Limits on the Higgs boson lifetime and width from its decay to four charged leptons

V. Khachatryan et al. a
(CMS Collaboration)
(Received 23 July 2015; published 22 October 2015)

Constraints on the lifetime and width of the Higgs boson are obtained from $H \rightarrow ZZ \rightarrow 4\ell$ events using data recorded by the CMS experiment during the LHC run 1 with an integrated luminosity of 5.1 and 19.7 fb$^{-1}$ at a center-of-mass energy of 7 and 8 TeV, respectively. The measurement of the Higgs boson lifetime is derived from its flight distance in the CMS detector with an upper bound of $\tau_H < 1.9 \times 10^{-13}$ s at the 95% confidence level (C.L.), corresponding to a lower bound on the width of $\Gamma_H > 3.5 \times 10^{-6}$ MeV. The measurement of the width is obtained from an off-shell production technique, generalized to include anomalous couplings of the Higgs boson to two electroweak bosons. From this measurement, a joint constraint is set on the Higgs boson width and a parameter $f_{\Delta Q}$ that expresses an anomalous coupling contribution as an on-shell cross-section fraction. The limit on the Higgs boson width is $\Gamma_H < 46$ MeV with $f_{\Delta Q}$ unconstrained and $\Gamma_H < 26$ MeV for $f_{\Delta Q} = 0$ at the 95% C.L. The constraint $f_{\Delta Q} < 3.8 \times 10^{-3}$ at the 95% C.L. is obtained for the expected standard model Higgs boson width.

I. INTRODUCTION

The discovery of a new boson with mass of about 125 GeV by the ATLAS and CMS experiments [1–3] at the CERN LHC provides support for the standard model (SM) mechanism with a field responsible for generating the masses of elementary particles [4–9]. This new particle is believed to be a Higgs boson ($H$), the scalar particle appearing as an excitation of this field. The measurement of its properties, such as the lifetime, width, and structure of its couplings to the known SM particles, is of high priority to determine its nature.

The CMS and ATLAS experiments have set constraints of $\Gamma_H < 22$ MeV at 95% confidence level (C.L.) on the $H$ boson total width [10,11] from the ratio of off-shell to on-shell production. The precision on $\Gamma_H$ from direct on-shell measurements alone is approximately 1 GeV [12,13], which is significantly larger. The two experiments have also set constraints on the spin-parity properties and anomalous couplings of the $H$ boson [14–18], finding its quantum numbers to be consistent with $J^{PC} = 0^{++}$ but allowing small anomalous coupling contributions. No direct experimental limit on the $H$ boson lifetime was set, and the possible presence of anomalous couplings was not considered in the constraints on the $H$ boson width. This paper provides these two measurements.

aFull author list given at the end of the article.

The measurement of the $H$ boson lifetime in this paper is derived from its flight distance in the CMS detector [19], and the measurement of the width is obtained from the off-shell production technique, generalized to include anomalous couplings of the $H$ boson to two electroweak bosons, WW and ZZ. From the latter measurement, a joint constraint is set on the $H$ boson width and a parameter that quantifies an anomalous coupling contribution as an on-shell cross-section fraction. The event reconstruction and analysis techniques rely on the previously published results [10,16,17,20], and their implementations are discussed in detail. Only the final state with four charged leptons is considered in this paper, but the constraints on the width could be improved by including final states with neutrinos in the off-shell production [10,11]. Indirect constraints on the $H$ boson width and lifetime are also possible through the combination of data on $H$ boson production and decay rates [12,21]. While such a combination tests the compatibility of the data with the SM $H$ boson, it relies on stronger theoretical assumptions such as SM-like coupling ratios among the different final states.

Section II in this paper discusses the analysis methods for measuring the $H$ boson lifetime and for relating the anomalous couplings of the $H$ boson to the measurement of $\Gamma_H$ through the off-shell production technique. Section III discusses the CMS detector and event simulation, and Sec. IV defines the selection criteria used in the analysis. Section V describes the analysis observables, categorization, and any related uncertainty. Section VI provides the constraints on the $H$ boson lifetime, while Sec. VII provides the upper limits for both the $H$ boson width and the anomalous coupling parameter investigated in this paper. The summary of results is provided in Sec. VIII.
II. ANALYSIS TECHNIQUES

The lifetime of each $H$ boson candidate in its rest frame is determined in a four-lepton event as

$$\Delta t = \frac{m_{4\ell}}{p_T} (\Delta \hat{r}_T \cdot \hat{p}_T),$$

(1)

where $m_{4\ell}$ is the four-lepton invariant mass, $\Delta \hat{r}_T$ is the displacement vector between the decay vertex and the production vertex of the $H$ boson in the plane transverse to the beam axis, and $\hat{p}_T$ and $p_T$ are respectively the unit vector and the magnitude of the $H$ boson transverse momentum. The average $\Delta t$ is inversely proportional to the total width:

$$\langle \Delta t \rangle = \tau_H = \frac{\hbar}{\Gamma_H}.$$

(2)

The distribution of the measured lifetime $\Delta t$ is used to set an upper limit on the average lifetime of the $H$ boson, or equivalently a lower limit on its width $\Gamma_H$, and it follows the exponential distribution if known perfectly. The expected SM $H$ boson average lifetime is $\tau_H \approx 48 \text{ fm}/c$ ($16 \times 10^{-8} \text{ fs}$) and is beyond instrumental precision. The technique summarized in Eq. (1) nonetheless allows the first direct experimental constraint on $\tau_H$.

The upper bound on $\Gamma_H$ is set using the off-shell production method [22–24] and follows the technique developed by CMS [10], where the gluon fusion and weak vector boson fusion (VBF) production mechanisms were considered in the analysis. The technique considers the $H$ boson production relationship between the on-shell ($105.6 < m_{4\ell} < 140.6 \text{ GeV}$) and off-shell ($220 < m_{4\ell} < 1600 \text{ GeV}$) regions. Denoting each production mechanism with $vv \rightarrow H \rightarrow ZZ$ for $H$ boson coupling to either strong ($vv = gg$) or weak ($vv = VV$) vector bosons $vv$, the on-shell and off-shell yields are related by

$$\sigma_{\text{on-shell}}^{\nu\nu \rightarrow H \rightarrow ZZ} \propto \mu_{\nu\nu H} \Gamma_H \text{ and } \sigma_{\text{off-shell}}^{\nu\nu \rightarrow H \rightarrow ZZ} \propto \mu_{\nu\nu H} \Gamma_H.$$

(3)

where $\mu_{\nu\nu H}$ is the on-shell signal strength, the ratio of the observed and expected on-shell production cross sections for the four-lepton final state, which is denoted by either $\mu_{ggH}$ for gluon fusion production or $\mu_{VVH}$ for VBF production. The $t\bar{t}H$ process is driven by the $H$ boson couplings to heavy quarks like the gluon fusion process, and the $VH$ process by the $H$ boson couplings to weak vector bosons like the VBF process. They are therefore parametrized with the same on-shell signal strengths $\mu_{ggH}$ and $\mu_{VVH}$, respectively. The effects of signal-background interference are not shown in Eq. (3) for illustration but are taken into account in the analysis.

The relationship in Eq. (3) implies variations of the $vvH$ couplings as a function of $m_{4\ell}$. This variation is assumed to be as in the SM in the gluon fusion process. The assumption

is valid as long as the production is dominated by the top-quark loop and no new particles contribute to this loop. Variation of the $HVV$ couplings, either in the VBF or VH production or in the $H \rightarrow ZZ$ decay, may depend on anomalous coupling contributions. An enhancement of the off-shell signal production is suggested with anomalous $HVV$ couplings [10,25–27], but neither experimental studies of off-shell production nor realistic treatment of signal-background interference has been done with these anomalous couplings. We extend the methodology of the recent analysis of anomalous $HVV$ couplings of the $H$ boson [17] to study these couplings and introduce in the scattering amplitude an additional term that depends on the $H$ boson invariant mass, $(q_{V1} + q_{V2})^2$:

$$A(HVV) \propto \left[ a_1 - e^{i\phi_{1Q}} \frac{(q_{V1} + q_{V2})^2 - e^{i\phi_{1Q}} \frac{q_{V1}^2 + q_{V2}^2}{(\Lambda_Q)^2}}{(\Lambda_{1})^2} \right] \times m_V^2 \epsilon_{V1}^\ast \epsilon_{V2}^\ast + a_2 f^{(2)}_{\mu\nu} + a_3 f^{(1)}_{\mu\nu} f^{(2)}_{\mu\nu},$$

(4)

where $f^{(i)}_{\mu\nu} = e_{V1}^\mu q_{V1}^\nu - e_{V2}^\mu q_{V2}^\nu$ is the field strength tensor of a gauge boson with momentum $q_{V1}$ and polarization vector $e_{V1}$, $\tilde{f}^{(2)}_{\mu
u} = \frac{1}{2} \epsilon_{\mu\rho\nu\sigma} f^{(2)}_{\rho\sigma}$ is the dual field strength tensor, the superscript * designates a complex conjugate, and $m_V$ is the pole mass of a vector boson. The $a_i$ are complex coefficients, and the $\phi_{1Q}$ or $\Lambda_Q$ may be interpreted as the scales of beyond-the-SM (BSM) physics. The complex phase of the $\Lambda_{1}$ and $\Lambda_Q$ terms are explicitly given as $\phi_{1Q}$ and $\phi_{Q\Omega}$, respectively. Equation (4) describes all anomalous contributions up to dimension five operators. In the SM, only the $a_1$ term appears at tree level in couplings to $ZZ$ and $WW$, and it remains dominant after loop corrections. Constraints on the anomalous contributions from the $a_2$, $a_3$ and $\Lambda_1$ terms to the $H \rightarrow VV$ decay have been set by the CMS and ATLAS experiments [16–18] through on-shell $H$ boson production.

The $\Lambda_Q$ term depends only on the invariant mass of the $H$ boson, so its contribution is not distinguishable from the SM in the on-shell region. This paper tests the $\Lambda_Q$ term through the on-shell region. Equation (4) describes both $ZZ$ and $WW$ couplings, and it is assumed that $\Lambda_Q$ is the same for both. The ratio of any loop contribution from a heavy particle in the $HVV$ scattering amplitude to the SM tree-level $a_1$ term would be predominantly real, and the imaginary part of the ratio would be small. If the contribution instead comes from an additional term to the SM Lagrangian itself, this ratio can only be real. Therefore, only real coupling ratios are tested such that $\cos \phi_{1Q} = \pm 1$ and $a_1 \geq 0$, where $a_1 = 2$ and $\Lambda_Q \rightarrow \infty$ correspond to the tree-level SM $HVV$ scattering with $\mu_{ggH} = \mu_{VVH} = 1$. The effective cross-section fraction due to the $\Lambda_Q$ term, denoted as $f_{\Lambda_{Q}}$, allows a parameterization similar to the conventions of $\Lambda_1$ in Ref. [17]. It is defined for the on-shell
The $gg \rightarrow H \rightarrow VV$ process assuming no contribution from other anomalous couplings as

$$f_{\lambda Q} = \frac{m_H^4 / \Lambda_Q^4}{|a|^2 + m_H^4 / \Lambda_Q^4}. \quad (5)$$

The $HVV$ couplings in Eq. (4) appear in both production and decay for the VBF and $VH$ mechanisms while they appear only in decay for $H$ boson production through gluon fusion. Isolating the former two production mechanisms, therefore, enhances the sensitivity to the contribution of anomalous couplings. While the previous study of the $H$ boson width [10] employs dijet tagging only in the on-shell region, VBF jet identification is also extended to the off-shell region in this analysis with techniques from Ref. [20]. A joint constraint is obtained on $\Gamma_H, f_{\lambda Q}, \mu_{ggH}$, and $\mu_{VVH}$, where the latter two parameters correspond to the $H$ production strength in gluon fusion, and VBF or $VH$ production mechanisms in the on-shell region, respectively.

The CMS detector, described in detail in Ref. [19], provides excellent resolution for the measurement of electron and muon momenta and impact parameters near the LHC beam interaction region. Within the superconducting solenoid (3.8 T) volume of CMS, there are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL) and a brass and scintillator hadron calorimeter. Muons are identified in gas-ionization detectors embedded in the iron flux return placed outside the solenoid. The data samples used in this analysis are the same as those described in Refs. [10,16,17,20], corresponding to an integrated luminosity of 5.1 fb$^{-1}$ collected in proton-proton collisions at LHC with center-of-mass energy of 7 TeV in 2011 and 19.7 fb$^{-1}$ at 8 TeV in 2012. The uncertainties in the integrated luminosity measurement are 2.2% and 2.6% for the 2011 and 2012 data sets, respectively [28,29].

The $H$ boson signal production through gluon fusion or in association with two fermions from either vector boson fusion or associated vector boson production may interfere with the background $4\ell^+$ production with the same initial and final states. The background $4\ell^+$ production is considered to be any process that does not include a contribution from the $H$ boson signal. The on-shell Monte Carlo (MC) simulation does not require interference with the background because of the relatively small $H$ boson width [10]. The off-shell production leads to a broad $m_{4\ell}$ spectrum and is generated using the full treatment of the interference between the signal and background for each production mechanism. Therefore, different techniques and tools have been used for on-shell and off-shell simulation. The simulation of the $H$ boson signal is performed at the measured value of the $H$ boson pole mass $m_H = 125.6$ GeV in the $4\ell^+$ final state [16], and the expected SM $H$ boson width $\Gamma_H^{SM} = 4.15$ MeV [30,31] along with several other $\Gamma_H$ reference values.

The two dominant $H$ boson production mechanisms, gluon fusion and VBF, are generated on-shell at next-to-leading order (NLO) in perturbative quantum chromodynamics (QCD) using the powheg [32-34] event generator. The decay of the $H$ boson via $H \rightarrow ZZ \rightarrow 4\ell^+$, including interference effects of identical leptons in the final state and nonzero lifetime of the $H$ boson, is modeled with JHU/Gen 4.8.1 [35-37]. In addition, gluon fusion production with up to two jets at NLO in QCD has been generated using POWHEG with the HJJ program [38], where the MINLO procedure [39] is used to resum all large logarithms associated with the presence of a scale for merging the matrix element and the parton shower contributions. In all of the above cases, simulations with a wide range of masses $m_H$ up to 1000 GeV [20] for $H$ boson on-shell signal production at NLO in QCD have been used to calibrate the behavior of associated particles in the simulation of off-shell $H$ boson signal at leading order (LO) in QCD, which is described below. The $VH$ and $ttH$ production mechanisms of the $H$ boson, which have the smallest expected cross sections, and the subsequent $H$ boson prompt decays are simulated on-shell using PYTHIA 6.4.24 [40].

Four different values of the $H$ boson lifetime have been generated with $c\tau_H = 0$, 100, 500, 1000 $\mu$m for the gluon fusion production mechanism, and these samples are reweighted to model the values of lifetime in between the generated values. The only difference between gluon fusion and the other production mechanisms relevant for the constraint on the lifetime is the $H$ boson $p_T$ spectrum, so reweighting as a function of $p_T$ allows the modeling of the different production mechanisms with nonzero $H$ boson lifetime. Following the formalism in Eq. (4) for spin-zero and including nonzero spin hypotheses, JHU/Gen simulations for a variety of $H$ boson production (gluon fusion, VBF, $VH$, $ttH$, $q\bar{q}$) and decay ($H \rightarrow ZZ/Z^0/\gamma^*/\gamma\gamma^* \rightarrow 4\ell^+$) modes have been generated with SM and BSM couplings to validate model independence of the lifetime analysis. This simulation is detailed in Ref. [17].

The off-shell $H$ boson signal and the interference effects with the background are included at LO in QCD for gluon fusion, VBF, and $VH$ mechanisms, while the $ttH$ production is highly suppressed at higher masses and is therefore not simulated off-shell [30,31]. On-shell and off-shell events from gluon fusion production are generated with the MCFM 6.7 [24,41,42] and GG2VV 3.1.5 [43] MC generators while those for the VBF and associated production with an electroweak boson $V$ are generated with PHANTOM 1.2.3 [44]. The leptonic decay of the associated $V$ boson is modeled with a reweighting procedure based on the branching ratios of the $V$ boson [45], and the relatively small contribution of $HH$ production is removed from the PHANTOM simulation. Pure signal, pure background, and
analytical reweighting for the anomalous couplings in off-shell allows for both reweighting and event simulation with five signal models with the production, its background, and their interference for the with the above technique, which includes BSM models correspond to the effective fractions enhancements are seen in the off-shell region. The four Γ terms in Eq. (4). In all cases, the on-shell yield and the Γ SM total. An Γ background K factor have a small contributions. Uncertainties due to the limited theoretical also assumed for the background and interference contributions. The same K factors as in signal are corrections are known to an accuracy of NNLO for the VBF background[46]. Similarly, QCD and electroweak corrections are known to an accuracy of NNLO for the signal and interference terms [49]. Therefore, the same K factor is used for the signal and background [46]. Similarly, QCD and electroweak corrections are known to an accuracy of NNLO for the VBF and VH signal contributions [30,31,50], but no calculation exists beyond the LO for the gg → ZZ continuum background, it has been recently shown [47] that the soft collinear approximation is able to describe the background cross section and the interference term at NNLO. Further calculations also show that the K factors are very similar at NLO for the signal and background [48] and at NNLO for the signal and interference terms [49]. Therefore, the same K factor is used for the signal and background [46]. Similarly, QCD and electroweak corrections are known to an accuracy of NNLO for the VBF and VH signal contributions [30,31,50], but no calculation exists beyond the LO for the corresponding background contributions. The same K factors as in signal are also assumed for the background and interference contributions. Uncertainties due to the limited theoretical knowledge of the background K factor have a small impact on the final results.

The background q̅q → ZZ process is simulated using POWHEG at NLO in QCD with no interference with H boson signal production. The NLO electroweak calculations [51,52] predict negative, m_{4ℓ}-dependent corrections to this process for on-shell Z boson pairs and are taken into account. In addition, a two-jet inclusive MadGraph 5.1.3.30 [53] simulation is used to check jet categorization in the q̅q → ZZ process. PYTHIA is used to simulate parton showering and hadronization for all MC signal and background events. The generated MC events are subsequently processed with the CMS full detector simulation, based on Geant4 [54], and reconstructed using the same algorithm used for the events in data.

The background from Z production with associated jets, denoted as Z + X, comes from the production of Z and WZ bosons in association with jets as well as from tt production with one or two jets misidentified as an electron or a muon. The estimation of the Z + X background in the four-lepton final state is obtained from data control regions without relying on simulation [16].

![Figure 1](image_url)
IV. EVENT SELECTION

The event reconstruction and selection requirements are the same as those in the previous measurements of the $H$ boson properties in the $H \rightarrow 4\ell$ channel \cite{10,16,17,20}. Only small modifications are made to the lepton impact parameter requirements in the lifetime analysis to retain potential signal with a displaced four-lepton vertex.

As in previous measurements \cite{10,16,17,20}, events are triggered by requiring the presence of two leptons (electrons or muons) with asymmetric requirements on their $p_T$. A triple-electron trigger is also used. Electron candidates are defined by a reconstructed charged-particle track in the tracker pointing to an energy deposition in the ECAL. A muon candidate is identified as a charged-particle track in the muon system that matches a track reconstructed in the tracker. The electron energy is measured primarily from the ECAL cluster energy, while the muon momentum and the charged-lepton impact parameters near the interaction region are measured primarily by the tracker. Electrons and muons are required to be isolated from other charged and neutral particles \cite{16}. Electrons (muons) are reconstructed for $p_T > 7.5$ GeV within the geometrical acceptance $|\eta| < 2.4$ \cite{55,56}. Trigger and reconstruction efficiencies for muons and electrons are found to be independent on the lifetime of the $H$ boson, similar to other studies of long-lived particles \cite{57,58}.

Events are selected with at least four identified and isolated electrons or muons to form the four-lepton candidate. Two $Z \rightarrow \ell^+\ell^-$ candidates originating from a pair of leptons of the same flavor and opposite charge are required. The $\ell^+\ell^-$ pair with an invariant mass, $m_1$, nearest to the nominal $Z$ boson mass is denoted $Z_1$ and is retained if it is in the range $40 < m_1 < 120$ GeV. A second $\ell^+\ell^-$ pair, denoted $Z_2$, is required to have an invariant mass $12 < m_2 < 120$ GeV. If more than one $Z_2$ candidate satisfies all criteria, the pair of leptons with the highest scalar $p_T$ sum is chosen. The lepton $p_T$ selection is tightened with respect to the trigger by requiring at least one lepton to have $p_T > 20$ GeV, another one to have $p_T > 10$ GeV, and any oppositely charged pair of leptons among the four selected to satisfy $m_{\ell\ell} > 4$ GeV regardless of flavor. A $Z$ boson decay into a lepton pair can be accompanied by final state radiation where the radiated photon is associated to the corresponding lepton to form the $Z$ boson candidate as $Z \rightarrow \ell^+\ell^-\gamma$ \cite{16}.

The electrons and muons that comprise the four-lepton candidate are checked for consistency with a reference vertex. In the width analysis, this comparison is done with respect to the primary vertex of each event, defined as the one passing the standard vertex requirements \cite{59} and having the largest $\sum p_T^4$ of all associated charged tracks. The significance of the three-dimensional impact parameter (SIP) of each lepton, calculated from the track parameters and their uncertainties at the point of closest approach to this primary vertex, is required to be less than 4 \cite{16}. This requirement does not allow for a displaced vertex, so in order to constrain the lifetime of the $H$ boson, the reference of the comparison is switched to the vertex formed by the two leptons from the $Z_1$ candidate. The SIP of the two leptons from $Z_1$ is required to be less than 4, and that of the remaining two leptons is required to be less than 5. An additional requirement $\chi^2_{\ell\ell}/\text{dof} < 6$ for the four-lepton vertex is applied to further suppress the $Z + X$ background. Both analyses also require the presence of the reconstructed proton-proton collision vertex in each event. The combination of these requirements allows for the detection of a displaced $H$ boson decay while keeping the selection efficiencies similar between the two criteria.

After selection, the prompt-decay backgrounds originate from the $q\bar{q} \rightarrow ZZ/Z\ell^+ \rightarrow 4\ell$ and $gg \rightarrow ZZ/Z\ell^+ \rightarrow 4\ell$ processes together with $4\ell$ production with associated fermions, such as VBF and associated $V$ production. These backgrounds are evaluated from simulation following Refs. \cite{10,16}. The $Z + X$ background may include displaced vertices due to b-quark jets and is evaluated using the observed control samples as discussed in Ref. \cite{16}, which employs the tight-to-loose lepton misidentification method. While the misidentification rates are consistent between the two different vertex selection requirements, the overall number of selected $Z + X$ background events is about 15% higher when using the vertex requirements of the lifetime measurement. The number of prompt-decay signal and background events is about 2% higher with these lifetime measurement requirements.

In the width analysis, the presence of jets is used as an indication of VBF or associated production with an electroweak boson decaying hadronically, such as $WH$ or $ZH$. The CMS particle-flow (PF) algorithm \cite{60-63}, which combines information from all subdetectors, is used to provide an event description in the form of reconstructed particle candidates. The PF candidates are then used to build jets and lepton isolation quantities. Jets are reconstructed using the anti-$k_T$ clustering algorithm \cite{64} with a distance parameter of 0.5, as implemented in the FastJet package \cite{65,66}. Jet energy corrections are applied as a function of the jet $p_T$ and $\eta$ \cite{67}. An offset correction based on the jet area method is applied to subtract the energy contribution not associated with the high-$p_T$ scattering such as electronic noise and pileup, the latter of which results primarily from other pp collisions in the same bunch crossing \cite{67-69}. Jets are only considered if they have $p_T > 30$ GeV and $|\eta| < 4.7$, and if they are separated from the lepton candidates and identified final-state radiation photons.

Within the tracker acceptance, the jets are reconstructed with the constraint that the charged particles are compatible with the primary vertex. In addition, jets arising from the primary interaction are separated using a multivariate discriminator from those reconstructed due to energy deposits associated with pileup interactions, particularly...
those from neutral particles not associated with the primary vertex of the event. The discrimination is based on the differences in the jet shapes, the relative multiplicity of charged and neutral components, and the fraction of \( p_T \) carried by the hardest components [70]. In the width analysis, the events are split into two categories: those with two or more selected jets (dijet category) and the remaining events (nondijet category). When more than two jets are selected, the two jets with the highest \( p_T \) are chosen for further analysis.

The systematic uncertainties in the event selection are generally the same as those investigated in Refs. [10,16,17,20]. Among the yield uncertainties, experimental systematic uncertainties are evaluated from data for the lepton trigger efficiency and the combination of object reconstruction, identification, and isolation efficiencies. Signal and background uncertainties after the lifetime analysis selection are found to be consistent with the width analysis selection. Most of the signal normalization uncertainties are statistical in nature because the signal strength is left unconstrained and because the systematic uncertainties affect only the relative efficiency of \( 4e, 4\mu, \) and \( 2e2\mu \) reconstruction. The overall predicted signal cross section is, therefore, not directly used in the analysis, while the theoretical uncertainties in the \( 4\ell \) background remain unchanged compared to Refs. [10,16]. The \( Z + X \) yield uncertainties are estimated to be 20%, 40%, and 25% for the \( 4e, 4\mu, \) and \( 2e2\mu \) decay channels, respectively, and also remain unchanged compared to Ref. [16].

\[
\begin{align*}
D_{\text{jet}} &= \left[ 1 + \frac{\mathcal{P}_{\text{VBF}}(\tilde{\Omega}^{H+\ell}_H, m_{4\ell})}{\mathcal{P}_{\text{HJJ}}(\tilde{\Omega}^{H+\ell}_H, m_{4\ell})} \right]^{-1},
\end{align*}
\]

where \( \mathcal{P}_{\text{VBF}} \) and \( \mathcal{P}_{\text{HJJ}} \) are probabilities obtained from the HUGen matrix elements for the VBF process and gluon fusion in association with two jets \((H+2\text{jets})\) within the MELA framework [20]. This discriminant is equally efficient in separating VBF from either \( gg \rightarrow H+2\text{jets} \) signal or \( gg \) or \( q\bar{q} \rightarrow 4\ell+2\text{jets} \) background because jet correlations in these processes are distinct from the VBF process.

In the on-shell region, the \( D_{\text{jet}} \) discriminant is one of the width analysis observables used in the dijet category. The \( D_{\text{jet}} \) distribution shown in Fig. 2 (top) is used to distinguish gluon fusion, VBF, and \( VH \) production mechanisms in this category. The \( p_T \) of the \( 4\ell \) system is used to distinguish the production mechanism of the remaining on-shell events in the nondijet category. In the off-shell region, the requirement \( D_{\text{jet}} \geq 0.5 \) is applied instead, keeping nearly half of the VBF events and less than 4% of all other processes, with only a small dependence on \( m_{4\ell} \). Events that fail this requirement enter the nondijet category in the off-shell region. The different treatment of \( D_{\text{jet}} \) between the on-shell and off-shell regions keeps the observables the same as in the previous width analysis [10].

Uncertainties in modeling the jet distributions affect the separation of events between the two dijet categories but do not affect the combined yield of either signal or background events. For the on-shell dijet category, a 30% normalization uncertainty is taken into account for the \( gg \rightarrow H+2\text{jets} \) signal cross section while the uncertainty in the selection of two or more jets from VBF production is 10%. The \( D_{\text{jet}} \) distribution uncertainties other than those for \( Z + X \) are estimated by comparing alternative MC generators and

V. OBSERVABLES

Several observables, such as the four-lepton invariant mass, \( m_{4\ell} \), or the measured lifetime of each \( H \) boson candidate, \( \Delta t \), are used either as input to likelihood fits or to categorize events in this paper. The full list of observables in each category is shown in Table I, and they are discussed in detail below. The full kinematic information from each event is extracted using the MELA kinematic discriminants, which make use of the correlation between either the two jets and the \( H \) boson to identify the production mechanism, or the \( H \rightarrow 4\ell \) decay products to identify the decay kinematics. These discriminants use either five, in the case of production, or seven, in the case of decay, mass and angular input observables \( \tilde{\Omega} [35,37] \) to describe kinematics at LO in QCD. The \( p_T \) of either the combined \( H \) boson and 2 jets system for the production discriminant (\( D_{\text{jet}} \)) [20] or the \( H \) boson itself for the decay discriminants (\( D_{\text{kin}} \)) [2] is not included in the input observables in order to reduce associated uncertainties.

The discriminant sensitive to the VBF signal topology is calculated as

\[
\Delta t = \frac{1}{\mathcal{P}_{\text{HJJ}}(\tilde{\Omega}^{H+\ell}_H, m_{4\ell}) + \mathcal{P}_{\text{VBF}}(\tilde{\Omega}^{H+\ell}_H, m_{4\ell})},
\]
tunings, where smaller effects from uncertainties due to jet energy scale and resolution are also included.

In the off-shell region, the uncertainties in the $D_{jet}$ distribution imply uncertainties in the categorization requirement $D_{jet} > 0.5$. To determine the uncertainty in the dijet selection, NLO QCD simulation with POWHEG is compared to the two LO generators PHANTOM and JHUGen for the VBF production, all with parton showering simulated with PYTHIA. For this comparison, $VH$ production is omitted from the PHANTOM simulation since no events in association with electroweak boson production pass the $D_{jet} > 0.5$ requirement. The efficiency of categorization for VBF-like events is stable within 5%, and the main difference comes from the uncertainty in the additional jet radiation after the hadronization of simulated events at LO or NLO in QCD using PYTHIA. A similar comparison of the signal production in gluon fusion is performed between the POWHEG simulations at NLO in QCD with and without the MINLO procedure for multijet simulation, and two LO generators MCFM and GG2VV. With proper matching of the hadronization scale for the LO generators in PYTHIA [71], a good agreement within 15% is found between all generators, with absolute dijet categorization efficiency of approximately 3%. The $m_{4\ell}$ dependence of the categorization efficiency is found to be similar between the different generators.

With the above uncertainties, the contributions of the signal, background, and their interference in the off-shell region for each category are obtained with the PHANTOM generator for the VBF and associated electroweak boson production, and with the MCFM generator for the gluon fusion production. The dijet categorization efficiency as a function of $m_{4\ell}$ is reweighted to the POWHEG+MINLO prediction for gluon fusion signal contribution, and the same reweighting is used in the background and interference contributions. For the $q\bar{q} \rightarrow ZZ$ background, the comparison of the NLO QCD simulation with POWHEG with the two-jet inclusive MadGraph simulation leads to a 25% uncertainty in the dijet categorization. Both dijet categorization and its uncertainty have negligible $m_{4\ell}$ dependence, and the dijet categorization efficiency is around 0.6%. An uncertainty of 100% is assigned to the categorization of $Z + X$ events, primarily due to statistical limitations in the data-driven estimate. This uncertainty has a negligible contribution to the results since the contribution of $Z + X$ is small in the total off-shell expected yield and negligible in the dijet category.

The discriminant sensitive to the $gg \rightarrow 4\ell$ kinematics is calculated as

$$D_{kin} = \left[ 1 + \frac{\alpha P_{bkg}^{gg}(\Omega_{H \rightarrow 4\ell}, m_{4\ell})}{\beta P_{in}^{gg}(\Omega_{H \rightarrow 4\ell}, m_{4\ell}) + \beta P_{bkg}^{gg}(\Omega_{H \rightarrow 4\ell}, m_{4\ell})} \right]^{-1},$$

where the denominator contains the sum of the probability contributions from the signal ($P_{sig}^{gg}$), the background ($P_{bkg}^{gg}$), and their interference ($P_{in}^{gg}$) to the total $gg \rightarrow 4\ell$ process, and the numerator includes the probability for the $q\bar{q} \rightarrow 4\ell$ background process, all calculated either with the JHUGen or MCFM matrix elements within the MELA framework [10,16,17]. The two coefficients $\alpha$ and $\beta$ are tuned differently in the on-shell and off-shell width analysis samples. Signal-background interference effects are negligible in the on-shell region, so the kinematic discriminant is tuned to isolate signal from the dominant background process with $D_{bkg}^{kin} = D_{kin}(\alpha = 1, \beta = 0)$ [2,36]. In the off-shell region, the discriminant is tuned to isolate the full gluon fusion process, including the interference term, for the ratio $\Gamma_{H}^{\text{SM}}/\Gamma_{H} \sim \alpha = \beta = 0.1$ close to the expected sensitivity of the analysis. The discriminant is, therefore, labeled as $D_{gg}^{kin} = D_{kin}(\alpha = \beta = 0.1)$ [10].

Apart from the above kinematic discriminants and $p_T$, the width analysis employs the four-lepton invariant mass $m_{4\ell}$ as the main observable, which provides signal and background separation in the on-shell region and which is sensitive to the $\Gamma_{H}$ values and anomalous couplings in the off-shell region. The $m_{4\ell}$ distributions are illustrated in Fig. 3 for the on-shell and off-shell regions without any kinematic requirements, Fig. 2 (bottom) for the on-shell region with the requirement $D_{bkg}^{kin} > 0.5$, and Fig. 4 for the two event categories in the off-shell region, with the requirement $D_{gg} > 2/3$ on the nondijet category. The requirements on the kinematic discriminants $D_{bkg}^{kin}$ or $D_{gg}$ suppress the relative contribution of background in the illustration of event distributions. In the lifetime analysis, the $m_{4\ell}$ and $D_{bkg}^{kin}$ observables are combined into one, called $D_{bkg}$ [14,17,37], in order to reduce the number of observables. It is constructed by multiplying the matrix element probability ratio in Eq. (7) by the ratio of probabilities for $m_{4\ell}$ from the nonresonant $q\bar{q} \rightarrow 4\ell$ process and the resonant production $gg \rightarrow H \rightarrow 4\ell$ for the measured $m_H = 125.6$ GeV. The $D_{bkg}$ distribution in the lifetime analysis is shown in Fig. 5. To account for the lepton momentum scale and resolution uncertainty in the $m_{4\ell}$ or $D_{bkg}$ distributions, alternative signal distributions are taken from the variations of both of these contributions.

The lifetime analysis makes use of the observable $\Delta t$ calculated following Eq. (1). The reference point for the $H$ boson production vertex is taken to the beam spot, which
is the pp collision point determined by fitting charged-particle tracks from events in multiple collisions, and the value of $\Delta r_T$ is calculated as the displacement from the beam spot to the $4\ell$ vertex in the plane transverse to

FIG. 2 (color online). Distributions of $D_{\text{jet}}$ (top) and the four-lepton invariant mass $m_{4\ell}$ (bottom) in the on-shell region of the $H$ boson width analysis. The $D_{\text{jet}}$ distributions show events in the dijet category with a requirement $120 < m_{4\ell} < 130$ GeV. The $m_{4\ell}$ distributions combine the nondijet and dijet categories, the former with an additional requirement $D_{\text{kin}}^{\text{bkg}} > 0.5$ to suppress the dominant $q\bar{q} \to 4\ell$ background. The points with error bars represent the observed data, and the histograms represent the expected contributions from the SM backgrounds and the $H$ boson signal. The contribution from the VBF and $VH$ production is shown separately.

FIG. 3 (color online). Distributions of the four-lepton invariant mass $m_{4\ell}$ in the on-shell (top) and off-shell (bottom) regions of the $H$ boson width analysis for all observed and expected events. The points with error bars represent the observed data in both on-shell and off-shell region distributions. The histograms for the on-shell region represent the expected contributions from the SM backgrounds and the $H$ boson signal, combining gluon fusion, VBF, and $VH$ processes. The contribution from the VBF and $VH$ production is shown separately. The filled histograms for the off-shell region represent the expected contributions from the SM backgrounds and $H$ boson signal, combining gluon fusion, VBF, and $VH$ processes. Alternative $H$ boson width and coupling scenarios are shown as open histograms with the assumption $\phi_{\lambda Q} = 0$ unless specified otherwise, and the overflow bin includes events up to $m_{4\ell} = 1600$ GeV.
the beam axis. An alternative calculation of \( \Delta t \) has also been considered using the primary vertex of each event instead of the beam spot, but the different associated particles in the \( H \) boson production and their multiplicity

\[
\Gamma_{\text{SM}} = 100 \text{ GeV}
\]

\[
\Delta \tau_H = 100 \mu \text{m}
\]

FIG. 4 (color online). Distribution of the four-lepton invariant mass \( m_4l \) in the off-shell region in the nondijet (top) and dijet (bottom) categories. A requirement \( D_{gg} > 2/3 \) is applied in the nondijet category to suppress the dominant \( q\bar{q} \to 4l \) background. The points with error bars represent the observed data, and the filled histograms represent the expected contributions from the SM backgrounds and \( H \) boson signal, combining gluon fusion, VBF, and \( VH \) processes. Alternative \( H \) boson width and coupling scenarios are shown as open histograms. The overflow bins include events up to \( m_4l = 1600 \text{ GeV} \), and \( \phi_{\Delta Q} = 0 \) is assumed where it is unspecified.

FIG. 5 (color online). Distributions of \( D_{bkg} \) (top) and \( c\Delta t \) (bottom) in the lifetime analysis with \( D_{bkg} > 0.5 \) required for the latter to suppress the background. The points with error bars represent the observed data, and the filled histograms stacked on top of each other represent the expected contributions from the SM backgrounds. Stacked on the total background contribution, the open histograms show the combination of all production mechanisms expected in the SM for the \( H \) boson signal with either the SM lifetime or \( c\tau_H = 100 \mu \text{m} \). Each signal contribution in the different open histograms are the same as the total number of events expected from the combination of all production mechanisms in the SM. All signal distributions are shown with the total number of events expected in the SM. The first and last bins of the \( c\Delta t \) distributions include all events beyond \( |c\Delta t| > 500 \mu \text{m} \).
would introduce additional model dependence in the primary vertex resolution.

The \( \Delta t \) value is non-negative and follows the exponential decay distribution if it is known perfectly for each event. However, resolution effects arising mostly from limited precision of the \( \Delta r_T \) measurement allow negative \( \Delta t \) values. This feature allows for an effective self-calibration of the resolution from the data. Symmetric broadening of the \( \Delta t \) distribution indicates resolution effects while positive skew indicates sizable signal lifetime. Figure 5 displays the \( \Delta t \) distributions. The resolution in \( \Delta t \) also depends on the \( p_T \) spectrum of the produced \( H \) boson, which differs among the production mechanisms, and this dependence is accounted for in the fit procedure as described in detail in Sec. VI. The distributions of \( \Delta \tau \) and \( p_T \) are shown in Figs. 5 and 6, respectively. Since the discriminant \( D_{\text{bkg}} \) is optimal for signal separation in the on-shell region, a requirement \( D_{\text{bkg}} > 0.5 \) is applied to reduce the background when showing these distributions.

Uncertainties in the \( \Delta t \) distribution for the signal and the prompt background are obtained from a comparison of the expected and observed distributions in the \( m_{4\ell} \) sidebands, \( 70 < m_{4\ell} < 105.6 \) GeV and \( 170 < m_{4\ell} < 800 \) GeV. These uncertainties obtained from this comparison correspond to varying the \( \Delta t \) resolution by \( +17/-15\% \), \( +14/-12\% \), and \( +20/-17\% \) for the 4\( e \), 4\( \mu \), and 2\( e\mu \) final states, respectively. The \( Z + X \) parametrization is obtained from the control region in the analysis mass range \( 105.6 < m_{4\ell} < 140.6 \) GeV, and its alternative parametrization obtained from the control region events in the mass range \( 140.6 < m_{4\ell} < 170 \) GeV reflects the uncertainties in the data-driven estimate. A cross-check of the \( \Delta t \) distributions is also performed with the 3\( \ell \) control samples enriched in \( WZ \) prompt decay, and the distributions are found to be consistent with simulation.

VI. CONSTRAINTS ON THE LIFETIME

The \( H \) boson lifetime analysis is based on two observables \( \bar{x} = (\Delta \tau, D_{\text{bkg}}) \), which allow the measurement of the average signal lifetime \( \tau_H \) and the discrimination of the \( H \) boson signal from background using a simultaneous likelihood fit. The extended likelihood function is defined for \( N_{\text{ev}} \) candidate events as

\[
\mathcal{L} = \exp \left( -n_{\text{sig}} - \sum_k n_{\text{bkg}}^{(k)} \prod_p \right) \sum_{\xi} \left( n_{\text{sig}} \mathcal{P}_{\text{sig}}(\bar{x}; \xi) + \sum_{k} n_{\text{bkg}}^{(k)} \mathcal{P}_{\text{bkg}}^{(k)}(\bar{x}; \xi) \right),
\]

where \( n_{\text{sig}} \) is the number of signal events and \( n_{\text{bkg}}^{(k)} \) is the number of background events of type \( k \) (\( gg \to 4\ell \),\( q\bar{q} \to 4\ell \), \( Z \) + \( X \)). The probability density functions, \( \mathcal{P}_{\text{sig}} \) for signal and \( \mathcal{P}_{\text{bkg}}^{(k)} \) for each background process \( k \), are described as histograms (templates). The likelihood parametrization is constructed independently in each of the 4\( e \), 4\( \mu \), or 2\( e\mu \) final states, and for 7 and 8 TeV pp collision energy. The parameters \( \xi \) for the signal and \( \bar{x} \) for the background processes include parametrization uncertainties, and \( \bar{x} \) also includes \( \tau_H \) as the parameter of interest. The likelihood in Eq. (8) is maximized with respect to the parameters \( n_{\text{sig}}, n_{\text{bkg}}^{(k)}, \xi \) and \( \bar{x} \), which constitute the nuisance parameters and the parameter of interest. The nuisance parameters are either constrained within the associated uncertainties or left unconstrained in the fit.

The kinematics of the four-lepton decay, affecting \( D_{\text{bkg}} \), and the four-lepton vertex position and resolution, affecting \( \Delta t \), are found to be independent. Therefore, the two-dimensional probability distributions of \( \mathcal{P}(\Delta \tau, D_{\text{bkg}}) \) are constructed as the product of two one-dimensional distributions. In the case of the signal probability, the \( \Delta t \) templates are conditional on the parameter of interest \( \tau_H \). The signal \( \Delta t \) parametrization is obtained for the range \( 0 \leq c\tau_H \leq 1000 \) \( \mu \)m by reweighting the simulation.
available for the gluon fusion process at $c\tau_H = 0, 100, 500,$ and $1000 \, \mu m$ to $c\tau_H$ values in steps of $10 \, \mu m$ and interpolating linearly for any intermediate value.

The $\Delta t$ parametrization for all SM $H$ boson production mechanisms (gluon fusion, VBF, $WH$, $ZH$, and $t\bar{t}H$) is obtained by reweighting gluon fusion production events as a function of $p_T$ at each of the $\tau_H$ values. This procedure reproduces $\Delta t$ resolution effects predicted from the simulation for prompt signal (i.e. $\tau_H = 0$) and is, therefore, valid for nonzero lifetime. As shown in Fig. 6, the gluon fusion production mechanism has the softest $p_T$ spectrum while $t\bar{t}H$ production yields the hardest $p_T$, and the distribution of $\Delta t$ is thus wider in gluon fusion and narrower in $t\bar{t}H$ production, with other production mechanisms in between. Gluon fusion production and $t\bar{t}H$ distributions, with their respective yields scaled to the total SM production cross section, are therefore taken as the two extreme variations while the nominal $\Delta t$ distribution is parametrized with the SM combination of the different production mechanisms. The $\Delta t$ distribution used in the likelihood is varied from the nominal prediction between these two extremes with a continuous production parameter included in $\tilde{\xi}$ in Eq. (8).

Any other production mechanism or a mixture can be described with this parametrization, and the values of the production parameter corresponding to the $p_T$ spectrum of either pure VBF, $WH$, $ZH$, or $t\bar{t}H$ mechanisms are excluded at more than 95% C.L. from a fit to data. This information is consistent with the observed $p_T$ spectrum in Fig. 6.

While the $\Delta t$ and $D_{\text{bkg}}$ parametrizations are obtained for the SM couplings in the $H \to ZZ \to 4\ell$ decay, and for $p_T$ spectra as in SM-like production mechanisms (gluon fusion, VBF, $WH$, $ZH$, and $t\bar{t}H$), the analysis has little dependence on anomalous couplings in either the production or the decay of the $H$ boson. It has already been established [17] that the kinematics of the $H \to 4\ell$ decay are consistent with the kinematics of the SM $H$ boson decay and inconsistent with a wide range of exotic models. The $\Delta t$ and $D_{\text{bkg}}$ distributions have little variation within the allowed range of exotic couplings in the $H \to 4\ell$ decay. The expected $\tau_H$ constraint remains stable within 10% when the simulation for those exotic models is tested instead of the simulation with SM couplings. Anomalous couplings in production are found to have a substantial effect on the $p_T$ spectrum, typically making the spectrum harder in the VBF, $WH$, $ZH$, and $t\bar{t}H$ production mechanisms. Extreme variations in the $p_T$ spectrum, however, are already excluded by the data, and $p_T$ variations allowed by the data are reflected in the $\Delta t$ parametrization with the parameter describing the production mechanisms.

Figure 7 shows the likelihood distribution as a function of $c\tau_H$. The allowed 68% and 95% C.L. intervals are defined using the respective profile likelihood function values $-2\ln(\mathcal{L}/\mathcal{L}_{\text{max}}) = 1.00$ and 3.84 for which exact coverage is expected in the asymptotic limit [72]. The approximate coverage has been tested with the generated samples at different $c\tau_H$ values, and the quoted results have been found to be conservative. The observed (expected) average lifetime is $c\tau_H = 2^{+25}_{-2} (0^{+24}_{-0})$ $\mu m$ ($\tau_H = 10^{-10} \, \text{fs}$ for the observation and $\tau_H = 0^{+80}_{-80} \, \text{fs}$ for the expectation), and the allowed region at the 95% C.L. is $c\tau_H < 57 (56) \, \mu m$ ($\tau_H < 190 \, \text{fs}$ for both the observation and the expectation). The observed number of signal events remains consistent with Ref. [16]. The observed (expected) upper limit on the average lifetime at 95% C.L. corresponds through Eq. (2) to the lower limit on the $H$ boson width $\Gamma_H > 3.5 \times 10^{-9} \, \text{MeV} (\Gamma_H > 3.6 \times 10^{-9} \, \text{MeV})$ regardless of the value of $f_{\Lambda_Q}$.

**VII. CONSTRAINTS ON THE WIDTH**

The $H$ boson width $\Gamma_H$ and the effective fraction $f_{\Lambda_Q}$ for the $\Lambda_Q$ anomalous coupling are measured in an unbinned maximum likelihood fit of a signal-plus-background model following Eq. (8). In addition to the event categories already defined in the lifetime analysis for the final states and pp collision energy, events are also split into dijet and nondijet categories, and into on-shell and off-shell regions. In the on-shell region, a three-dimensional distribution of $\tilde{x} = (m_{4\ell}, D_{\text{bkg}}^{\text{lim}}; p_T \text{ or } D_{\text{jet}})$ is analyzed, following the methodology described in Ref. [16]. In the off-shell region, a two-dimensional distribution $\tilde{x} = (m_{4\ell}, D_{\text{bg}})$ is analyzed following the methodology described in Ref. [10] with the events split into the two dijet categories defined in Table I.
The probability distribution functions are built using the full detector simulation or data control regions and are defined for both the signal \( P_{\text{sig}} \) and the background \( P_{\text{bkg}} \) contributions as well as their interference \( P_{\text{int}} \), as a function of the observables \( \bar{x} \) discussed above. Several production mechanisms such as gluon fusion \((gg)\), VBF, \(WH\) and \(ZH\) \((VH)\) are considered for the signal. The total probability distribution function for the off-shell region is written as

\[
P_{\text{tot}}^{\text{off-shell}}(\bar{x}; \Gamma_H, f_{\Lambda Q}) = \left[ \mu_{ggH} \frac{\Gamma_H}{\Gamma_0} P_{\text{sig}}^{gg}(\bar{x}; f_{\Lambda Q}) + \sqrt{\mu_{ggH} \frac{\Gamma_H}{\Gamma_0} P_{\text{int}}^{gg}(\bar{x}; f_{\Lambda Q}) + P_{\text{bkg}}^{gg}(\bar{x})} \right] + \mu_{V VH} \frac{\Gamma_H}{\Gamma_0} P_{\text{sig}}^{V VH}(\bar{x}; f_{\Lambda Q}) + \sqrt{\mu_{V VH} \frac{\Gamma_H}{\Gamma_0} P_{\text{int}}^{V VH}(\bar{x}; f_{\Lambda Q}) + P_{\text{bkg}}^{V VH}(\bar{x})} + P_{\text{bkg}}^{\text{ZZ}}(\bar{x}) + P_{\text{bkg}}^{\text{WX}}(\bar{x}), \tag{9}
\]

where \( \Gamma_0 \) is a reference value used in simulation and \( VV \) stands for a combination of VBF and associated electro-weak boson production taken together. Under the assumption \( \phi_{\Lambda Q} = 0 \) or \( \pi \), any contribution to the \( HVV \) scattering amplitude in Eq. (4) from the \( a_1 \) term is proportional to \( \sqrt{1 - f_{\Lambda Q}} \), while that from the \( \Lambda_Q \) term is proportional to \( \sqrt{f_{\Lambda Q}} \cos(\phi_{\Lambda Q}) \). The dependence on \( f_{\Lambda Q} \) in Eq. (9) can thus be parametrized with the factor

\[
\left( \sqrt{1 - f_{\Lambda Q}} - \sqrt{f_{\Lambda Q}} \cos(\phi_{\Lambda Q}) \frac{m_V^2}{m_H^2} \right)^N, \tag{10}
\]

where the power \( N \) depends on the power of the \( HVV \) couplings. The couplings appear twice in the VBF and \( VH \) cases, in both production and decay, so the power of the factor is twice as large. Thus, for gluon fusion, \( N = 1 \) for the interference component \( P_{\text{int}}^{gg} \) and \( N = 2 \) for the signal \( P_{\text{sig}}^{gg} \); for VBF and \( VH \), \( N = 2 \) \( P_{\text{int}}^{V VH} \) and 4 \( P_{\text{sig}}^{V VH} \), respectively. Both \( HZZ \) and \( HWW \) couplings contribute to the VBF and \( VH \) production couplings, and this analysis assumes the same \( \Lambda_Q \) would contribute to the \( HZZ \) and \( HWW \) couplings in Eq. (4). The effective fraction \( f_{\Lambda Q} \) is therefore the same for the \( HZZ \) and \( HWW \) amplitudes.

In the on-shell region, the parametrization includes the small contribution of the \( t\bar{t}H \) production mechanism, which is related to the gluon fusion production. The total probability distribution function for the on-shell region is

\[
P_{\text{tot}}^{\text{on-shell}}(\bar{x}) = \mu_{ggH} P_{\text{sig}}^{gg+\bar{t}\bar{t}H}(\bar{x}) + \mu_{V VH} P_{\text{sig}}^{V VH}(\bar{x}) + P_{\text{bkg}}^{gg}(\bar{x}) + P_{\text{bkg}}^{V VH}(\bar{x}) + P_{\text{bkg}}^{\text{WW}}(\bar{x}). \tag{11}
\]

The normalization of the signal and background distributions is incorporated in the probability functions \( P \) in Eqs. (9) and (11), but the overall signal yield is left unconstrained with the independent signal strength parameters \( \mu_{ggH} \) and \( \mu_{V VH} \), corresponding to the \( H \) production mechanisms through coupling to either fermions or weak vector bosons, respectively. The observed \( \mu_{ggH} \) and \( \mu_{V VH} \) values are found to be consistent with those obtained in Refs. [10,16].

The allowed 68\% and 95\% C.L. intervals are defined using the profile likelihood function values \(-2 \ln(L/L_{max}) = 2.30 \) and 5.99, respectively, for the two-parameter constraints presented, and \(-2 \ln(L/L_{max}) = 1.00 \) and 3.84, respectively, for the one-parameter constraints. Exact coverage is expected in the asymptotic limit [72], and the approximate coverage has been tested at several different parameter values with the quoted results having been found to be conservative. The observed distribution of the likelihood as a two-parameter function of \( \Gamma_H \) and \( f_{\Lambda Q} \cos(\phi_{\Lambda Q}) \), with \( \phi_{\Lambda Q} = 0 \) or \( \pi \), is shown in Fig. 8. Also shown is the one-parameter, conditional likelihood scan of \( f_{\Lambda Q} \cos(\phi_{\Lambda Q}) \) for a given \( \Gamma_H \), where the \(-2 \ln(L/L_{max}) \) distribution is shown for \( L_{max} \) adjusted according to the most likely value of \( f_{\Lambda Q} \cos(\phi_{\Lambda Q}) \) at the given value of \( \Gamma_H \). The observed and expected likelihood distributions as a function of \( \Gamma_H \) are shown in Fig. 9, where \( f_{\Lambda Q} \) is either constrained to zero or left unconstrained. The observed (expected) central values with 68\% C.L. uncertainties are \( \Gamma_H = 2_{-9}^{+9}(4_{-17}^{+17}) \) MeV with \( f_{\Lambda Q} = 0 \), and \( \Gamma_H = 2_{-15}^{+15}(4_{-22}^{+20}) \) MeV with \( f_{\Lambda Q} \) unconstrained and \( \phi_{\Lambda Q} = 0 \) or \( \pi \). The observed (expected) constraints at 95\% C.L. are \( \Gamma_H < 26(41) \) MeV with \( f_{\Lambda Q} = 0 \), and \( \Gamma_H < 46(73) \) MeV with \( f_{\Lambda Q} \) unconstrained and \( \phi_{\Lambda Q} = 0 \) or \( \pi \). These observed (expected) upper limits on the \( H \) boson width at 95\% C.L. correspond through Eq. (2) to the lower limits on the \( H \) boson average lifetime \( \tau_H > 2.5 \times 10^{-8}(1.6 \times 10^{-8}) \) fs with \( f_{\Lambda Q} = 0 \) and \( \tau_H > 1.4 \times 10^{-9}(9 \times 10^{-9}) \) fs with \( f_{\Lambda Q} \) unconstrained and \( \phi_{\Lambda Q} = 0 \) or \( \pi \).

The result with the constraint \( f_{\Lambda Q} = 0 \) is consistent with the earlier one from the \( H \to ZZ \to 4\ell \) channel [10]. It can be reinterpreted as an off-shell signal strength with the change of parameters \( \mu_{V VH}^{\text{off-shell}} = \mu_{V VH} \Gamma_H / \Gamma_H^{SM} \), provided the signal strength \( \mu_{V VH} \) for the on-shell region is uncorrelated with the signal strength \( \mu_{V VH}^{\text{off-shell}} \) for the off-shell region in the likelihood scan. The observed (expected) central values and the 68\% C.L. uncertainties of \( \Gamma_H \) with the \( f_{\Lambda Q} = 0 \)
Constraints on the lifetime and the width of the $H$ boson are obtained from $H \rightarrow ZZ \rightarrow 4\ell$ events using the data...
TABLE II. Observed and expected allowed intervals at the 95% C.L. on the $H$ boson average lifetime $\tau_H$ and width $\Gamma_H$ obtained combining the width and lifetime analyses. The constraints are separated into the two conditions used in the width measurement, with either the constraint $f_{\Lambda Q} = 0$, or $f_{\Lambda Q}$ left unconstrained and $\phi_{\Lambda Q} = 0$ or $\pi$. The upper (lower) limits on $H$ boson average lifetime $\tau_H$ are related to the lower (upper) limits on $H$ boson width $\Gamma_H$ through Eq. (2).

TABLE III. Observed and expected allowed intervals at the 95% C.L. on the $f_{\Lambda Q}$ on-shell effective cross-section fraction and its interpretation in terms of the anomalous coupling parameter $\Lambda Q$ assuming $\Gamma_H = \Gamma_H^{SM}$. Results are presented assuming either $\phi_{\Lambda Q} = 0$ or $\phi_{\Lambda Q} = \pi$. The allowed intervals on $f_{\Lambda Q}$ are also translated to the equivalent quantity $\sqrt{a_1} \Lambda Q$ through Eq. (5), where the coefficient $a_1$ is allowed to be different from its SM value $a_1 = 2$.

recorded by the CMS experiment during the LHC run 1.

The measurement of the $H$ boson lifetime is derived from its flight distance in the CMS detector with the upper bound $\tau_H < 190$ fs at the 95% C.L., corresponding to a lower bound on the width $\Gamma_H > 3.5 \times 10^{-9}$ MeV. The measurement of the width is obtained from an off-shell production technique, generalized to include additional anomalous couplings of the $H$ boson to two electroweak bosons. This measurement provides a joint constraint on the $H$ boson width and a parameter that quantifies an anomalous contribution through an on-shell cross-section fraction $f_{\Lambda Q}$. The observed limit on the $H$ boson width is $\Gamma_H < 46$ MeV at the 95% C.L. with $f_{\Lambda Q}$ left unconstrained while it is $\Gamma_H < 26$ MeV at the 95% C.L. for $f_{\Lambda Q} = 0$. The constraint $f_{\Lambda Q} < 3.8 \times 10^{-3}$ at the 95% C.L. is obtained assuming the $H$ boson width expected in the SM, and the $f_{\Lambda Q}$ constraints given any other width value are also presented. Table II summarizes the width and corresponding lifetime limits, and Table III summarizes the limits on $f_{\Lambda Q}$ under the different $\phi_{\Lambda Q}$ scenarios that can be interpreted from this analysis, and provides the corresponding limits on $\sqrt{a_1} \Lambda Q$.

ACKNOWLEDGMENTS

We thank Markus Schulze for optimizing the JHUGen Monte Carlo simulation program and matrix element library for this analysis. We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Science, Research and Economy and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport, and the Croatian Science Foundation; the Research Promotion Foundation, Cyprus; the Ministry of Education and Research, Estonian Research Council via IUT23-4 and IUT23-6 and European Regional Development Fund, Estonia; the Academy of Finland, Finnish Ministry of Education and Culture, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules/CNRS, and Commissariat à l’Énergie Atomique et aux Energies Alternatives/CEA, France; the Bundesministerium für Bildung und Forschung, Deutsche Forschungsgemeinschaft, and Helmholtz-Gemeinschaft Deutscher Forschungszentren, Germany; the General Secretariat for Research and Technology, Greece; the National Scientific Research Foundation, and National Innovation Office, Hungary; the Department of Atomic Energy and the Department of Science and Technology,
