Air-Heating Solar Collectors for Humidification-Dehumidification Desalination Systems

Relative to solar water heaters, solar air heaters have received relatively little investigation and have resulted in few commercial products. However, in the context of a humidification-dehumidification (HDH) desalination cycle, air heating accounts for advantages in cycle performance. Solar collectors can be over 40% of an air-heated HDH system’s cost; thus, design optimization is crucial. Best design practices and sensitivity to material properties for solar air heaters are investigated, and absorber solar absorptivity and glazing transmissivity are found to have the strongest effect on performance. Wind speed is also found to have an impact on performance. Additionally, a well designed, and likely low cost, collector includes a double glazing and roughened absorber plates for superior heat transfer to the airstream. A collector in this configuration performs better than current collectors with an efficiency of 58% at a normalized gain of 0.06 K m²/W. [DOI: 10.1115/1.4003295]

1 Introduction

Solar water heaters have been thoroughly investigated and developed commercially [1–3], whereas there has been relatively little investigation and almost no commercial development of solar air heaters. These heaters can amount to over 40% of the total cost [4] of a humidification-dehumidification (HDH) system and so the development of a cost effective and efficient solar collector is essential to the system’s overall feasibility.

1.1 The Humidification-Dehumidification Cycle. Humidification-dehumidification desalination is a thermal desalination cycle that operates similar to the natural water cycle, where water is evaporated from the oceans by the sun and condenses into fresh water precipitation, which returns to earth and can be used for drinking. This basic principle is behind the operation of a solar still, where the sun evaporates seawater and the vapor condenses on the cooler glazing of the still where it can be recovered for drinking. However, in the process of condensation all the latent heat of evaporation of the water is lost to the environment, leading to poor thermal performance. The HDH cycle improves on this principle by separating the evaporation and condensation processes into different devices thereby recovering the latent heat of evaporation and using it to heat the seawater.

The HDH cycle can be configured in a variety of ways. Figure 1 shows a typical configuration of a HDH cycle. Heating of the air allows greater moisture content by increasing the saturation humidity ratio. However, Narayan et al. [5] found that the cycle attains greater thermal performance when the air stream is closed and when the heater is placed at the humidifier, as shown in Fig. 2. It has been found [5] that the cycle performs better using air heating as opposed to water heating. The result is that the heater now has to deal with greater moisture content in the air and has to be robust against corrosion, in addition to being simple and cost effective.

2 Comparing Existing Collectors

Nayaran et al. [6] reviewed potential solar air heaters and compared their efficiency and top temperature output to other collectors in the literature as well as those manufactured commercially. The standard metric of a solar air heater’s performance is the collector thermal efficiency. It is defined by Eq. (1).

\[ \eta = \frac{m_c(T_{\text{out}} - T_{\text{in}})}{I_f A_p} \]  

This definition of performance is that used by the ASHRAE 93-2003 Standard for solar collector testing [7] and it defines both the instantaneous and time averaged efficiencies when evaluating dynamically changing solar radiation inputs and temperature profiles.

In solar collectors, efficiency decreases with fluid temperature gain, as heat losses are directly proportional to temperature. The most common way of showing solar air heater efficiency is to plot the efficiency versus the normalized heat gain as defined by Eq. (2). It has the units K m²/W.

\[ \text{NG} = \frac{(T_{\text{out}} - T_{\text{air}})}{I_f} \]

The normalized gain will decrease with increasing air mass flow rate. Figure 3 [6] shows the reported efficiencies of solar air heaters in the research literature [4,8–19] as a function of normalized heat gain, where better performing heaters are more to the top right portion of the graph, as they deliver the highest air temperature at the highest efficiency. The highest efficiency commercial solar collector, the SunMate Sm-14 [16], is included for comparison. The highest performing heaters are indicated as gray points on the graph, which will set the standard by which new designs will be compared. Of the points indicated in gray, the majority are experimental studies with only one [9] being a theoretical study.

Two outliers [10,12] that do not follow the trend of the other data were excluded from the gray shaded group. Reference [10] is a theoretical study that claims an extremely large efficiency improvement with an addition of porous media as an absorber, with 75% efficiency at 0.12 K m²/W of normalized gain. However, experiments conducted on a collector in a similar configuration [20] show only 60% efficiency at a normalized gain of 0.017, which is significantly lower. Romdhane [12] provided an experimental study with various types of surface roughening. He reports a near constant efficiency through increasing normalized gain to his highest normalized gain and efficiency. However, when experiments are done by varying the mass flow rate, the same collector shows a linearly increasing trend with increasing mass flow.
rate, which is expected. The increase in mass flow rate is accompanied by a decrease in temperature rise (and normalized gain) as the air has a shorter residence time in the collector. This appears to be inconsistent with the reported results for varying normalized gain. By comparing the designs of the five best heaters, a list of apparent best design practices can be obtained.

Air flow over the absorber plate. Having air flow above the absorber decreases losses from the top of the absorber plate and eliminates conduction resistance through the plate. Many modern air heaters use this method [8,9,17].

Packing materials. Packing materials in the air stream improve heat transfer by mixing the air and providing more surface area to absorb radiation. Packing also provides sensible heat storage but comes at the cost of high pressure drop [9,13]. In the context of HDH, the materials have to be moisture and corrosion resistant. Since they add effective energy storage to the collector, they will be considered in a separate study of transient solar collector designs.

Roughened absorber plate. A roughened absorber plate improves convection heat transfer into the air. A rough configuration also increases pressure drop, but only marginally when compared with a smooth plate for duct cross-sections used in solar air heating. Roughening for increased convection has been extensively investigated and has shown performance improvements in collectors [10,17].

Multiple passes of air through the collector. Multiple passes of air through the collector improves heat gain by increasing contact with the absorber and makes the absorber run cooler, decreasing losses [13]. However the same can be accomplished with a rough absorber plate without having a very thermally conductive absorber. This allows many more materials to be used as absorber surfaces, such as those with low thermal conductivity.

Multiple glazing layers. Multiple glazing layers reduce heat loss by infrared radiation and trap an insulating air layer between the glazings. However, this comes at a greater material cost and lower solar transmissivity. All of the top performing heaters except those used by Sahu and Bhagoria [17] use a double glazing.

Glass and metal construction. Glass and metal construction provides better heat transfer characteristics and better durability. All the best performing collectors used glass and metal construction, as polymer alternatives, especially for glazings, suffer from low durability, although initially providing optical properties comparable to glass [21].

3 Sensitivity of Heater Performance to Material Properties and Environmental Conditions

3.1 Baseline Design. Using information gleaned from the literature review, a simple baseline design was devised. To obtain the required temperature rise, a long and narrow collector was necessary, and it has a cross-section as illustrated in Fig. 4. In reality, this long effective collector can be achieved by placing shorter modules in series. The total length of the collector is 10 m, and it consists of an aluminum absorber coated with carbon black paint, and low-iron glass glazing panels. The outside is insulated with fiberglass insulation. The outdoor wind speed is assumed to be a moderate 5 m/s, which is consistent with averages for a desert climate like the one found in Saudi Arabia [22]. The characteristic length over which wind blows is the average of the width and length of the collector as wind direction is highly variable. The absorber is roughened with transverse ribs to increase turbulence and heat transfer. The ribs have a constant height and pitch throughout the channel. Tables I and 2 outline the fixed parameters of the baseline design. The dimensions of the flow

3.2 Governing Equations. In steady state, the heat transfer processes in the collector can be modeled as a series of thermal resistances. They are shown in Fig. 5. If control volumes are taken around the two glazings, the absorber and the air stream, and the processes in the collector can be modeled as a series of thermal resistances. Therefore, sky temperature is included in these calculations and $T_{amb}$ is defined as a sol-air temperature of the environment by Eq. (4). A correlation [21] for sky temperature based on dew point temperature is used. The sol-air temperature is used for the total loss despite the fact that there is no radiation from the back surface to the sky. This does not have a large effect on the loss, as the bottom loss is only 3% of total loss in the baseline configuration.

$$T_{amb} = T_{air} + \frac{-h_{rad, 2-sky}(T_{air} - T_{sky})}{h_{amb} + h_{rad, 2-sky}}$$

Heat transfer coefficients are calculated using commonly used correlations for natural and forced convection heat transfer [23]. Radiation heat transfer coefficients are linearized radiation heat transfer expressions in the form of $h_{rad} = 4\sigma T^2$, as given by Lienhard and Lienhard [24]. The surface was modeled as having transverse rib roughening using the equations developed by Dalle Donne and Meyer [25]. The roughening parameters are given in Table 3.

Since the glazings are made of glass, they are assumed to be opaque in the infrared. Polymeric glazings that may be beneficial for cost and thermal performance are not always opaque in the infrared. Polymeric glazings may be very thin and thus hard to clean or susceptible to damage by UV radiation and blown sand; and they will not be considered here.

Equation (5) is a combined loss coefficient resulting from algebraic manipulations of Eq. (3).

$$U_L = \frac{(U_t + U_h)(h_t h_2 + h_t h_1 + h_1 h_2) + U_t U_h}{h_1 h_t + h_1 U_t + h_2 h_1 + h_1 h_2}$$

With a combined loss coefficient, a simple energy balance leads to Eq. (6)

$$q_u = [S - U_L(T_e - T_{amb})]$$

where $q_u$ is useful heat gained by the air. Since the mean plate temperature is unknown, it needs to be found iteratively. Equation (7) gives the integrated solution in terms of a heat removal factor and loss factor given by Eq. (8).

$$\frac{\bar{T}_u}{U_b} = T_{amb} + \frac{q_u}{F_R U_L} (1 - F_R)$$

$$F_R = A_P m_c \frac{1 - \exp \left[-A_P U_L F' \right]}{m_c}$$

$$F' = \frac{h_t h_1 + h_2 U_t + h_t h_2 + h_1 h_2}{(U_t + h_t)(U_h + h_1 + h_2) - h_t}$$
The efficiency versus normalized gain curve takes the form of Eq. (6) and the useful heat is divided by the total solar irradiation to obtain an efficiency. The air temperature rise is given by dividing the useful heat by the capacity rate of the air, mc_p. To characterize how the efficiency behaves versus the temperature rise in the collector, an equivalent effectiveness [21] is defined by Eq. (9).

\[ F_O = \frac{m_c_p}{A_f U_f} \left[ 1 - \exp \left( \frac{-A_f U_f E_f}{m_c_p} \right) \right] \]

The efficiency versus normalized gain curve takes the form of Eq. (10).

\[ Efficiency = F_O \left( \alpha, \varepsilon \right) = \frac{m_c_p}{A_f U_f} \left[ \frac{T_{out} - T_{amb}}{I_f} \right] \]

The normalized gain in Eq. (10) is different from Eq. (2) in that it is based on the outlet and ambient temperature difference. However, since the calculations on the baseline collector were done by fixing the air inlet T_{in} to T_{amb}, this equation can describe the efficiency versus normalized gain with normalized gain as it is defined in Eq. (2). F_O is analogous to a heat exchanger effectiveness. Therefore, the collector performs better at higher normalized gain if it has high glazing transmissivity and absorber absorptivity of solar radiation, if losses are minimized, and if the heat transfer coefficient from the absorber to the air is high.

3.3 Sensitivity Analysis Results. A sensitivity study investigated the effect of various material properties on performance of the collector, as well as how environmental conditions affect the performance when certain materials are used.

3.4 Material Properties. The material properties that have the greatest impact on performance are the infrared emissivities of the glazing and absorber plates, the glazing stack solar transmissivity, and absorber solar absorptivity. Figure 6 shows the relative effect of each parameter as it is varied from 0 to 1. The operating point was based on the operation of a HDH cycle in a desert environment. For the 10 m long collector, a normalized gain of 0.06 K m^2/W is obtained at a mass flow rate of 0.029 kg/s. The calculations assume that the conduction resistances of the glazings and absorber are negligible, owing to their small thickness. Heater dimensions can be optimized for the desired temperature rise, and optima are easily found for the dimensions of roughness features or spacing between the plates and will not be discussed here. The graph shows that the two most important parameters are absorber solar absorptivity and glazing solar transmissivity. Using an absorber with a selective coating (\(\alpha=0.9-1\), \(\varepsilon=0.02-0.3\) \[26\]) does not offer significant performance gains with only 4% efficiency improvement. This can be an expensive design addition, as selective surfaces often made of somewhat exotic materials, such as quartz, can involve expensive manufacturing processes and are limited to only a few substrates. Using a low \(\varepsilon\) coating for the glazing plates offers a larger improvement of 10%, but also can be an expensive addition.

To ascertain the efficiency “value” of various design attributes, heaters were simulated in different configurations, adding various design improvements onto a collector with a smooth, nonselective absorber with a single glazing. As can be seen from Fig. 7, the addition of surface roughness increases performance by the greatest amount in the HDH operating range. A typical value for a fully roughened surface using the parameters in Table 3 can increase the heat transfer coefficient 8 times over that for a smooth plate. The use of a selective adsorber coating (\(\varepsilon=0.05\)) also improves performance by a small amount. For low normalized gain, a selective surface does not improve performance for over a roughened absorber, although it is more important at higher temperatures where radiative losses dominate. Figure 8 shows how the baseline design compares with existing air heaters that include Chafik’s HDH collector \[4\] and the SunMate commercial collector \[16\] for which the performance curve is available. It is clearly shown that the baseline collector, which incorporates all of the design enhancements beside a selective absorber, outperforms existing collectors in the HDH operating range.

3.5 Environmental Conditions. Environmental conditions also influence how a collector can be designed and the importance of design enhancements. The environmental parameters of most importance are the ambient air temperature, the dew point temperature, which affects sky temperature, and ambient wind speed. As suggested in the literature \[21\] ambient air temperature has a small effect on performance when compared with ambient wind speed. A variation in dew point temperature from -4°C to 36°C translates into a 1–2% efficiency change in the HDH operating range, and a change in ambient air temperature from 0°C to 40°C translates into a 3–4% efficiency change in the HDH operating range.

Wind speed has a larger effect on performance. Figure 9 shows
that wind speed can have a substantial effect on performance in the HDH operating range, with an efficiency change of 10–12%.

Figures 10 and 11 show the effect of wind speed on performance at varying infrared emissivities for glazing and absorber plates. The lines each represent a different wind speed from 2 m/s ($h_{\text{amb}}=3.07$ W/$\text{m}^2$ K) to 20 m/s ($h_{\text{amb}}=39.74$ W/$\text{m}^2$ K) in increments of 2 m/s. The graphs show that using low $\varepsilon$ surfaces is of low importance in calm environments with only marginal improvement in windy ones.

4 Conclusion

Air heating solar collectors have been studied for conditions typical of a HDH desalination system. Overall, improving the transmissivity of the glazing by using highly transmissive polymer films or low iron glass, and using a very absorptive absorber, which is inexpensively accomplished by including a carbon black coating, would have the largest impact on performance. The greatest improvement to a collector’s performance can be accomplished by using a double glazing, resulting in a 20% efficiency increase in the HDH operating range compared with a single glazed collector. This reduces radiative losses as glass is opaque to infrared radiation. An insulating layer of trapped air between the plates also lowers the outer collector temperature and further decreases convective and radiative losses. The second most important enhancement is the addition of a rough surface on the absorber plate, which improves convection from the heat source to the air. This offers up to 12% efficiency increase without the need for a selective surface on the absorber. Adding a selective surface to the absorber, or a low emissivity coating to the glazing, can add cost as a result of the use of exotic materials. In the HDH operating range these improvements have limited impact on performance, even when environmental conditions change adversely. Of the environmental conditions that affect performance, wind speed has the greatest impact. The wind speed increases the already dominant convective losses from the collector. A collector with a double glazing, a highly roughened absorber, and a carbon black coated absorber, results in a collector efficiency of 58% at a normalized gain of 0.06 $K m^2/W$. This offers significant performance gains over existing solar air heaters, which is accomplished in a simple and possibly inexpensive design.
