ABSTRACT

Purpose: Both humans and software are notoriously challenging to account for in traditional hazard analysis models. The purpose of this work is to investigate and demonstrate the application of a new, extended accident causality model, called Systems Theoretic Accident Model and Processes (STAMP), to radiation oncology. Specifically, a hazard analysis technique based on STAMP, System-Theoretic Process Analysis (STPA), is used to perform a hazard analysis.

Methods: The STPA procedure starts with the definition of high-level accidents for radiation oncology at the medical center and the hazards leading to those accidents. From there, the hierarchical safety control structure of the radiation oncology clinic is modeled, i.e., the controls that are used to prevent accidents and provide effective treatment. Using STPA, unsafe control actions (behaviors) are identified that can lead to the hazards as well as causal scenarios that can lead to the identified unsafe control. This information can be used to eliminate or mitigate potential hazards. The STPA procedure is demonstrated on a new on-line adaptive cranial radiosurgery procedure that omits the CT Simulation step and uses CBCT for localization, planning, and surface imaging system during treatment.

Results: The STPA procedure generated a comprehensive set of causal scenarios that are traced back to system hazards and accidents. Ten control loops were created for the new SRS procedure, which covered the areas of hospital and department management, treatment design and delivery, and vendor service. Eighty three unsafe control actions were identified as well as 472 causal scenarios that could lead to those unsafe control actions.

Conclusions: STPA provides a method for understanding the role of management decisions and hospital operations on system safety and generating process design requirements to prevent hazards and accidents. The interaction of people, hardware, and software are highlighted. The method of STPA produces results can be used to improve safety and prevent accidents and warrants further investigation.
1. INTRODUCTION

The process of radiation oncology occurs within a complex sociotechnical system that is heavily reliant on human operators. This reality contributes to deviations in care\textsuperscript{1} and catastrophic accidents\textsuperscript{2,3}. Recognizing this situation, safety management and prospective risk assessment by Failure Modes and Effects Analysis (FMEA) and Fault Tree Analysis (FTA) are actively being promoted by the American Association of Physicists in Medicine\textsuperscript{4}. Formal risk analysis techniques have been applied to radiation oncology over a decade ago using root-cause-analysis trees, process trees, and FTA to analyze brachytherapy errors\textsuperscript{5}. More recently, FMEA has been applied to a department-wide risk assessment effort\textsuperscript{6}. There have also been efforts to study the implementation of FMEA and FTA techniques in radiation oncology\textsuperscript{7-15}. Existing studies also give reason to at least question the reliability and validity of FMEA results\textsuperscript{16-18}. It is therefore worthwhile to investigate other risk assessment strategies.

Hazard or risk analysis involves identifying the causes of accidents in order to use that information to eliminate or control them. The analysis requires a search process. If all possible system states could be identified, then the risk analysis could find all possible hazardous scenarios. Unfortunately, such an exhaustive search is never possible in a real system due to the enormous number of states that complex systems can potentially reach, particularly when component failures are considered in addition to the designed behavior. As shown in Figure 1, two possible alternative search approaches have been used in lieu of being able to identify all hazardous causes by complete analysis. These search techniques can be characterized as either forward (inductive) or backward (deductive).

![Figure 1: Schematic comparison of forward (inductive) and backward (deductive) search used in hazard or risk analysis.](image)
Forward search techniques start from some initiating event, usually some type of failure, and identify the final states that can result. FMEA is an example of a hazard or risk analysis technique that employs an inductive or forward search. It is not feasible to consider combinations of failures (considering all single failures is extremely time consuming) so for practical reasons, only single failures are considered.

Deductive search techniques, including FTA and the technique called STPA described in this paper, start from a hazardous state and work backward to identify paths to that hazard. Backward search is theoretically more economical than forward search because only hazardous paths are explored and not all paths forward from a failure (which may not lead to hazardous behavior). Unlike forward search, backward search can find combinations of initiating events that lead to the hazard. FTA identifies combinations of system component failures and faults that lead to the hazard and models the relationships between multiple failures and faults using Boolean logic. FTA is limited in the types of interactions that can be included in the analysis and only identify accident causes involving component failures and faults. Many accidents in complex systems involve design errors, where no system components may fail but the designers inadvertently create flawed designs and procedures. Design errors are not found by search techniques that only look at failures or faults because design errors may not involve any failures but simply the ‘correct’ (as designed) execution of a flawed process or unsafe interactions among system components that are each operating as intended.

Human behavior is realistically modeled as a feedback control loop where the next action is affected by the environment (context) in which it occurs and by the results of the previous action rather than as a linear sequence of steps without taking into account feedback from previous steps. Accident causality models based on systems theory have been developed to address the shortcomings of the failure-based models. One such model, Systems-Theoretic Accident Model and Processes (STAMP), treats safety as a system control problem rather than a component failure problem. The idea is to ensure that constraints on the behavior of the system (safety constraints) are enforced by the operation of the system as a whole. For example, a safety constraint for radiation oncology is that the patient never receives a larger (or smaller) dose than is prescribed and safe. A safe treatment system should enforce that constraint, that is, control the amount of radiation the patient receives. Accidents can occur when the system controls created to prevent overdoses are not effective. The STAMP model of accident causality was designed to allow software, human behavior, organizational culture, and process changes over time to be included naturally in the hazard analysis while also including failure of process steps and system components.
System Theoretic Process Analysis (STPA) is a deductive hazard analysis method based on STAMP. The goal of STPA is to identify how the safety constraints may be inadequately controlled in a particular setting and to provide the information to create more effective controls and thus reduce or eliminate accidents. The purpose of this work is to demonstrate the applicability of STPA to hazard analysis in a clinical setting. The development and characteristics of STPA are described for use in radiation oncology by focusing on a clinical example. To help provide a qualitative assessment of the STPA methodology, an FMEA is also performed on the same clinical example.

2. METHODS

In systems theory, systems or processes are modeled as hierarchical levels of control where each level of the system controls the behavior of the level below\(^2\textsuperscript{-4}\). It is assumed that safety is jeopardized when the controls and controllers do not enforce safe behavior, thus allowing accidents to occur.

Control theory is a basic engineering concept. Figure 2 illustrates a typical feedback control loop (drawn for clarity and consistency with systems theory) where controllers issue control actions that impact the behavior of a controlled process\(^2\textsuperscript{-4}\). In return, the controller gets feedback about the impact of the control action and the current state of the controlled process. For example, the medical physicist provides a treatment plan and gets feedback from the radiation oncologist about the status of the treatment plan. Using this feedback information about the effectiveness of the control action and the current state of the controlled process, modifications or additional plans may be developed.

![Feedback Control Loop Diagram](image)

**Figure 2:** A standard engineering feedback control loop for a controlled process. The downward arrow represents the actions by the controller to control the process. The upward arrow represents the feedback that the controller receives from the controlled process. The control algorithm contains a
comparison of the current state of the process with the desired state and generates control actions necessary to bring them into alignment. The process model is the controller’s understanding of the current state of the controlled process.

The controller includes both an algorithm and a process model that is used to determine the appropriate control action to provide. The process model, control algorithm, and safety responsibilities of the controller need to be described. If the controller is a human, some type of human oriented decision-making process serves as the algorithm. The decision about the appropriate control action is at least partly based on a model of the current state of the controlled process. The process model is kept up to date by feedback from the process and other environmental inputs. For humans, the process model is usually called a ‘mental model’. Human decisions and control actions are strongly affected by the equipment and the environment and are based on factors other than simple fixed steps\(^{25,26}\). For example, based on their training, experience, and specific information about the patient combined with department equipment and the environment; the medical physicist generates a treatment plan. Feedback will be provided during or after the plan is completed, which is used to update the controller’s (i.e., medical physicist’s) mental model to reflect the current state of the controlled process (i.e., planning and treatment). Process controllers also learn and improve their decision-making processes and mental models about proper treatment over time.

The individual control loops are part of a larger hierarchical safety control structure. Control loops differ from a process map in that the steps are not drawn in chronological order but are modeled as a series of control actions. Figure 3 shows an example of a high level safety control structure for a radiation oncology department. In Figure 3, regulatory processes control the vendors and the hospital management and each level controls the level below via the control actions listed on the downward arrows. The regulators provide standards and policies for equipment production and treatment provision using that equipment. Accreditation and licensing are other types of control actions by regulators. Hospital and department controllers get feedback in terms of incident reports and various types of performance data. That feedback should be used to alter their future behavior (control actions), for example, requiring that equipment designs or the procedures for using the equipment be altered. The vendors have control over the safety of the equipment they provide and the hospital management and operations provide controls over treatment delivery. With this basic background information, the steps used in STPA are described next.
Figure 3: Example high level control structure for radiation oncology (PM = preventative maintenance, FDA = Food and Drug Administration, SOP = standard operating procedure).

2.A. Create a system description.

The first step is simply to create a description of the system being analyzed, including all organizational and system components. The goal is to define and specify the scope of the analysis.

2.B. Create a list of high level accidents (A).

An accident is defined as an unacceptable loss involving mission, life, health, equipment, or money. Creating the high level accident list can be accomplished by reviewing publicly available past accidents, data from an incident learning system, or brainstorming sessions. Domain knowledge can be helpful but is not essential because subtle deviations of care are not relevant in defining the high level accidents. In radiation oncology (or any domain), the defined accidents (losses) will almost always be the same. For
example, patient or healthcare worker injury or equipment damage are losses that can be used in all areas of healthcare. Accidents or losses may be prioritized with respect to importance.

2.C. Create a list of system hazards (H).
A hazard is a state of the system that would lead to one of the identified accidents given worst case conditions. For example, a hazard may be incorrect patient treatment being administered. While such treatment may not always lead to an accident (loss), under the worst case conditions, it could. The analysis will later identify those conditions and identify the scenarios that could lead to an accident.

A small number of high-level hazards (typically less than 10 to 12) is usually identified at the beginning. Identifying a large number of hazards would mean that the list is too detailed, which can lead to missing hazards, redundancies, and mixing up causes and effects. The short, high level list will later be refined into more detailed information if needed. A stepwise refinement process, where more detailed hazards are generated, is easier to review and find omissions or mistakes. The same list of high-level hazards will typically apply to all radiation oncology facilities.

2.D. Create the safety control structure.
The next step in STPA is to create the hierarchical control structure (Figure 3) and associated control actions and known feedback. Missing feedback that can lead to hazards will be identified by the analysis. Construction of the safety control structure model is facilitated by using the system description from Section 2.A. Most radiation oncology operations are similar in terms of the high-level control structure and thus existing models can be used and simply modified to match the specifics of the particular hospital or system being analyzed. In addition, the control loops can first be described in terms of high-level controllers and then later refined into more detailed descriptions. Figure 3 shows high-level controllers for treatment design and treatment delivery. These are refined into more detailed control loops to be presented in the Results Section.

The output of this part of the procedure is a model of the safety control structure, including more detailed individual control loops with associated control actions. Also to be identified at this stage is the process model and safety responsibilities for each controller.

As previously mentioned, the hierarchical control model is very different than a process map. A control model describes the overall function being performed, but there is no separation into sequential steps nor any specification of an ordering of the control actions. In some processes, control actions can be done in different orders without affecting the outcome of the process. If an order of actions is required,
then it is implied in the control model where a specific input is required before the next action is taken. A process map specifies a procedure as a number of sequential steps and naturally limits flexibility in how process goals are achieved. In practice, steps in a process are often taken in a different order than what is specified in a process map, for a variety of good or bad reasons. The safety of the procedure should not be compromised by this reality.

2.E. Identify unsafe control actions (UCAs).

Hazards usually result from UCAs, for example, inadequate treatment provided to a patient, incorrect positioning of patients or exposure of staff to radiation. The first step in the analysis (which is done on the model created in Step 2.D.) is to identify what types of unsafe control actions can occur.

There are four possible types of unsafe control: 1) a control action not being provided can lead to a hazard, 2) a control action can be provided that leads to a hazard, 3) control actions can be provided at the wrong time or in the wrong order, and 4) a continuous control action can be stopped too soon or applied too long. Examples of each type of unsafe control are presented in the Results Section.

Identifying the conditions under which control actions become unsafe is the first step in the analysis process. The next step is to determine how the identified conditions could occur and then eliminating those causes from the system or introducing controls to mitigate their impact if elimination is not possible.

The identified conditions under which control actions are unsafe can also be used to generate high-level safety requirements for the entire treatment system, including the safety requirements for regulation, management, treatment planning, and treatment delivery.

2.F. Determine how each unsafe control action could occur.

Potential causes for UCAs are determined by identifying the ways in which each UCA might occur, that is, by creating causal scenarios for each UCA that was developed in Section 2.E. A causal scenario should include the context in which the UCA could occur. There is likely more than one scenario per UCA and include things such as improperly performing equipment, process drifts or mistakes, and human cognitive biases. Besides identifying scenarios leading to unsafe control actions, one other type of unsafe behavior needs to be included in the causal analysis and that is when a safe control action is correctly issued but never executed. The causes here typically involve component failures.

While there is not yet any rigorously defined method for creating causal scenarios, there are templates and heuristics to help identify them. For example, they can be developed in part by considering the
following potential causes: i) the process model is incomplete or inconsistent (how could this occur?), ii) flaws in the control algorithm, perhaps because the software or human was not informed about the complete requirements for the algorithm, iii) delayed, missing, or incorrect process inputs or outputs including controller-to-controller communication problems, iv) feedback that is delayed, missing, or wrong including measurement inaccuracies, v) equipment or component failure or simply process drifts caused by changing human behavior over time as they get more familiar with the procedures and start to take short cuts and (vi) unidentified or out-of-range process disturbances.

For this work, two members of the team brainstormed a list of ways that each UCA could occur. These were considered a list of initial causal scenarios. The initial scenarios were then checked by talking to a broader team of radiation oncologists, therapists, and physicists. Finally, the two team members went back to identify the context(s) that could lead to the initial scenarios.

2. G. Failure Modes and Effects Analysis.

A bullet point list outlining the new radiosurgery procedure was provided to the analysis team for developing the FMEA. The team was experienced in performing FMEA and also completely independent of the STPA analysis team. The methodology used to perform the FMEA was based on Ford et al’s streamlined approach\(^\text{11}\). The analysis was performed as follows:

1. Create a process map that describes the steps involved in the proposed treatment process.
2. For each step in the proposed treatment process, ask ‘What could go wrong?’ The result of this is a series of failure modes. There could be multiple failure modes for each process step.
3. For each failure mode, ask ‘How could this have gone wrong?’ The result of this is a number of causes for each failure mode. There could be multiple causes for each failure mode.
4. Determine the severity (S), probability of occurrence (O), and likelihood of detection (D) values for each failure mode/cause following TG-100 tables and calculate the Risk Priority Number (RPN) for each failure mode/cause combination.
5. Use the Risk Priority Number to rank the Failure Modes. Review the top Failure Modes (Risk Priority Number ≥ 300).

The physicists described the proposed treatment process, and the facilitator (one of the physicists) created the process map that was distributed to the analysis group for review. The analysis group consisted of two physicists, one physics resident, two therapists, two dosimetrists, and one radiation oncologist. The list of top failure modes (i.e., those having a risk priority number ≥ 300) was distributed
to the analysis team and individuals were asked to propose corrective actions for each failure mode/cause. The analysis team reconvened at a single in-person meeting to discuss and finalize the proposed corrective actions.

3. RESULTS

3.A. System description.

Cranial stereotactic radiosurgery is now routinely performed in a minimally invasive or non-invasive (i.e., frameless) mode\textsuperscript{27}. One method of frameless radiosurgery is to use an open mask with a real-time optical surface imaging and monitoring system\textsuperscript{28}. Surface monitoring refers to the use of a structured light pattern that is projected on the surface of the patient and imaged using a three camera system and algorithm to determine a three dimensional surface map that is compared to a reference surface map. This system can be used to determine the translations and rotations of the patient relative to a reference surface map in real-time. This type of frameless radiosurgery treatment process involves a consultation with a radiation oncologist, acquisition of an MR scan for target delineation, acquisition of a treatment planning CT scan (CT simulation), treatment planning, and then the patient returns to the department for treatment. The patient makes 3 trips to the radiation oncology department (consultation, CT simulation, and treatment). Reducing the number of trips to the department would be helpful for patients and their families and would also free up time on the CT simulator. The proposal is to create a new linac-based radiosurgery procedure that omits the CT simulation. Technology advancements have reached the point where this is now possible.

The proposed new procedure involves only 2 trips to the radiation oncology department and includes the following: consultation with the patient is performed as usual followed by an MR scan for target delineation. After the MR scan, the radiation oncologist delineates the target and critical structures and provides the prescription to the medical physicist. The medical physicist then creates a pre-plan based on the MR scan. Once the MR pre-plan is approved by the radiation oncologist, the patient is scheduled for treatment. Upon arrival to the department for treatment, the patient proceeds directly to the linac room. Surface monitoring is initiated and a cone beam CT (CBCT) acquired. The MR and MR pre-plan are then fused to the CBCT, which indicates the patient’s actual position relative to the isocenter. The final treatment plan is calculated on the CBCT (and re-optimized if necessary). The treatment is then immediately delivered to the patient.
In compressing the workflow, traditional safety checks may be removed or changed in nature, technological limits will be pushed, and new sources of time pressure and communication problems may be introduced. New software and immobilization technologies will be needed. All of these aspects indicate the need for a prospective hazard analysis that would guide the development of a new procedure such as this.

3.B. High level accidents.

After the system description, the list of high level accidents (i.e., losses) was created. The list for radiation oncology is the following:

A1. The patient is injured or killed from over exposure or under treatment.
A2. A non-patient is injured or killed by radiation.
A3. Damage or loss of equipment.

These accidents were deemed as important to the system and serve as a focus for the analysis.

3.C. High level hazards.

A list of high level hazards was created that could lead to the high level accidents. The hazards relate to the accidents and frame the rest of the analysis. The list created is the following:

H1. Wrong dose: Dose delivered to patient is wrong in either amount, location, or timing (A1).
   H1.1. Right Patient, Right Dose, Wrong Location
   H1.2. Right Patient, Wrong dose, Right Location
   H1.3. Right Patient, Wrong dose, Wrong Location
   H1.4. Wrong Patient
H2. A non-patient is unnecessarily exposed to radiation (A2).
H3. Equipment is subject to unnecessary stress (A3).
H4. Persons are subjected to non-radiological injury (A4).

3.D. Control loops and control actions.
Figure 3 presents a high level control loops for a radiation oncology department. Regulatory is at the top and refers to any external bodies that the hospital, department, or vendor is required to satisfy such as the Joint Commission, the Food and Drug Administration, the Nuclear Regulatory Commission, etc. To scope the hazard analysis, it was deemed appropriate to include only hospital and department management, vendor service (not the vendor itself), and clinical operations in this study.

Clinical operations is divided into treatment design and treatment delivery. The treatment design controller involves creating the general procedures and the treatment plan that will be eventually delivered to the patient. The process being modeled here is the development of the MR pre-plan for the patient, bringing the patient to the treatment room for positioning, and then creating a final optimized plan. The optimized plan is then sent to the treatment delivery controller so treatment can proceed. The analysis was focused on the controllers whose roles change in the new process and where a reasonable chance of affecting change is possible. For example, changing regulatory agencies or vendor equipment design is not likely to happen in the short term. Treatment planning and treatment delivery controllers include the radiation oncologist, the medical physicist, and the radiation therapist as well as all of the equipment and software used in the new procedure. This includes both existing equipment and software as well as equipment and software that may need to be developed.

The high level control loops (treatment design and treatment delivery) of Figure 3 were refined to include more detail as shown in Figure 4 and in the Appendix (Figure A1). By using multiple levels of refinement, complex safety control structures can be more easily understood. In the remaining Results Section, the ‘Treatment Design’ box of Figure 3 is described and control action 4.1 (shown in Table 1) is presented in detail, namely, the medical physicist control action to fuse MR and pre-plan to CBCT. The remaining results are presented in the Appendix.

Figure 4 shows the detailed control structure of the Treatment Design box in Figure 3. The control loops of Figure 4 include the assessment of the patient to provide a recommendation for the use of radiation oncology to treat the patient’s disease using the new radiosurgery procedure. Also included are the MR pre-plan and the modification to the pre-plan on the day of treatment including a dose calculation on the CBCT and possible re-optimization if the calculated dose distribution is not acceptable.
**Table 1:** List of the controllers, job functions, safety responsibilities, and associated control actions as part of the STPA for the new linac-based radiosurgery procedure.

</table>
| Radiation Oncologist            | The radiation oncologist uses their medical and specialty knowledge when evaluating the patient for treatment and uses the dose distribution, DVHs, and imaging for setup and optimal treatment plan. | • Ensure that radiation, the Rx and contours are appropriate to treat the patient’s disease.  
• Verify that the final plan and patient setup are acceptable prior to treatment.  
• Observe and manage any unexpected complications during and after treatment. | • Pass prescription and contours  
• Approve pre-plan  
• Approve fusion and final plan  
• Recommend patient for treatment  
• See patient for follow-up |
| Medical Physicist               | The medical physicist uses their knowledge of treatment planning system, fusion algorithms, and imaging techniques to prepare treatment plans and evaluate patient setup. | • Ensure that the plan (linac instructions) is able to be delivered without error and that equipment is functioning properly.  
• Verify that the treatment plan meets the radiation oncologist’s Rx and has all the necessary information for the radiation therapist. | • Set-up procedures  
• Fuse MR and pre-plan to CBCT  
• Re-optimize & calculation  
• Send new plan to RT EMR  
• Schedule for treatment |
| Radiation Therapist             | The radiation therapist uses their clinical experience and knowledge to interact with and position the patient per the setup protocol and execute treatment per the treatment plan. | • Ensure the patient is comfortable and follows instructions for treatment.  
• Ensure that the patient is setup per the treatment plan and procedures are followed as designed.  
• Verify that the equipment is functioning properly during the treatment. | • Ensuring patient is relaxed  
• Immobilization and positioning  
• Acquire CBCT  
• Mode up final plan  
• Initiate treatment  
• Halt treatment |
| Hospital Administration         | The hospital administrators sets productivity goals for the department and use patient census, satisfaction surveys and billing data from the department to evaluate department performance as well as provides staffing and equipment to achieve those goals. | • Ensure that the department has sufficient resources to perform the treatments.  
• Verify that the department has appropriate resources to meet performance goals. | • Set performance expectations  
• Provide staff and equipment resources |
| Department Administration       | The department administrators use feedback from the staff and the Incident Learning System to understand needs to perform daily activities as well as sets department culture. | • Ensure that the treatment policy and procedures are documented and accessible.  
• Ensure that appropriate resources are allocated for the procedure.  
• Ensure that the department follows a safety culture. | • Approve standard operating procedures  
• Allocate staff and equipment resources  
• Create and maintain department culture  
• Maintain equipment and procedures |
| Clinical Operations Team        | The planning and treatment teams addresses anomalous equipment behavior in part by providing the vendor with feedback when faults or error messages arise. | • Notify appropriate persons or vendor when anomalous equipment behavior is detected. | • Staff notify vendor of an issue |
Figure 4: Details of the treatment design controller of Figure 3 (Rx = prescription, MRI = MR scan, CBCT = cone beam computed tomography, TPS = Conventional Treatment Planning System).

The medical physicist controller can provide five types of control actions. Prior to implementation of the new SRS procedure, the medical physicist leads a team to define the set-up procedures. The medical physicist uses the MR scan, the pre-plan, and the CBCT as process input and the first action is to fuse the MR scan and pre-plan to the CBCT. The medical physicist uses their process model, which includes clinical experience, to ensure the CBCT quality is acceptable and the patient is in an appropriate position. The second action is to re-optimize (if necessary) and calculate the dose distribution on the CBCT. The medical physicist also uses their knowledge of the software to perform and analyze the MR and pre-plan fusion to the CBCT and then to review the final dose calculation results by comparing them to the MR pre-plan. Based on the acceptability of this comparison, the medical physicist may initiate a
re-optimization and subsequent dose calculation and repeat the review process. Once the medical physicist is comfortable with the treatment plan, the radiation oncologist will be notified to review the plan and use their clinical knowledge and experience to approve the final plan to treat the patient. The radiation oncologist will also be comparing the treatment plan to the MR pre-plan results and may require knowledge of how to use the fusion software.

3.E. Unsafe control actions (STPA Step 1).

For the twenty three (23) control actions shown in Table 1, there were 83 conditions under which the control actions could be unsafe. The unsafe control actions (UCAs) for the medical physicist controller are shown in Table 2. New software will be developed to perform the fusion (MR and pre-plan to the CBCT) and used to determine the quality of the fusion.

Table 2: STPA Step 1 table of UCAs for the medical physicist controller (see Figure 3 and Figure A1 in the Appendix).

The medical physicist schedules the final plan for treatment with too many or too few fractions when using the RT EMR scheduling software. [H1]

The medical physicist takes too long to schedule the plan for treatment after it has been approved by the radiation oncologist. [H1]

For the set-up procedures control action and fuse MR and pre-plan to CBCT actions, there is a UCA for each of the four possible unsafe conditions of the control action. For control action Re-optimize and calculate, there are four UCAs but none for the state of ‘given at the wrong time or wrong order’ which is similar to the schedule for treatment control except it has only three UCAs. The send new plan to RT EMR control has UCAs for the control action given incorrectly and the control action given at the wrong time or wrong order.

3.F. UCA Causal Scenarios (STPA Step 2).

This step determined why the UCAs might occur, that is, the causal scenarios leading to those unsafe control actions. This information was used to generate design and operational requirements and controls to prevent the unsafe control actions. There were no assumptions made as to any existing controls such as pre-treatment physics QA checks. This allowed for the new radiosurgery procedure to be evaluated for hazards without being encumbered by existing procedures, which may or may not be relevant.

For the 83 UCAs, there were 472 causal scenarios identified. As one example, some causal scenarios for the medical physicist’s unsafe provision of the control action fuse MR and pre-plan to CBCT are the following:

Scenario 1. The CBCT scan does not get to the new software because the CBCT is not automatically stored correctly or sent to the new software and imported.

Scenario 2. The CBCT scan does not get to the new software because the person assigned to the task forgets to transfer, or otherwise process, the CBCT scan for the next step.
Scenario 3. The medical physicist is distracted by issues related to the case or otherwise pre-occupied with other non-case related clinical issues and the case proceeds in a suboptimal way without the medical physicist’s input because the radiation oncologist does the fusion without sufficient knowledge about how the new software works.

Scenario 4. The medical physicist does not know where to find the software or how to use it because there is inadequate training for the medical physicist on how to use the software.

Scenario 5. The medical physicist does not know where to find the software or how to use it because the medical physicist is new or not otherwise experienced and there is no sufficient competency assessment procedure.

Scenario 6. There is a software crash that the medical physicist cannot recover from because the error message is non-existent or not helpful and the vendor software service is slow to respond with expert assistance. An assumption is made that if the software can be restarted again, then all future operations will be safe, which is not necessarily true.

To provide some context for the 472 causal scenarios generated by the STPA for the new radiosurgery procedure, the causal scenarios were mapped onto the causality table in Appendix D from the consensus recommendations for incident learning database structures in radiation oncology. The breakdown of causality is provided in Table 3 and compared to those identified by the FMEA performed on the same system. The ‘other’ causality category was largely related to issues of software use, case delays, or other general workflow related issues that did not fit in one of the other categories.

3.G. Failure Modes and Effects Analysis.

The process map developed by the group is shown in Figure 5. It consists of 5 main process steps and 20 sub-processes and describes the process in sufficient detail to allow a focused analysis of each step in the process.

Overall, there were 132 failure modes/causes identified during the analysis. Table 4 lists Failure Modes with Risk Priority Numbers > 300. These are indicated in Figure 5 by the numbered ellipses. The numbers inside the ellipses correspond to the failure modes as listed in Table 4. Grouped into the main process steps, the number of failure modes were the following: pre-consultation had 51 (39%), consultation had 7 (5%), pre-treatment in treatment room had 25 (19%), final treatment planning had 32 (24%), and treatment had 17 (13%).
There were seven other failure modes for eight different steps with RPN = 300 (S = 10, O = 3, and D = 10). The step, sub-step, and failure mode for each is provided in the following list:

- **Pre-treatment – in treatment room**
  - *Surface imaging is used to set baseline patient position*
    - Baseline patient position set incorrectly

- **Final treatment planning**
  - *Fuse CBCT scan with pre-treatment MR scan*
    - Incorrect fusion because the wrong algorithm was used or not checked
  - *Physician reviews plan*
    - Passing the plan even though normal tissue doses were exceeded

- **Treatment**
  - *Confirm patient position using surface imaging*
    - Patient positioned incorrectly because surface imaging system does not register motion
  - *Adjust the patient’s head to match CBCT*
    - Surface imaging indicates patient is correctly positioned when they are not
  - *Use surface imaging to monitor head position during delivery*
    - Patient’s head motion is not correct from the surface imaging system
    - Surface imaging indicates that the patient’s head is out of alignment but the beam is not stopped
  - *Patient stable during treatment?*
    - Surface imaging indicates that the patient’s head is out of alignment but the beam is not stopped

The analysis team that performed the FMEA also mapped the failure modes onto the causality table and the breakdown is shown in Table 3. There were no external factors identified by either method as it was not explicitly included in the analyses.
Table 3: Causal scenarios were mapped onto the causality table in Appendix D from the consensus recommendations for incident learning database structures in radiation oncology\textsuperscript{29}. The causal scenarios were grouped into the higher level categories found in Appendix D as shown in this table.

4. DISCUSSION

In previous work, STPA has been applied to a medical device used in proton therapy\(^{30}\) and other healthcare settings including radiation oncology\(^ {31}\). The novel aspect of the current work is the application and assessment of STPA from the clinical perspective. The STPA for the new radiosurgery procedure resulted in 6 controllers, 10 control loops, and 23 control actions. The safety responsibilities related to each controller are shown in Table 1. Besides obvious equipment failures, frequently identified hazards were time pressures and communication issues. Other, perhaps non-obvious, recurring hazards were the lack of training and competency assessment as well as keeping the staff educated about the new procedure. Designing clinical tools such that normal workflow is facilitated rather than inhibited would be important to mitigate hazards. This was also realized early on in the analysis and to address time pressures and communication issues, new software should be created that facilitates many routine planning functions. The new software was built into the control loops as shown in Figure 3 and was explicitly part of the hazard analysis.

Pursuing this work from a clinical perspective has highlighted some differences between FMEA and STPA. Even though both FMEA and STPA end up with causal scenarios, how one arrives at those causal scenarios is very different. Therefore, the two approaches should not be expected to give the same results. STPA facilitates a hazard analysis on a truly de novo treatment strategy because it doesn’t require a strict definition of how it will be operationalized. FMEA can oversimplify human behavioral failure modes because after creating the process map, the analyst then determines what could go wrong at each step of the process. This is different than determining what are the unsafe interaction conditions of the people and equipment in a process. Nevertheless, there could be hazards that are not identified by either FMEA (reliability theory-based method) or STPA (systems theory-based method). The challenge is that there is no way of validating the completeness of any hazard analysis. Any such analysis is subject to the limitations of the analysts as well as things like time available. It is very possible that problems can still occur that were not identified or that the protection against the identified hazards is inadequate in practice.

There was some similarity in the FMEA and STPA results. Equipment failures or otherwise catastrophic errors were similar. These included things such as poor imaging, imaging or delivery systems not working, and incorrect use of equipment. There were also some human behavior issues identified with both approaches such as a covering radiation oncologist not being familiar with the patient or procedure. FMEA identified the potential for equipment collisions and several specific failures, e.g., all
the ways that a physics plan check could miss something such as incorrect MUs, insufficient PTV coverage, incorrect energy, suboptimal gradient index, etc. As previously mentioned, hazards uniquely identified by STPA were the importance of competency training and assessment, various time pressures for different controllers and workflow issues related to possible changes in the procedure over time.

Some larger hazard categories identified as important in the STPA but not included in the FMEA were not seeing the patient in follow-up thus potentially missing subtle late effects that could indicate a problem with the new procedure, adequate communication with the vendor in expeditiously resolving equipment issues during the procedure, department administration effects, and hospital administration effects. Each of these resulted in its own control loop and a total of 9 control actions. It is not obvious how effects of poor administration could be brought into an FMEA, which is reflected in the 6% of failure mode being included in the organization management category of Table 3.

It is interesting to note that both analysis teams were given the same general goals of the new procedure but the FMEA team ultimately did not include new software to facilitate the proposed procedure even though it was contemplated during their meetings. In the FMEA version of the analysis, the procedure required a therapist to get the patient’s head in the same position for treatment as was true for the MR scan. Therefore, a failure mode of ‘head position not reproducible – leads to difficulties performing registration’ would not show up in the STPA version of the analysis because new software is assumed that would adapt the plan to the patient’s current position as determined by CBCT. On the other hand, different failure modes/causes could have been identified had the FMEA team included new software in the analysis. However, this would require analyzing a process that is not well-defined and not suitable for the FMEA methodology. One last point on the comparison is that TG-100 recommends using both tools (in addition to process mapping). In this work, STPA was compared to FMEA rather than TG-100. However, it is noted that while FTA is a deductive approach and FMEA is an inductive approach, they cannot simply be thought of as complementary tools that when used together provide a complete analysis to covers all possible failure modes. Future work should include testing of multiple different hazard analysis tools such as HAZOP, ETA, and TG-100.

For the STPA, one of the unsafe control actions for the therapists is acquiring the CBCT after the patient has been lying on the table for a long time. This is clearly not a failure of the hardware, software or human behavior and most likely would not cause any harm at all. In fact, it happens routinely in many clinics. But, this does put the system in an unsafe state and thus should be considered a hazard that needs to be mitigated. The unsafe control action ‘patient on the table for a long time before the CBCT’
could also have been identified as a potential cause of a failure in FMEA but only if the analysis team identifies a specific failure mode that leads to this conclusion. At a high level, this scenario can be characterized as a failure but it would be an oversimplification to conclude that any single aspect of the process failed. Accidents can, and frequently, do happen as a result of system components interacting in a suboptimal way even though there has not been an explicit failure.

The hierarchical control structures developed in STPA can provide unique documentation of how a system operates, where the unsafe control actions (and scenarios) are linked to their associated hazards, thus lending traceability between the design specifications and hazards. Therefore, the STPA output can be used to develop a risk management plan as part of a comprehensive quality management strategy. Ultimately, the STPA causal scenarios generated from the identified unsafe control actions will be translated into design requirements or safety constraints. These requirements or constraints should prevent potentially dangerous interactions of the system components (people, processes, and equipment) if implemented in the system design. The exact methodology or format of the requirements may depend on who is receiving the recommendations. For example, formatting a list of constraints for internal departmental use may be significantly different than a list of requirements for a vendor’s engineering team. The requirements can also serve as a bridge between the clinical workflow designers and other domain experts such as the software engineers and human design experts. Because some software and equipment does not yet exist to support this new treatment procedure described in this research, any associated risks found at this stage could be either designed out of the system or given proper controls.

It should be pointed out that nurses were not included in the current analysis even though nurses have important safety responsibilities for any radiation oncology treatment. This was a decision made by the STPA analysis team to scope the project. There was no evaluation done on how this might have affected the results. Similarly, it is not possible to comment on how the team size for the creation of causal scenarios (e.g., two individuals doing the majority of the brainstorming and being ‘checked’ by a broader audience) or effort required affects the results. Even with the FMEA and STPA comparison, a study would need to be developed that is specifically designed to answer those questions, which is beyond the scope of this work. Efficiency, completeness, and ease of use may be a concern in selecting an analysis technique and this topic can be the subject of future work.

Finally, while only a single example of STPA for a clinical case is presented in this work, the STPA procedures is generalizable to all aspects of radiation oncology for analyzing both new processes as well
as existing processes. For an existing process, the STPA steps would be the same. Since the process would already exist, the analysis might be more straightforward because the process would be better understood than would be for a new process. There would also be an even better knowledge of existing hazards.

5. CONCLUSION

All hazard models and risk assessment techniques are meant to provide a framework to characterize and identify potential sources of accidents that are not immediately obvious. As a clinical tool for prospective hazard analysis, STPA worked quite well but is a new way of thinking about the problem. The interaction of people, hardware, and software are highlighted through the STPA procedure in a way that is uniquely different than FMEA. STPA provides a hierarchical model for understanding the role of management decisions in impacting system safety so that a system design requirement can be traced back to the hazard and accident that it is intended to mitigate. Management decisions can also be straightforwardly included in the risk analysis. Further investigation of STPA is warranted for radiation oncology safety improvement and quality management.
