free electron and hole carriers. It is formally given by the difference between the ionization potential (IP) and electron affinity (EA), $E_t = IP - EA$. In OSCs the gap is modulated both by the heterogeneity of the system (which gives rise to a distribution of local IPs and EAs) and the intrinsic band width, which is governed by the electronic coupling $V_{RP}$ (also called the hopping integral). Meanwhile, the carrier mobility ($\mu_{e,h}$) is determined by the Marcus ET rates, which is in turn are influenced both by energetic disorder and the magnitude of $V_{RP}$.\textsuperscript{2,5}

4.1 Transport Gap

The prescription for computing the transport gap in Alq$_3$ is straightforward. For a given snapshot, we choose a single monomer and compute QM/MM energies for the cation, anion, and neutral states yielding the transport gap, $E_t = E_+ + E_-$.
By computing $E_t$ for different monomers at a variety of snapshots, we can obtain an estimate of the variations in the gap due to disorder.

In Figure 3, simulation results for EAs and IPs are presented. At a crude level, we first compute the gap with fixed MM point charges, and obtain an EA (IP) of $0.6 \pm 0.05$ ($6.3 \pm 0.06$) eV and a transport gap of 5.4 eV (as measured from the IP and EA onsets). Blurring of the MM charges blue-shifts both EA and IP by .15 eV yielding no effect on $E_t$. Including polarization corrections in the FF blue-shifts the EA onset to $1.3 \pm 0.05$ eV and red-shifts the IP onset to $5.7 \pm 0.05$ eV to give an edge-to-edge transport gap of 4.3 eV. This 1.3 eV polarization correction is a result of the strong interactions of the anion and cation with the charged Drude particles. Indeed, assuming each charge sits in a sphere of radius .7 nm surrounded by a dielectric medium with $\varepsilon_s = 2.9$, we obtain $\Delta E_{pol} = 0.68$ eV for each charge - very close to the observed polarization shift of 0.55 eV (0.65 eV) for the IP (EA). A small representative set of calculations performed using the aug-cc-pVDZ basis red-shifts the $E_t$ modestly by 0.2 eV. Combining the basis set and polarization corrections gives a corrected estimate of 4.1 eV for the transport gap. Thus we see that disorder has a very small effect on the transport levels of Alq$_3$: the shot-to-shot variation in IP or EA is only 0.05 eV, and the site to site variation (not shown) is only 0.01-0.02 eV.

A variety of experimental and theoretical results are available for comparison. Experimentally, IPs and EAs of Alq$_3$ have been determined, yielding band gaps in the range 3.6 - 4.1 eV.\textsuperscript{24,25,33} Our result is at the higher edge of this range. Previous theoretical studies on Alq$_3$ monomers within a PCM report an EA (IP) of 1.7 eV (5.8 eV)\textsuperscript{9} yielding a transport gap of 4.2 eV. Our results are in excellent agreement with these predictions. Although the less expensive PCM calculations agree well with our results, they can only give average values of EA/IP, while the QM/MM treatment also yields distributions describing the effect of disorder on the energetics in OSCs.
4.2 Electronic Coupling

To obtain electronic couplings, we compute the matrix elements \( \langle A^- A | \hat{H} | A^- \rangle \) (for electron transport) and \( \langle A^+ A | \hat{H} | A^+ \rangle \) (for hole transport). We take the quantum region to be a pair of Alq₃ molecules with an excess electron or hole. Two CDFT states are constructed in which the excess charge is constrained to be on one molecule or the other and the electronic coupling between these states is computed using Eq. 4. This is repeated for several near-neighbor pairs at a large number of snapshots. While nuclear heterogeneity has little effect on electron and hole energies, it is expected to significantly influence the electron and hole couplings because of their strong dependence on relative orientation.

Figure 4 shows the B3LYP/3-21G electron and hole hopping parameters for several different pairs (indexed by the lattice vector separating them) with fixed MM point charges. The inset shows that while charge blurring can change individual couplings up to 100 meV, the distributions are not significantly shifted. For a given dimer we note the coupling can vary by as much as a factor of five as a function of time - suggesting significant dynamic heterogeneity of the hopping rate on the nanosecond timescale. There is also obvious static structure in the data: despite the width of the distributions, the couplings typically obey \( V^h(1,-1,1) < V^h(1,0,0) \approx V^h(0,0,0) \) and \( V^e(1,-1,1) < V^e(0,0,0) < V^e(1,0,0) \). Finally, we note that holes tend to have a higher density of very small couplings, while electrons account for most of the high couplings.

Previous theoretical efforts have shown that electron couplings in the perfect \( \beta \) crystal can be up to 289 meV - ten times as large as the largest hole coupling. Meanwhile, in an amorphous sample both electron and hole couplings are in the 0-100 meV range. As our simulations are on a thermalized crystal structure, lying somewhere between the two aforementioned systems, we see...
that disorder tends to progressively enhance small hole couplings while disrupting some of the strong electron transport pathways in Alq₃.

### 4.3 Reorganization and Mobility

$\lambda^e$ ($\lambda^h$) can be computed by: 1) constraining the electron (hole) to be on one monomer and relaxing the structure of the whole system, 2) repeating the process with the electron (hole) constrained on the opposite monomer, and 3) computing $\lambda$ as in Eq. 3. This process takes tens to hundreds of times longer than an energy calculation, and so it is not computationally feasible to compute $\lambda$ for every pair of monomers or every snapshot. In order to generate Table 1, we have therefore modeled only a handful of dimers from a single snapshot.

**Table 1**: Calculated Marcus parameters and rates for various donor/acceptor pairs within Alq₃ crystal, labelled by the lattice vector between the monomers. All energies are reported in meV except for $\Delta G^{CT}$ (eV). Rates are reported in s⁻¹. Rows are arranged in order of increasing Al-Al separation.

As shown in Table 1, the typical electron (hole) reorganization energy in Alq₃ is 337 ± 63 meV (223 ± 47 meV). These values are significantly larger than the typical $V_{RP}$, consistent with the generally poor transport properties (and high reorganization barriers) of organic materials. Meanwhile, the distribution of $\Delta G$ (± 48 meV) is consistent with the width of the IP and EA distributions in Figure 3.
We can further estimate $\lambda_i$ by performing a gas-phase calculation to find $\lambda^e_i = 216$ meV and $\lambda^h_i = 208$ meV so that $\lambda^e_o \approx 111$ meV while $\lambda^h_o \approx 15$ meV. Thus, the reorganization energy for electrons is larger primarily because the environment traps an excess electron more strongly than an excess hole. This effect can be rationalized by noting that the electron wavefunction is typically more delocalized and therefore more susceptible to environmental fluctuations.

As illustrated in Table 1, with $\lambda$, $\Delta G$, and $V_{RP}$ for a given pair, we can predict the rate of ET via Eq. 1, and we note that in 8 of 11 cases the rate of ET is larger than that for hole transfer. The primary differentiating factor is that the typical hopping integral for electrons is considerably larger than for holes. In most cases, this is enough to overcome the difference in activation barriers, which typically favors holes. Our finding agrees qualitatively with the experimental observation that Alq$_3$ is a good electron transport material, with $\mu_e \approx 100 \mu_h$. Because of heterogeneity in $k_e$ and $k_h$, it is not a trivial matter to make a quantitative prediction of the mobility based on these rates. Since $\mu$ is most sensitive to the slow, rate limiting values of $k$, one must simulate carrier diffusion using the given hopping rates to obtain mobilities. Such a simulation is beyond the scope of this tutorial, but the feasibility of such mesoscopic simulations provides the final link between atomistic data and bulk properties.

5 Optical Properties

The optical response of Alq$_3$ is dominated by two Frenkel-type excitons: a singlet state that fluoresces in the green and a triplet that phosphoresces in the red. However, the activity of Alq$_3$ in OLEDs also depends critically on the distribution of CT excitons, which are intermediates in the process of electron-hole recombination. In contrast with transport properties that describe ground state behavior, optical properties pertain to excited states making them somewhat more challenging from a simulation perspective. In what follows, we focus on just two features: the spectral densities of the various states and the rate of CT recombination to the ground state.
5.1 Spectral Density

To generate singlet and triplet exciton spectral densities, the quantum region of the QM/MM system was chosen to be a single monomer, and TDDFT was used to obtain the lowest lying singlet and triplet states at a variety of snapshots. For CT excitons, a (0,0,0) dimer pair was chosen as the quantum region and intermolecular CT energies were computed as the difference between the CDFT $A^+A^-$ and AA state energies for each geometry snapshot. The resulting spectral densities are presented in Figure 5.

Figure 5 shows singlet excitons centered at 2.6 ± 0.08eV, triplet excitons at 2.0 ± 0.04 eV and CT state energies at 3.7 ± 0.2 eV (all with charge blurring). Thus we see immediately that exciton and CT energies are more sensitive to disorder than either IP or EA. As a result, diffusion of these states will be more strongly influenced by energetic trapping than was the case for charge transport, where fluctuations in the hopping parameter dominated the mobility. The singlet and triplet exciton results can be compared to a range of experimental and theoretical studies. Optical absorbance studies place the singlet exciton at 2.7 eV, while a gas-phase TDDFT calculation finds an exciton energy of 2.8 eV. For the triplet, phosphorescence studies find energies of 2.03-2.10 eV while gas-phase calculations report 2.1 eV. Our exciton energies are thus fairly consistent with the existing data and suggest only a very small environmental effect on the Frenkel-type exciton energies.

One important point is that while triplet and CT excitons are insensitive to blurring (as all properties discussed so far have been) the singlet is quite sensitive to blurring (Figure 5,inset). The average singlet energy shifts by 0.3 eV as $\sigma$ is increased from zero (point MM charges) to infinity.
(no MM charges). For the value of $\sigma=3.5$ Å used here, there is only a small ($<0.1$ eV) difference between the QM/MM and pure QM calculations for the singlet, which is physically realistic.

Little is known experimentally about the CT states, so that calculations like the ones presented here are the primary source of information about these intermediates. Figure 5 includes the distribution of CT energies both with and without polarization; polarization shifts the average CT energy by 0.2 eV and clearly increases the density of deeply trapped CT states (i.e. states $>1$ eV below the band edge). These deeply trapped states could play an important role in OLEDs as the penultimate state of the electron-hole pair.

5.2 Electronic Coupling

To predict the electronic coupling between the neutral ground state and CT exciton, we need to compute the matrix element $\langle A^+A^-|\hat{H}|AA \rangle$ using Eq. 4. As previously, we model heterogeneity by computing $V_{RP}$ for multiple geometry snapshots sampled from the MM trajectory. Figure 6 shows the resulting CT electronic coupling for the (0,0,0) dimer using 3-21G. While the distribution is broad, we note that these CT couplings are 2-3 times larger than the typical electron and hole couplings in Figure 4, reflecting the fact that in the CT state the electron and hole attract one another, leading to larger overlap.

We consider two corrections to the results in Figure 6. We see that blurring somewhat narrows, but does not shift, the distribution. Further, applying the polarizable FF is expected to have only a small effect on $V_{RP}$, which primarily involves the reactant and product wavefunctions, not their energies. Thus our results suggest that the CT-to-ground coupling is significantly larger than the electron or hole coupling, tending to increase the charge recombination rate.
5.3 Charge-Transfer Reorganization

Just as for charge transport, there is a $\lambda$ associated with the formation of a localized CT state. However, while charge transport typically occurs in the normal regime ($\Delta G < \lambda$), the inverted regime ($\Delta G > \lambda$) is relevant for CT states. Thus, while small values of $\lambda$ speed up transport, they slow charge recombination. To evaluate the significance of this, we compute the CT reorganization energy for a number of snapshots using Eq. 3 with $R = A^+A^-$ and $P = AA$ (Table 1).

We find $\lambda^{CT} = 384 \pm 133$ meV. If the monomers did not interact, we would expect $\lambda^{CT}$ to be the average of electron and hole reorganization energies: $\frac{1}{2}(\lambda^e + \lambda^h) = 315$ meV. However, the dimers here are nearest-neighbors so that a significant portion of the relaxation energy comes from the two monomers approaching each other in the relaxed $A^+A^-$ structure, improving the attractive Coulomb interaction and increasing $\lambda_i^{CT}$ relative to the isolated monomers’ value. We find that the pairs with the largest $\lambda^{CT}$ also tend to have the smallest Al-Al separations, further supporting this conclusion.

Finally, with the Marcus parameters in hand for several pairs, we can predict the rate of charge recombination to the ground state ($k_{cr}$) using Eq. 1. The results in Table 1 yield extremely slow rates, with a typical CT lifetime of $\gg 1$ s. This long lifetime is primarily due to the large disparity between $\Delta G (\approx 3.5$ eV) and $\lambda^{CT} (\approx 4$ eV) leading to extremely slow rates in the inverted regime. Thus, direct charge recombination to the ground state is not likely to be a significant loss mechanism for Alq$_3$ in OLED applications, where the rate of exciton formation will be many orders of magnitude faster than these recombination rates.

6 Conclusions

In this tutorial, we have demonstrated how simulation can be used as a tool to study disordered OSCs. Taking Alq$_3$ as a prototypical example, we have shown how to compute its electronic properties within a complex, heterogeneous environment. Our results are in good agreement with existing experimental findings, and reinforce the idea that while exciton transport in Alq$_3$ may be
limited by energetic disorder, charge transport is limited by fluctuations in electronic coupling.

The basis of our investigation is a synthesis of tools that together provide an efficient means of computing accurate electronic properties in a large, disordered system. The primary approximation is the assumption that the electronic states are localized, which is a necessary component for the QM/MM decomposition. This is not generally valid in inorganic devices but is thought to hold quite generally in OSCs, where Anderson localization dominates the energy landscape.

Moving forward, a number of extensions of the present work should be explored. Most importantly, to make simulations of this type into a predictive tool, these ideas should be applied to a wider array of OSC systems. Here we demonstrate the techniques on a single material while carefully testing sensitivity to the computational parameters. Similar calculations for the alphabet soup of popular OSC materials - C\(_{60}\), TPD, P3HT, CuPc ... - will lead to a recipe of simulation parameters most accurate for a range of systems. Guidelines of this sort are crucial in addressing technologically relevant structures, such as donor-acceptor interfaces and bulk heterojunctions.

On a technical level, the weakest step in our methodology is clearly the process of MM sampling. We use a single, long MM trajectory to sample the configuration space. Because these materials are glassy, better phase space sampling could be obtained either from Monte Carlo or parallel tempering simulations. These effects would be particularly important for charge transport, where mobilities are dominated by rare trap configurations in the wings of the distribution.\(^8\) Further, it is not entirely clear that MM provides an adequate picture of the energy landscape. In this respect, it would be interesting to explore the impact of intramolecular reorganization on the exciton bands using a full QM/MM trajectory. Another key area of improvement is the \textit{ab initio} description of the molecular excited states. Even with the best existing functionals, TDDFT cannot predict exciton energies to a precision better than 0.3-0.4 eV.\(^{32,39}\) Clearly this is unacceptable if one wants to have truly black-box tools for describing a wide range of materials.

The methodology presented above can be further extended to explore an even wider range of essential material properties. Here, we have not computed any charge carrier mobilities, but a prediction of this type is within reach by employing our calculated rates in kinetic Monte Carlo
simulations. Alternatively, although the present tutorial has focused on parameters governing charge transfer, analogous simulations of exciton transfer could reveal exciton diffusion lengths in disordered materials. All of the above applications would require some enhancement of our existing computational machinery, but would augment our ability to understand and predict the properties of OSCs.
