Stochastic hybrid models for predicting the behavior of drivers facing the yellow-light-dilemma

The MIT Faculty has made this article openly available. Please share how this access benefits you. Your story matters.
Abstract—We address the problem of predicting whether a driver facing the yellow-light-dilemma will cross the intersection with the red light. Based on driving simulator data, we propose a stochastic hybrid system model for driver behavior. Using this model combined with Gaussian process estimation and Monte Carlo simulations, we obtain an upper bound for the probability of crossing with the red light. This upper bound has a prescribed confidence level and can be calculated quickly on-line in a recursive fashion as more data become available. Calculating also a lower bound we can show that the upper bound is on average less than 3% higher than the true probability. Moreover, tests on driving simulator data show that 99% of the actual red light violations, are predicted to cross on red with probability greater than 0.95 while less than 5% of the compliant trajectories are predicted to have an equally high probability of crossing. Determining the probability of crossing with the red light will be important for the development of warning systems that prevent red light violations.

I. INTRODUCTION

In 2012 approximately 2.36 million people were injured in motor vehicle traffic crashes, about 30% of these injuries happened on or near signaled intersections [1]. Statistics show that driver distraction or inattention is the most prevalent contributing factor for all crashes at signaled intersections [2].

In [3], experiments have shown that using an on-board warning system, red light running could be reduced by 77%. Our objective is to design safety systems that are able to predict the probability of a red light violation. This ability will be used to issue warnings and if necessary, take control over the vehicle to prevent red light violations. In [4], [5], [6], [7], [8], [9] safety systems were proposed for intersections without signals and by representing driver inputs as a disturbance. In this paper we present a combined experimental/theoretical study where suitably designed experiments in the driving simulator are used to create a stochastic model of driver behavior near signalized intersections. Considering the situation when the traffic light changes from green to yellow upon intersection approach (yellow-light-dilemma), we use this model to compute the probability of the driver being on the intersection while the traffic light is red.

Classification of driver behavior is an active area of research and several different approaches, mainly using machine learning techniques, have been proposed, see for instance [10], [11], [12], [13], [14], [15] and the references therein. Most of these studies try to predict specific driving actions, such as turning left, going straight or stopping. In [10] the focus is on the prediction of traffic light violations and in [13] the authors suggest two methods to predict whether a driver is going to stop after observing a switch of the traffic light from green to yellow.

In this paper, instead, we seek to estimate the actual probability of reaching some given state (stochastic reachability problem). In particular, for the yellow-light-dilemma we estimate the probability of crossing the intersection on red. Moreover, we provide a complete model of driving behavior near intersections, which may be used for other purposes, including the design of safety-enforcing supervisors.

Stochastic reachability problems have been studied in the stochastic hybrid systems literature, see [16], [17], [18], [19]. Exact computation of reach probabilities remains a challenging problem but Monte Carlo methods have proven to be an efficient way to deal with the complexity of stochastic hybrid systems, see [17].

By modeling driver behavior near intersections as a stochastic hybrid system, we make use of the existing stochastic reachability literature in order to formally define the probability of crossing on red. This probability is then computed by a combined Gaussian process estimation and Monte Carlo simulation approach. Tests on driving simulator data show the accuracy of the computed crossing probability. The method therefore provides a quantification of the danger instead of just a binary output (safe, dangerous).

In Section II, we state the problem and introduce the mathematical model. Then, in Section III, we present our solution algorithm and in Section IV we provide the experimental results.

II. SYSTEM MODEL AND PROBLEM FORMULATION

We start by describing the intersection encounter scenarios that we are considering and then introduce the mathematical model.

A. Application

When the traffic light changes from green to yellow, the driver has to decide whether he wants to brake and stop at the stop line or continue and try to make it through the intersection before the traffic light turns red. This is known as the yellow-light-dilemma. The question that we address is: What is the probability that the driver is going to be on
the intersection while the traffic light is red? We shall call this the crossing probability.

The intersection scenarios that we consider start when the traffic light of the subject vehicle switches from green to yellow. The vehicle state \( x = (p, v) \in \mathbb{R} \times \mathbb{R}_+ \) is given by the vehicle position \( p \in \mathbb{R} \), which represents the signed distance of the center of gravity of the subject vehicle to the intersection center and the subject vehicle’s longitudinal speed \( v \in \mathbb{R}_+ \) (Figure 1). We assume that the vehicle state \( x \) is measured. In practice, this implies that the subject vehicle is equipped with differential GPS and a map of the area. In order to be able to estimate the crossing probability we make the additional assumption that the durations of the yellow and red light, denoted respectively by \( \tau_y \) and \( \tau_r \), are known. This implies that the infrastructure should be able to communicate these durations to the vehicle (V2I communication).

Figure 2 shows speed over position trajectories for different drivers once a yellow light is observed. We see clearly four different dynamical behaviors based on the driver’s intended driving maneuver (action), namely coasting, braking, accelerating and waiting for the green light after the car has stopped. That is, a different dynamical system belongs to each driver’s action.

Based on Figure 2, we seek a driver model with the following properties:

1) drivers have a finite set of basic actions that they can perform such as braking, coasting and waiting;
2) each basic action has its corresponding stochastic continuous dynamics;
3) the action initially intended by the driver (intention after observing the yellow traffic light) is unknown.

The framework of (general) stochastic hybrid systems \([18]\) is adapted to build a driver model that satisfies these requirements. The next section introduces the mathematical definition of such a model.

B. Hybrid system model

In what follows, we introduce the stochastic hybrid system model and state some of its properties. A much more detailed treatment of the subject can be found for instance in \([18]\).

a) State space: Hybrid systems have continuous states, that is, states that evolve according to a differential equation and discrete states, called modes, that evolve according to discrete transitions.

Let \( n \in \mathbb{N} \) be given. The set of modes is denoted by \( Q \) and we define the set-valued map \( \mathcal{X} : Q \rightsquigarrow \mathbb{R}^n \) which assigns to each mode \( q \in Q \) an open set in \( \mathbb{R}^n \). With this we define the hybrid state space,

\[
\mathcal{X}(Q, \mathcal{X}) := \bigcup_{q \in Q} \{ q \} \times \mathcal{X}(q).
\]

A hybrid state \((q, x) := s \in \mathcal{X}(Q, \mathcal{X})\) is a tuple formed by the mode \( q \in Q \) and a continuous state \( x \in \mathcal{X}(q) \). Here \( \mathcal{S} \) denotes the closure of the set \( S \).

b) Formal definition and properties: Let \( T > 0 \) be a finite constant and let \( m \in \mathbb{N} \). We denote by \( \{ W_t \}_{t \in [0, T]} \) the \( m \)-dimensional standard Brownian motion, see for instance \([20, \text{Ch. 2}]\). A relevant property for this paper is that its increments are independent, normally distributed and have zero mean.

Definition 1: A (linear) stochastic hybrid system is a collection \( H = (Q, \mathcal{X}, A, b, \sigma, R, Init, x_0) \) where

- \( Q \) is a finite set;
- \( \mathcal{X} : Q \rightsquigarrow \mathbb{R}^n \) is a set-valued map with open images;
- \( x_0 \in \mathbb{R}^n \) is the initial continuous state;
- \( A : Q \rightarrow \mathbb{R}^{n \times n} \) is a matrix-valued map;
- \( b : Q \rightarrow \mathbb{R}^n \) is a vector-valued map;
- \( \sigma : Q \rightarrow \mathbb{R}^{n \times m} \) is a matrix-valued map;
- \( R : Q \rightarrow [0, 1] \) is the transition measure;
- \( Init : Q \rightarrow [0, 1] \) is the initial probability distribution on the modes.

The linear stochastic hybrid system defined here is a special case of a general stochastic hybrid system, see for instance \([18, \text{Defs. 4.1}]\), where dynamics are linear and only the modes can have jumps.

Definition 2: A stochastic process \( \{ s(t) \}_{t \in [0, T]} = \{(q(t), x(t))\}_{t \in [0, T]} \) is an execution of a stochastic hybrid system \( H \) if there exist stopping times \( T^0 = 0 \leq T^1 \leq \cdots \leq T^k \leq \cdots \leq T \) such that for each \( k \in \{0, 1, \ldots \} \),

1. \( s(0) = (q_0, x_0) \), where \( q_0 \) is a \( Q \)-valued random variable with probability distribution \( Init; \)
(ii) \( q(T^{k+1}) = q_{k+1} \), where \( q_{k+1} \) is a \( Q \)-valued random variable distributed according to \( R \);
(iii) For all \( t \in [T^k, T^{k+1}] \), where \( \lfloor \cdot \rfloor \) is closed when \( T^{k+1} = T \) and open otherwise, \( q(t) \equiv q_k \);
(iv) For all \( t \in [T^k, T^{k+1}] \), \( x(t) \) is the solution of
\[
dx(t) = (A(q_k)x(t) + b(q_k)) \, dt + \sigma(q_k) \, dW_t;
\]
(v) \( T^{k+1} = \inf \{ t \in [T^k, T] \mid x(t) \in \partial \mathcal{X}(q_k) \} \).

Definition 3: Let \( C \in \mathbb{R}^{n \times 1} \) be a given matrix, \( H \) a stochastic hybrid system and \( \{s(t)\}_{t \in [0, T]} \) an execution of \( H \). An output of \( H \) corresponding to the execution \( \{s(t)\}_{t \in [0, T]} \) and the output map \( C \) is a stochastic process \( \{y(t)\}_{t \in [0, T]} \) satisfying \( y(t) = Cx(t) \) for all \( t \in [0, T] \).

Definition 4: A mode \( q \in Q \) is stationary if \( A(q) = b(q) = \sigma(q) = 0 \).

Throughout the paper \( H = (Q, \mathcal{X}, A, b, \sigma, R, \text{Init}, x_0) \) represents a stochastic hybrid system which satisfies the standard assumptions [21, Assumption 1-3]. Other than regularity assumptions on the dynamics that are satisfied in the linear case, these assumptions demand that the executions have non-Zeno dynamics. We end the section with some properties of the hybrid system.

Fact 1 ([21]): Every stochastic hybrid system \( H \) with an execution that is a strong Markov process (see [20, p. 81]) which enjoys the càdlàg property, which means sample paths are continuous from the right and have left limits, [20, p. 4].

Using the terminology of [22], let \( q \in Q \) be given and recall that the fundamental matrix \( \Phi_q \colon [0, T] \to \mathbb{R}^{n \times n} \) of the linear system \( \dot{x}(t) = A(q)x(t) + b(q) \) is defined by
\[
\Phi_q(t) := e^{A(q)t} := \sum_{i=0}^{\infty} \frac{(A(q)t)^i}{i!}.
\]

Fact 2: Let \( H \) be a linear stochastic hybrid system, \( q \in Q \) and \( x \in \mathcal{X}(q) \). Then, the stochastic process \( \{x^q(t, x)\}_{t \in [0, T]} \) satisfying \( x^q(0, x) = x \) and
\[
dx(t, x) = (A(q)x(t) + b(q)) \, dt + \sigma(q) \, dW_t,
\]
is given for all \( t \in [0, T] \) by the stochastic integral
\[
x^q(t, x) = \Phi_q(t) \left( x + \int_0^t \Phi_q^{-1}(s)b(q)ds \right)
+ \Phi_q(t) \int_0^t \Phi_q^{-1}(s)\sigma(q)ds. \tag{3}
\]
Moreover, \( \{x^q(t, x)\}_{t \in [0, T]} \) is a diffusion, i.e., time-homogenous and strongly Markovian with continuous sample paths. Finally, the stochastic process \( \{E^q(t)\}_{t \in [0, T]} \) defined by
\[
E^q(t) := \Phi_q(t) \left( \int_0^t \Phi_q^{-1}(s)\sigma(q)ds \right), \tag{4}
\]
is a Gaussian process, where for all \( t, t' \in [0, T] \), \( \mathbb{E}(E^q(t)) = 0 \) and the covariance function \( \Sigma^q(t, t') \) is given by
\[
\Sigma^q(t, t') := \int_0^{\min\{t, t'\}} \left( \Phi_q(t - s)\sigma(q)\sigma(q)^T \Phi_q(t' - s)^T \right) ds. \tag{5}
\]

For a proof of these results see for instance [20] and [22]. The deterministic part of (3) is denoted by:
\[
\varphi^q(t, x) := \Phi_q(t) \left( x + \int_0^t \Phi_q^{-1}(s)b(q)ds \right). \tag{6}
\]

C. Problem formulation

We start with the data that we assume is available at all time.

Data: Let \( S \in [0, T] \) and for all \( q \in Q, N^q \in \mathbb{N} \). Then the following is given:

- \( I_x = [S, T] \) – time interval;
- \( I_y = [y_{\text{min}}, y_{\text{max}}] \) – target set for the output;
- For each mode \( q \in Q \), \( \{e^q_i(t), \ldots, e^q_{N^q}(t)\}_{t \in [0, T]} \) is a set of observed sample paths of \( N^q \) independent stochastic processes distributed as \( \{E^q(t)\}_{t \in [0, T]} \).

We impose the following assumptions on the stochastic hybrid system \( H \).

Assumption 1: (i) There exists a stationary mode \( \tilde{q} \in Q \) and \( \mathcal{X}(\tilde{q}) = \mathbb{R}^n \);
(ii) The transition measure is for all and \( q \in Q \) given by \( \mathbb{R}(q) = 1_{\{\tilde{q}\}}(q) \), where \( 1_{\mathcal{S}}(\cdot) \) is the indicator function of the set \( \mathcal{S} \);
(iii) There exists a set \( \mathcal{T} \subset \mathbb{R}^n \) such that for all \( q \in Q \setminus \tilde{q} \) we have that \( \partial \mathcal{X}(q) = \mathcal{T} \).

The assumption implies that when the continuous state enters set \( \mathcal{T} \), then a transition into the stationary mode \( \tilde{q} \) must occur. Moreover, once in the stationary mode, there cannot be any mode transitions anymore.

Problem 1: Let \( \alpha > 0 \), \( C \in \mathbb{R}^{n \times 1} \) and the above data be given. Moreover, let \( \{s(t)\}_{t \in [0, T]} = \{q(t), x(t)\}_{t \in [0, T]} \) be an execution of \( H \) and \( \{y(t)\}_{t \in [0, T]} \) be the output corresponding to \( C \). Finally, let \( N \in \mathbb{N} \) and \( x(t_0) = x_0, \ldots, x(t_N) = x_N \) be measurements of the continuous state trajectory, where \( 0 = t_0 < t_1 < \cdots < t_N < T \). Find a \( 1 - \alpha \) confidence upper bound for the probability
\[
P_N := \Pr(y(I^N_x) \cap I_y \neq \emptyset) \mid \begin{array}{c}
\mathbb{P}(t_0) = x_0, \ldots, \mathbb{P}(t_N) = x_N,
\end{array}
\]
where \( I^N_x := I_x \cap [t_N, T] \).

Determining a \( 1 - \alpha \) confidence upper bound implies that we seek an algorithm that will produce with probability \( 1 - \alpha \) an upper bound for the true probability \( P_N \). Notice that with an analogous approach we can also find a \( 1 - \alpha \) confidence lower bound to verify the tightness of the upper bound. The motivation for solving Problem 1 is to assess the risk of the output entering the set \( I_y \). Taking an upper bound guarantees that we do not underestimate that risk which provides a certain safety guarantee.

D. Illustration with application

We illustrate the previous definitions with the help of the application described in Section II-A.

The time interval that we are interested in is from the moment when the traffic light switches from green to yellow until it becomes green again. Hence \( T \) represents this time span, that is, \( T := \tau_y + \tau_r \) and time 0 is when the traffic light
Problem 1. Then we address these sub-problems.

A. Problem decomposition

With these definitions, the car is on the intersection if its duration of the yellow light is known, we set to the vehicles front, respectively to its rear. Using that the represent the distance from the vehicle’s center of gravity also has to be learned from data. The transition measure deviation from the nominal acceleration profile.

Problem 2: Let \(x_0, \ldots, x_N\) be as in Problem 1 and assume that \(x_N \not\in \mathcal{T}\). For all \(q \in Q\) compute the probability

\[ P_N^*(q) = \Pr(q(0) = q | x_N, \ldots, x_0). \]

The problem is solved by using Bayes’ theorem and then standard Gaussian process theory techniques, see [23].

Since \(x_N \not\in \mathcal{T}\) there have not been any mode transitions. When setting \(q(0) = q\), it follows from Fact 2 that \(x(t) = x^q(t, x_0)\) for all \(t \in [0, t_N]\). The process \(\{x^q(t, x_0)\}_{t \in [0, t_N]}\) is Gaussian and it follows from the definition of its covariance function \(\Sigma^q\), given by (5), that the random variables \(x^q(t_1, x_0), \ldots, x^q(t_N, x_0)\) have a joint probability density. For all \(1 \leq i \leq j \leq N\), we denote by \(f_{i,j}^q\) the joint density function of the random variables \(x^q(t_i, x_0), x^q(t_i+1, x_0), \ldots, x^q(t_j, x_0)\), that is,

\[ f_{i,j}^q(x) = f_{x(t_i), x(t_{i+1}), \ldots, x(t_j)}(x | q(0) = q). \]

Analogously, for \(i \in \{1, \ldots, N\}\), the density of \(x^q(t_i, x_0)\) is denoted by \(f_i^q\), that is,

\[ f_i^q(x) = f_{x(t_i)}(x | q(0) = q). \]

We use a similar notation for the covariance function. Thus, for all \(i, j \in \{1, \ldots, N\}\) we set \(\Sigma^q_{i,j} := \Sigma^q(t_i, t_j)\) and \(\Sigma_i^q := \Sigma^q(t_i, t_i)\). Finally, recalling that the mean function of the Gaussian process \(\{x^q(t, x_0)\}_{t \in [0, t_N]}\) is given by (6), we set for all \(i \in \{1, \ldots, N\}\), \(\varphi^q := x_i - \varphi^q(t_i, x_0)\).

Fix an arbitrary \(q \in Q\). By Bayes’ formula we have then

\[ P_N(q) = \frac{f_N^q(x_1, \ldots, x_N) \text{Init}(q)}{\sum_{q \in Q} f_N^q(x_1, \ldots, x_N) \text{Init}(q)}. \]  

(11)

Efficient computation of (11) is achieved by using the following update formulas that exploit the Markov property of executions, see Fact 1.

\[ P_N^*(q) = \frac{f_i^q(x_i) \text{Init}(q)}{\sum_{q \in Q} f_i^q(x_i) \text{Init}(q)}. \]  

(12)
where
\[ f^q_i(x_i) = \frac{\exp\left(-\frac{1}{2} (\epsilon^q_i)^T (\Sigma^q_i)^{-1} \epsilon^q_i\right)}{\sqrt{(2\pi)^n \det(\Sigma^q_i)}}. \tag{13} \]

Moreover for all \( N > 1 \),
\[ P^q_N(q) = \frac{f^{q}_N(x_N \mid x_{N-1}) P^{q}_{N-1}(q)}{\sum_{\tilde{q} \in Q} f^{q}_N(x_N \mid x_{N-1}) P^{q}_{N-1}(\tilde{q})} \tag{14} \]
where
\[ f^q_N(x_N \mid x_{N-1}) = \frac{\exp\left(-\frac{1}{2} (\epsilon^q_N - \mu^q_N)^T (\Sigma^q_N)^{-1} (\epsilon^q_N - \mu^q_N)\right)}{\sqrt{(2\pi)^n \det(\Sigma^q_N)}} \tag{15} \]
and \( \mu^q_N := \Sigma^q_{N-1} (\Sigma^q_{N-1})^{-1} \epsilon^q_{N-1} \) and \( \Sigma^q_N := \Sigma^q_N - \Sigma^q_{N-1} (\Sigma^q_{N-1})^{-1} \Sigma^q_{N-1,N-1} \).

C. Stochastic reachability of an interval

For this section, let \( q \in Q \) be an arbitrary mode, assume that \( x_N \notin \mathcal{T} \) and \( \tilde{\alpha} \in [0,1] \). We solve the following problem:

**Problem 3:** Using the data provided in Section II-C, find a \( 1 - \tilde{\alpha} \) confidence upper bound for the probability
\[ P_N(q) := \Pr(y(I_N^q) \cap I_y \neq \emptyset \mid q(t_N) = q, x(t_N) = x_N). \]

We assume in the following that \( q \neq \tilde{q} \) because otherwise \( P_N(q) = 1_1(Cx_N) \).

To solve the problem we use \( N^q \) sample paths of the process \( \{y(t)\}_{t \in [0,T]} \) and then estimate for what fraction of the sample paths there exists a time in \( I_N^q \) for which the sample path takes values in \( I_y \). By (3), we know that
\[ x(t) = \varphi^q(t - t_N, x_N) + E^q(t - t_N), \quad \forall t \in [t_N, T], \]
where \( T^1 = \inf \{ t \in [t_N, T] \mid x(t) \in \mathcal{T} \} \). As \( \varphi^q(t - t_N, x_N) \) is a deterministic function, we have that defining for all \( i \in \{1, \ldots, N^q\} \) the functions
\[ x^q_i(t) := \varphi^q(t - t_N, x_N) + \epsilon^q_i(t), \quad \forall t \in [t_N, T], \]
\( \{x^q_i(t)\}_{t \in [t_N, T]} \) is a set of observed sample paths of \( N^q \) independent random processes that are distributed as \( \{\varphi^q(t - t_N, x_N) + E^q(t - t_N)\}_{t \in [t_N, T]} \). This leads to the corresponding set of observed stopping times \( T^1_i := \inf \{ t \in [t_N, T] \mid x^q_i(t) \in \mathcal{T} \} \). Finally, since by Assumption 1 \( q(t) = \tilde{q} \), for all \( t \geq T^1 \), we infer that by defining
\[ y^q_i(t) := \begin{cases} Cx^q_i(t) & \text{if } t < T^1_i \\ Cx^q_i(T^1_i) & \text{otherwise}, \end{cases} \]
\( \{y^q_i(t)\}_{t \in [t_N, T]} \) is a set of observed sample paths of \( N^q \) independent random processes \( \{y^q_i(t)\}_{t \in [t_N, T]} \) that are identically distributed as \( \{y(t)\}_{t \in [t_N, T]} \) given that \( s(t_N) = (q, x_N) \).

Let us now associate a Bernoulli variable with each of the random processes \( \{y^q_i(t)\}_{t \in [t_N, T]} \)
\[ Y^q_i := \begin{cases} 1 & \text{if } y^q_i(I_y^q) \cap I_y \neq \emptyset \\ 0 & \text{otherwise}. \end{cases} \tag{16} \]

Since the processes \( \{y^q_i(t)\} \) are independent and identically distributed, the same is true for \( Y^q_i \). Moreover, we have that \( P_N(q) = Pr(Y^q_i = 1) \) for all \( i \). Then it is well known that the sum \( Z^q := \sum_{i=1}^{N^q} Y^q_i \) has the binomial distribution \( B(N^q, P_N(q)) \). Set for all \( i \in \{1, \ldots, N^q\} \),
\[ \gamma^q_i := \begin{cases} 1 & \text{if } y^q_i(I_y^q) \cap I_y \neq \emptyset \\ 0 & \text{otherwise}. \end{cases} \]

The values \( \gamma^q_i \) correspond to realizations of the Bernoulli random variables \( Y^q_i \), hence \( z^q := \sum_{i=1}^{N^q} \gamma^q_i \) is a realization of the binomial variable \( Z^q \).

Providing a \( 1 - \alpha \) confidence upper bound for the parameter \( P \) of a binomial distribution \( B(N^q, P) \) from a given observation is a standard statistical problem. For this study, we use the upper bound of the classical Clopper-Pearson confidence interval [24]. Hence a \( 1 - \tilde{\alpha} \) confidence upper bound for \( P_N(q) \), for all \( q \in Q \setminus \tilde{q} \) is given by,
\[ u^q_N(\tilde{\alpha}) = Beta(1 \setminus \tilde{\alpha}; z^q + 1, N^q - z^q), \tag{17} \]
where \( Beta(\kappa; \nu, \nu) \) is the \( \kappa \)-quantile from a beta distribution with shape parameters \( \nu \) and \( \nu \). Finally, for \( \tilde{q} \) we have the exact probability
\[ u^q_N(\tilde{\alpha}) = 1_1(Cx_N). \tag{18} \]

To summarize, let \( N \in \mathbb{N} \), \( q \in Q \) and \( \tilde{\alpha} \in [0,1] \) be arbitrary. Equations (12)-(15) provide an exact formula for the probability \( P^q_N(q) \) and \( u^q_N(\tilde{\alpha}) \) is a \( 1 - \tilde{\alpha} \) confidence upper bound for the probability \( P_N(q) \). The probability that \( u^q_N(\tilde{\alpha}) \geq P_N(q) \) for all \( q \in Q \setminus \tilde{q} \) is \( (1 - \tilde{\alpha})^{r-1} \), where \( r \) is the number of modes. Consequently, setting
\[ \tilde{\alpha} := 1 - \gamma^{r-1}_{-1}, \tag{19} \]
and using Lemma 3.1, a \( 1 - \alpha \) confidence upper bound for the probability \( P_N \), is given by \( \sum_{q \in Q} P^q_N(q) u^q_N(\tilde{\alpha}) \).

D. Solution algorithm

Using the results of the previous sections, we provide an algorithm to solve Problem 1.

**Algorithm 1:** 1. For initialization let \( N = 0, t_0 = 0 \) and the initial state \( x_0 \) is observed. We define \( \tilde{\alpha} \) as in (19) and initialize \( P_0(q) := Init(q) \), for all \( q \in Q \). By (9) we have that \( P_0 := \sum_{q \in Q} P^q_0(q) u^q_0(\tilde{\alpha}) \), where \( u^q_0(\tilde{\alpha}) \) is defined by (17)-(18), is a \( 1 - \alpha \) confidence upper bound for \( P_0 \).

2. For \( N \rightarrow N + 1 \), let \( t_{N+1} \in [t_N, T] \) be the current time and \( x(t_{N+1}) = x_{N+1} \) the new state observation. If \( x_{N+1} \in \mathcal{T} \) or \( t_{N+1} = T \), then \( P_{N+1} = 1_1(Cx_{N+1}) \) and the algorithm stops. Otherwise \( P^q_{N+1}(q) \) is obtained from (12) and (14) and we set \( P_{N+1} := \sum_{q \in Q} P^q_{N+1}(q) u^q_{N+1}(\tilde{\alpha}) \), where \( u^q_{N+1}(\tilde{\alpha}) \) is defined by (17)-(18). \( P_{N+1} \) is a \( 1 - \alpha \) confidence upper bound for \( P_{N+1} \). Repeat step 2.
IV. APPLICATION

A. Experimental setup

We use driving simulator data that was gathered at the University of Michigan Transportation Research Institute (UMTRI), see Figure 3. There were 24 subjects in this experiment. Twelve were under age 30 and 12 were older than 60. Within each age group there was an equal number of men and women. Each subject drove two test blocks, each block consisting of 70 intersections 200m apart. The subjects were instructed not to turn at any of the intersections (to make motion sickness less likely and simplify construction of the virtual world). In some intersections, the traffic light would remain green, in others it would turn to yellow and for some it would already be red upon approach. All intersections were crosses, with a single lane in each direction and in each intersection scenario there were up to four cars in addition to the subject vehicle.

In order to prevent excess speed, there was always a lead vehicle present, that is, a vehicle driving in front of the subject vehicle. The lead vehicle would however always cross the intersection when the traffic light changed to yellow, leaving the decision of whether to comply with the signal completely to the subject. Notice that the behavior of other traffic participants was not taken into account in the prediction (no vehicle-to-vehicle communication).

For our purpose, mainly intersections where the traffic light changed to yellow were of interest. In total, we considered 1,534 such intersection approaches. The signal change from green to yellow would occur at three possible values for the time to intersection (TTI), which is the distance to the stop line divided by the current speed. Those values were respectively, 2.8s, 3.5s and 4.2s. Those are chosen such that in the case with the largest TTI the subject has a comfortable amount of time to react while with the smallest TTI the time to react is relatively short.

The data set provided by UMTRI includes position, speed and acceleration measurements for the subject vehicle as well as the traffic light information. Measurements were taken at a frequency of 60Hz.

B. System identification

This section is concerned with the identification of the model parameters $A$, $b$, $\sigma$ and $\text{Init}$ from data. Since we used standard methods, we mainly provide references to the relevant literature.

As a first step, we divided the data into a training and a test set both containing 767 intersection approaches. Only the training data was used for parameter identification. The separation into training and test data sets was done in a way that kept the ratios between male and female, old and young drivers, unchanged. Moreover, the training data was taken from subjects different from those of the test data in order to avoid correlation between the two sets.

The training data was then further divided by identifying the trajectories belonging to the same mode. For all $q \in \{1, 2\}$, the parameters $a_q^1$, $a_q^2$ and $b_q$ characterizing the maps given in (8) can then be identified in the same way as this was done in [25], i.e., by solving a least square optimization problem [25, (4)]. As a result we found the parameters $a_1^1 = -0.04$, $a_1^2 = -0.27$, $b_1 = -10.23$, $a_2^2 = -0.003$, $a_2^2 = 0.04$ and $b_2 = -2.12$.

The parameter $\sigma_q$ defined in (8) is a so-called hyperparameter of a Gaussian process. Hyperparameters of Gaussian processes are classically estimated with a maximum likelihood method, see [23, Ch. 5]. A general statement of the corresponding optimization problem is for instance given in [23, p. 113]. The resulting parameters are $\sigma_1 = 2.54$ and $\sigma_2 = 0.66$.

Consider next the problem of identifying the initial distribution $\text{Init}$. Let $\{s(t)\}_{t \in [0, T]} = \{(q(t), p(t), v(t))\}_{t \in [0, T]}$ be a hybrid state trajectory from the training set. As described in Section IV-A, experiments were performed with the traffic light changing at three different times to intersection. Hence $p(0)/v(0) \in \{2.8, 3.5, 4.2\} =: I$. We then define the distribution $\hat{\text{Init}} : Q \times I \rightarrow [0, 1]$ by the law of large numbers as relative frequencies, that is,

$$
\hat{\text{Init}}(q, \tau) := \frac{\# \text{ training trajectories s.t. } (q(0), \frac{p(0)}{v(0)}) = (q, \tau)}{\# \text{ of training trajectories}}.
$$

Then, using this we have the estimator $\hat{\hat{\text{Init}}}(q; p_0, v_0) := \hat{\text{Init}}(q, p_0/v_0)$ for the initial distribution $\hat{\text{Init}}$ of the hybrid system with initial state $x_0 = (p_0, v_0)$. In particular, we found that $\hat{\hat{\text{Init}}}(1, 4.2) = 0.93$, $\hat{\hat{\text{Init}}}(1, 3.5) = 0.81$, $\hat{\hat{\text{Init}}}(1, 2.8) = 0.47$, $\hat{\hat{\text{Init}}}(2, \tau) = 1 - \hat{\hat{\text{Init}}}(1, \tau)$ for all $\tau \in I$ and finally $\hat{\hat{\text{Init}}}(3, \tau) = 0$ for all $\tau \in I$. These values show that less drivers will brake when time to intersection decreases.

Algorithm 1 estimates the mode based on discrete observations of the vehicle’s state. These observations obviously only reflect the driver’s intended reaction to the traffic light change once the driver had time to recognize the change of the traffic light and react accordingly. Therefore we do not start Algorithm 1 at the moment when the traffic light changes but 2s later. The 2s value corresponds to the 90% quantile of the cumulative human response time distribution, see [26]. Response time was defined as the time from the...
moment the risk is presented to the driver until the driver input starts, see the SAE J2944 standard.

C. Experimental results

In this section, we provide results obtained from Algorithm 1. The algorithm was implemented in MATLAB and run on a 2.6GHz dual-core computer. Computing the mode update by using the formulas (12)-(15) takes less than 0.3ms. Computing $u_\tilde{N}(\tilde{\alpha})$, takes less than 5ms. A full iteration of Algorithm 1 is performed in less than 10ms. All results were obtained by running the algorithm on the 767 intersection approaches of the test data set and with parameter $\alpha = 0.05$. 478 of these approaches comply with the traffic light, the remaining 289 are violating trajectories.

The purpose of Algorithm 1 is to assess the risk that a car will cross on red. As it returns an $1 - \alpha$ confidence upper bound, it guarantees that the crossing probability is underestimated only with probability $\alpha$. Moreover, using an analogous procedure to compute the upper bound $\tilde{P}_N$, we can compute a corresponding $1 - \alpha$ confidence lower bound, that we denote by $\tilde{P}_N$. It follows that $P_N - \tilde{P}_N \leq \tilde{P}_N - P_N$ with probability $1 - 2\alpha$. Table I shows the average difference $\tilde{P}_N - P_N$ as a function of the number of observations $N$. Measurements were taken at a frequency of 10Hz and the average is taken over all 767 trajectories from the test set.

<table>
<thead>
<tr>
<th>Number of observations $N$</th>
<th>$\tilde{P}_N - P_N$</th>
<th>1</th>
<th>5</th>
<th>10</th>
<th>15</th>
</tr>
</thead>
<tbody>
<tr>
<td>Avg. of $\tilde{P}_N - P_N$</td>
<td>0.023</td>
<td>0.021</td>
<td>0.021</td>
<td>0.02</td>
<td></td>
</tr>
</tbody>
</table>

Table I shows that prediction accuracy increases slowly with the number of measurements and that independent of the number of measurements $N$, $P_N - \tilde{P}_N$ is on average less than 0.023. The standard deviation is always less than $4 \times 10^{-4}$. This bound is theoretical in the sense that it is based on the theoretical result that for all $q$, $P_N^*(q)$ is the actual probability of mode $q$. It is, however, confirmed by our experiments. We ran Algorithm 1 on each test trajectory and made predictions at a frequency of 10Hz, which led to a total of 14,623 predictions, of which at most 20 were taken from the same trajectory. In 98% of the 5,301 cases when $P_N$ was larger than 0.95, the vehicle would actually cross on red. Similarly, in less than 1% of the 7,979 cases when $P_N$ was lower than 0.05, the vehicle would cross on red.

A crucial question from an application point of view is how many observations are needed to predict a traffic light violation with high probability, assuming there will be one. To be more precise, call a prediction decisive when the crossing probability is above 0.95 and then define the detection rate at a given time as the percentage of traffic light violating trajectories that have gotten a decisive prediction at that time. Table II compares the detection rates for the algorithm if we take measurements and update the probability at 5, 10 and 30Hz respectively. Data was obtained by running the algorithm on all 289 traffic light violating intersection approaches.

<table>

<tr>
<td>Detection rate 5Hz</td>
<td>– – 92 98</td>
</tr>
</tbody>
</table>

As the results in Table II show, the traffic light violations are detected by the algorithm in most cases in less than 0.2s.

In the recent paper [10] the problem of detecting traffic light violations was studied. The authors argued that a behavior classification procedure should be able to provide an accurate classification at a time when traffic participants still have time to react to the danger. To ensure this, it was required that warnings are given (if necessary) before TTI becomes smaller than a lower bound $TTI_{min} > 0$, see Section IV-A. We use the same values for $TTI_{min}$ as in [10], i.e., $TTI_{min} \in \{1s, 1.6s, 2s\}$, corresponding to the human response time distribution percentiles 45%, 80% and 90% respectively, see [26]. Response time is defined as in Section IV-B. Table III shows the result for our red light crossing prediction. We say that crossing is detected at the time $TTI_{min}$ whenever crossing has a decisive prediction at that time. In addition to detection rate, the table shows the percentage of compliant trajectories that were classified as crossing, these are called false positives. Finally, the last row shows the percentage of violating trajectories within the trajectories that were classified as dangerous, this is called the percentage of justified warnings. As in [10], we took position measurements at a frequency of 10Hz during a maximum of 2s or until the bound on time to intersection was reached, whatever occurred first. In order to allow the drivers to respond to the yellow light before TTI would become smaller than $TTI_{min}$, we used only the 204 trajectories where the traffic light changed when TTI was 4.2s. 27 of these trajectories were traffic light violations.

<table>
<thead>
<tr>
<th>Detection and false positive rates at critical TTI values</th>
<th>$TTI_{min}$</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>1s</td>
</tr>
<tr>
<td>% Detected actual crossing</td>
<td>96</td>
</tr>
<tr>
<td>% Falsely detected crossing</td>
<td>0</td>
</tr>
<tr>
<td>% Justified warnings</td>
<td>100</td>
</tr>
</tbody>
</table>

We see in Table III that the detection rate is high, even with the largest $TTI_{min}$, while unjustified warnings remain on an acceptable level (24%). Moreover, there is a substantial increase in both the detection rate and the percentage of justified warnings when we decrease $TTI_{min}$ from 2s to 1.6s.
A major difference in our scenario compared to [10] is that we start the algorithm when the traffic light turns yellow. Consequently, the time window until $TTI_{\text{min}}$ varies from case to case, while in [10] the number of observations available to perform the classification was fixed. Moreover, we consider a scenario with a traffic light change while in [10] there is always a red light. The detection rate in this study is at least 10% higher in all cases, the false positive rate is always below the 5% of [10] and even in the worst case we have 76% justified warnings, while even in the best case in [10] it is only 63%1.

In [13] the experimental setting was very similar to ours, i.e., the authors proposed two algorithms to predict whether a car would cross after observing a yellow light. The methods were also compared with those of [10]. For $TTI_{\text{min}} = 1$s the detection rate in [13] is 100%, however for the other two cases our detection rate is at least 5% higher and we have lower false positive rates in all cases. Notice also that the methods in [10] and [13] use acceleration measurements while Algorithm 1 uses only position and speed.

V. CONCLUSIONS

In this paper, we studied the dilemma a driver is facing when the traffic light changes from green to yellow. Our objective was to determine an upper bound on the crossing probability, where the upper bound has a prescribed confidence level. The algorithm that we presented here is based on a stochastic hybrid system model with hidden modes and uses Gaussian process theory to estimate the mode online using measurements of the continuous state of the hybrid system. For testing we used 767 intersection approaches recorded during experiments in a driving simulator. We find that the percentage of actual crossing trajectories within the set of trajectories that were predicted to cross with a probability smaller than 0.05 was 1%. Similarly, the percentage of actual crossing trajectories within the set of trajectories that were predicted to cross with probability larger than 0.95 was 98%. Moreover, the percentage of crossing trajectories that were predicted to cross with probability larger than 0.95 within the set of all actual crossing trajectories is 99%. These results show the accuracy of the predictions and that in most cases crossing trajectories can be quite clearly identified.

An important direction for future research is the use of the constructed model to design warning/override systems to prevent red light violations and warn other traffic participants of dangerous situations.

REFERENCES

1This value is inferred from [10, Table IV] and the fact that there were 8,000 compliant and 800 violating trajectories [10, Section V].
