INTRODUCTION

With particular reference to circuits we study the jump behavior, that is, the seemingly discontinuous change in state of systems driven by constrained (or implicitly defined) dynamics; i.e., \( \dot{x} = f(x,y) \) where \( f(x,y) = 0 = g(x,y) \). To be specific, dynamics of a circuit are defined implicitly by specifying the velocities (time-derivatives) of capacitor voltages and inductor currents as well as the nonlinear resistive and Kirchhoff constraints that the branch voltages and currents must satisfy. These constraints represent a constraint manifold over the base space of capacitor voltages and inductor currents. The process of integrating the circuit dynamics to obtain the transient response of the circuit consists of "lifting" the specified velocities to a vector field on the constraint manifold ("lifting" is the inverse operation of projecting). Lifting may not, however, be possible at points of singularity of the projection map, from the constraint manifold to the base space. We propose a way of resolving these singularities, consistent with the interpretation that the constraint manifold is a degeneration of very fast or singularly-perturbed dynamics. The physical meaning of this degeneration is the neglect of certain parasitic elements in the course of modelling. The detailed development is in (1).

1. CONSTRAINED DIFFERENTIAL EQUATIONS

Dynamics of circuits, power systems [2] and several other engineering systems are specified (implicitly) by constrained differential equations of the form

\[ \begin{align*}
\dot{x} &= f(x,y) \\
0 &= g(x,y)
\end{align*} \tag{1.1, 1.2} \]

where \( x \in \mathbb{R}^n, y \in \mathbb{R}^m \); \( f: \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n \) and

\( g: \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^m \) are smooth functions. Further, assume that 0 is a regular value of \( g \). We try to interpret (1.1), (1.2) as describing a dynamical system on the \( n \)-dimensional configuration manifold for \( \Sigma \):

\[ M = \{ (x,y) : g(x,y) = 0 \} \subset \mathbb{R}^{n+m} \]

The vector field \( X \) on \( M \) is specified by specifying its projection on the \( x \)-axis, namely,

\[ \pi X (x,y) = f(x,y) \tag{1.3} \]

(here \( \pi: \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n \) is the projection map \( (x,y) \rightarrow x \)). At points at which \( \pi TM(x,y) \); the projection of the tangent space to \( M \) at \((x,y)\) is equal to

\[ \mathbb{R}^n \] it is clear that \( f(x,y) \) uniquely specifies \( X \). Difficulties arise when \( TM(x,y) \subset \mathbb{R}^n \) and \( f(x,y) \) is transverse to \( TM(x,y) \). As specimens, two different kind of behavior are illustrated in Figure 1 at a point where \( M \) has a "fold".

(i) (Figure 1a) \( f \) points out of the manifold \( M \) at \((x_0,y_0)\) so that it would seem that the trajectory would jump off the manifold \( M \), i.e. the \( y \)-coordinate changes discontinuously.

(ii) Figure 1b) \( f \) points into the manifold \( M \) at \((x_0,y_0)\) so that trajectories starting away from \((x_0,y_0)\) do not tend towards \((x_0,y_0)\).

These so called singular points of \( \Sigma \) are the points at which the implicit function theorem fails to hold in (1.2) in order to solve \( y \) as a function of \( x \). At such points \((x_0,y_0)\) it may not be possible to continuously extend an integral curve of \( \Sigma \) and it may be necessary to restart the integral curve of \( \Sigma \) at some \((x_1,y_1)\) satisfying (1.2). We give a physically meaningful way of choosing this \((x_0,y_0)\):

Empirical evidence leads us to postulate as in literature (a recent reference is [3]) that (1.2) is the degenerate limit of (1.1), (1.2) for \( \varepsilon > 0 \) is referred to as the augmented system \( \Sigma_\varepsilon \). For each \( \varepsilon > 0 \) the solution curves to \( \Sigma_\varepsilon \) are well defined.

The uniform limits of these solution curves as \( \varepsilon \downarrow 0 \) (provided they exist) are taken to be the solution concept for \( \Sigma \). This is in keeping with the notion of consistent solutions in singular perturbation theory [4]. Thus, we have the following definition of jump behavior.

Definition 1. (Jump Behavior)

The solution of the system \( \Sigma \) described by (1),(2) is said to admit of jump from \((x_0,y_0)\) to \((x_1,y_1)\) if given \( \delta > 0, J = 0, t_0 > 0 \) such that \( \forall \varepsilon > 0 \),

\[ |x_\varepsilon - x_0| + |y_\varepsilon - y_0| < \delta \]

and for \( t \in [t_0, \alpha] \)

\[ |x(t,\varepsilon) - x(t)| + |y(t,\varepsilon) - y(t)| < \delta \]

where \( x(t,\varepsilon), y(t,\varepsilon) \) is the trajectory of \( \Sigma_\varepsilon \) starting from \((x_\varepsilon,y_\varepsilon)\) at \( t = 0; \tilde{x}(t), \tilde{y}(t) \) is the

* Research supported by DOE under grant ET-A01-22957004.
trajectory of \( \Sigma \) starting from \((x_0, y_0)\)\(\in\)M at \(t=0\) and defined on \([0,a]\).

Remark: The intuitive content of our definition is that trajectories of the augmented system start close to one solution \((x_0, y_0)\) of \((1.2)\) and tend increasing rapidly towards trajectories starting for some other solution \((x_0', y_0')\) of \((1.2)\).

To get a feel for this definition rescale time \(M = \{(x,y) \mid g(x,y) = 0\}\) and defined on \([0,a]\).

\[
\begin{align*}
\frac{dx}{dt} &= f(x,y) \\
\frac{dy}{dt} &= g(x,y)
\end{align*}
\]  

so that in the limit that \(\epsilon \to 0\) equations \((1.5)\), \((1.6)\) would only describe the dynamics of the frozen boundary layer system: \(\Sigma_0 \)

\[
\frac{dy}{dt} = g(x_0, y) \quad \Sigma_0
\]

\[
\frac{dx}{dt} = f(x,y)
\]

The assumptions required for the limits in Definition 1 above to exist are:

**Assumption 1** (Complete Stability of \(\Sigma_0\))

For each \(x \in \Omega\), the system \(\Sigma_0\) is completely stable i.e. if \(\xi(t, y)\) is the trajectory of

\[
\frac{dy}{dt} = g(x_0, y), \quad y(0) = y
\]

then, \(\lim_{t \to 0} \xi(t, y)\) exists and \(G(\xi; g(x_0, y) = 0)\).

Equivalently \(\xi(t, y)\) converges to an equilibrium point of \(\Sigma_0\) for each \(y\).

**Assumption 2** (No Dynamic Bifurcation)

As \((x_0, y_0)\) moves over \(\Omega\), the eigenloci of \(D_2 g(x_0, y_0)\) cross the \(ju\)-axis only at the origin.

The first observation that we make in that definition 1 allows for jump from non-singular points: First some notation: let \(y_0\) be an equilibrium of the system \(\Sigma_0\) and let its attracting set or stable manifold be denoted

\[
S_{y_0} = \{y : \lim_{t \to \infty} \xi(t, y) = y_0\}.
\]

**Theorem 1** (Jump Characterization from Non-Singular Points)

Assume \(y_0\) to be a hyperbolic equilibrium of \(\Sigma_0\) and let \(\sigma(D_2 g(x_0, y_0)) \cap \mathbb{C}^+ \neq \emptyset\). Further let all sufficiently small neighbourhoods \(V\) of \(y_0\) in \(\{x_0\} \times \mathbb{R}^m\) be decomposed as

\[V = (V \cap S_{y_0}^i) \cup (V \cap S_{y_1}^i) \cup \ldots (V \cap S_{y_p}^i)\]

where \(V \cap S_{y_i}^i \neq \emptyset\) for \(i = 1, \ldots, p\) and \(S_{y_i}^i\) are the stable manifolds of the (hyperbolic) equilibria \(y_i\) of \(\Sigma_0\). Then \(\Sigma\) admits of jump from \((x_0, y_0)\) to \((x_0, y_1)\), \((x_0, y_2)\) to \((x_0, y_3)\), \ldots \((x_0, y_p)\) to \((x_0, y_p')\).

Comments: (i) The theorem is visualized in Fig. 2.

(ii) It is intuitive that a subset of \(\Omega\) that does not admit of jumps is \(M = \{(x, y) : g(x, y) = 0, \quad \sigma(D_2 g(x, y)) \cap \mathbb{C}^+ \neq \emptyset\}\). (iii) Of course, a similar theorem holds at singular points:

**Theorem 2** (Jump Characterization from Singular Points)

Let \(\sigma(D_2 g(x_0, y_0)) \cap \{0\} \neq \emptyset\). Then \(\Sigma\) admits of jump from \((x_0', y_0')\) if for all neighbourhoods \(V\) of \((y_0, y_0')\) in \(\{x_0\} \times \mathbb{R}^m\) be decomposed as

\[V = (V \cap S_{y_0}^i) \cup (V \cap S_{y_1}^i) \cup \ldots (V \cap S_{y_p}^i)\]

where \(V \cap S_{y_i}^i \neq \emptyset\) for \(i = 1, \ldots, p\) and the \(S_{y_i}^i\) are stable manifolds of hyperbolic equilibria \(y_i\) of \(\Sigma_0\). The \(\Sigma\) admits of jump from \((x_0, y_0')\) to \((x_0, y_1'), \ldots (x_0, y_p')\).

Comments: (ii) The theorem is visualized in Fig. 3.

(ii) In general the hypothesis of the theorem (equation \((1.7)\)) are verified by a study of the singularity using bifurcation theory. The detailed development is presented in [1]. Here, we show by pictures two of the singularities that occur if \(D_2 g(x_0, y_0')\) has a single zero-eigenvalue.

**Fold-Singularity**

This is shown in Fig. 4. From the viewpoint of \(\Sigma_0\) two equilibria of \(\Sigma_0\) come together and annihilate each other. The flow in the vicinity of the fold boundary is as shown in Fig. 4.

**Cusp-Singularity**

This is shown in Fig. 5. From the viewpoint of \(\Sigma_0\) three equilibria of \(\Sigma_0\) fuse together and result in one equilibrium (conserving index). No jump is necessary at the cusp point and in the vicinity of the cusp point are two fold surfaces which have been studied above.

**Other Singularities**

A complete zoo of other singularities is possible, see for instance [5].
invariant flux controlled. Let \( z \in \mathbb{R}^{n+1} \) represent charges on the capacitors \( (z_1 \in \mathbb{R}^{n_c}) \), fluxes in inductors \( (z_2 \in \mathbb{R}^{n_l}) \) and \( x \in \mathbb{R}^{n_c} \) represent capacitor voltages \( (x_1 \in \mathbb{R}^{n_c}) \) and inductor currents \( (x_2 \in \mathbb{R}^{n_l}) \). Then, we assume

\[
x = h(z)
\]

with \( h : \mathbb{R}^{n_c+n_l} \rightarrow \mathbb{R}^{n_c+n_l} \) a \( C^1 \) diffeomorphism.

We assume that the linear time-invariant resistive n-port has a global hybrid representation i.e. if \( y \) is the hybrid vector of capacitor port currents \( (y_1) \) and inductor port voltages \( (y_2) \) with \( x \) representing power into the n-port then there exists a partition \( \{1, \ldots, n\} \) such that

\[
\begin{align*}
\dot{x}_A &= f_A(y_A, x_B) \\
\dot{y}_B &= f_B(y_A, x_B)
\end{align*}
\]

Using equations (2.1), (2.2) and Coulomb’s, Faraday’s law we have

\[
x = -Dh(h^{-1}(x)) \begin{bmatrix} y_A \\ f_B(y_A, x_B) \end{bmatrix}
\]

\[
0 = x_A - f_A(y_A, x_B)
\]

Note that unless \( A = \emptyset \) (when we have normal form equations) equations (2.3), (2.4) are a pair of constrained differential equations to which we apply the theory of the previous section. The physical significance of various assumptions and perturbations introduced in the foregoing will be presented at the meeting (see, also [1]). We only make a brief comment on the singular-perturbation assumption - (2.4) is the limit as \( \varepsilon \rightarrow 0 \) of

\[
\begin{align*}
\varepsilon y &= x_A - f_A(y_A, x_B) \\
0 &= x_A - f_A(y_A, x_B)
\end{align*}
\]

This perturbation is shown dotted in Fig. 6, and is the multiport generalization of the following:

A current-controlled resistor is envisioned as the singularly perturbed limit as \( \varepsilon \rightarrow 0 \) of the resistor in series with a small linear parasitic inductor because current is the controlling variable. The dual is true for a voltage-controlled resistor.

3. DETERMINISTIC AND NOISY CONSTRAINED DYNAMICAL SYSTEMS

In [6] we study noisy constrained systems of the form

\[
\begin{align*}
\dot{x} &= f(x, y) + \sqrt{\mu} \xi(t) \\
\varepsilon \dot{y} &= g(x, y) + \sqrt{\varepsilon} \eta(t)
\end{align*}
\]

in the limit that \( \varepsilon \rightarrow 0 \) (weakly convergent limits). Here \( f(*) \) and \( g(*) \) are independent vector valued white noise and \( \lambda, \mu \) scale their variance. It is remarkable that in the limit of noise variance tending to zero \( (\lambda, \mu \rightarrow 0) \) the results for noisy constrained systems are quite different from those of the preceding section. Here we only illustrate the differences for the instance of a degenerate van der Pol oscillator.

Example 3.1 (Degenerate van der Pol oscillator).

\[
\begin{align*}
\dot{x} &= y \\
0 &= -x - y^3 + y
\end{align*}
\]

The phase portrait of the degenerate system including jumps from two fold singularities is shown in Fig. 7. Note the relaxation oscillation formed by including the two jumps.

Example 3.2 (Noisy degenerate van der Pol oscillator).

\[
\begin{align*}
\dot{x} &= y + \sqrt{\mu} \xi \\
\varepsilon \dot{y} &= -x - y^3 + y + \sqrt{\varepsilon} \eta
\end{align*}
\]

for \( \lambda, \mu > 0 \) as \( \varepsilon \rightarrow 0 \) the x-process converges (weakly on \( C([0, T], \mathbb{R}^n) \)) to one satisfying

\[
\begin{align*}
\dot{x} &= -x - y^3 + y \\
x &= 0
\end{align*}
\]

where \( y^\lambda \) is plotted for \( \lambda_1, \lambda_2 > 0 \) in Figure 8. In the further limit that \( \varepsilon \rightarrow 0 \) followed by \( \mu \rightarrow 0 \) we have

\[
\begin{align*}
\dot{x} &= f_A(y_A) + \sqrt{\varepsilon} \xi(t) \\
0 &= x_A - f_A(y_A)
\end{align*}
\]

where \( f_A(*) \) is shown heavy in Figure 8. Note the discontinuity of \( \psi \) at \( x = 0 \) and that the relaxation oscillation is broken up by the presence of small noise.
