Abstract

We consider the problem of a particle traveling from an initial configuration to a final configuration (given by a point in the plane along with a prescribed velocity vector) in minimum time with non-homogeneous velocity and with constraints on the minimum turning radius of the particle over multiple regions of the state space. Necessary conditions for optimality of these paths are derived to characterize the nature of optimal paths, both when the particle is inside a region and when it crosses boundaries between neighboring regions. These conditions are used to characterize families of optimal and nonoptimal paths. Among the optimality conditions, we derive a “refraction” law at the boundary of the regions that generalizes the so-called Snell’s law of refraction in optics to the case of paths with bounded curvature. Tools employed to deduce our results include recent principles of optimality for hybrid systems. The results are validated numerically.

1 Introduction

1.1 Background

Pontryagin’s Maximum Principle [14] is a very powerful tool to derive necessary conditions for optimality of solutions to a dynamical system. In other words, this principle establishes the existence of an adjoint function with the property that, along optimal system solutions, the Hamiltonian obtained by combining the system dynamics and the cost function associated to the optimal control problem is minimized. In its original form, this principle is applicable to optimal control problems with dynamics governed by differential equations with continuously differentiable right-hand sides.

The shortest path problem between two points with specific tangent directions and bounded maximum curvature has received wide attention in the literature. In his pioneer work in [6], by means of geometric arguments, Dubins showed that optimal paths to this problem consist of a concatenation of no more than three pieces, each of them describing either a straight line, denoted by $L$, or a circle, denoted by $C$ (when the circle is traveled clockwise, we label it as $C^+$, while when the circle is traveled counter-clockwise, $C^-$), and are either of type $CCC$ or $CLC$, that is, they are among the following six types of paths

$$C^-C^+C^-, C^+C^+C^-, C^+CLC^-, C^+CLC^+, C^+CLC^-,$$ (1)

in addition to any of the subpaths obtained when some of the pieces (but not all) have zero length. More recently, the authors in [3] recovered Dubins’ result by using Pontryagin’s Maximum Principle; see also [23]. Further investigations of the properties of optimal paths to this problem and other related applications of Pontryagin’s Maximum Principle include [19,2,4], to just list a few.

1.2 Contributions

We consider the minimum-time problem of having time-parameterized paths with bounded curvature for a particle, which, as in the problem by Dubins, travels from a given initial point to a final point with specified velocity vectors, but with non-homogeneous traveling speeds and curvature constraints: the velocity of the particle and the minimum turning radius are possibly different at certain regions of the state space. (Note that since the velocity of the particle in the problem by Dubins is constant, the minimum-length and minimum-time problems are equivalent; while the problem with different velocities and curvature constraints is most interesting for the minimum-time case.) Such a heterogeneity arises in several robotic motion planning problems across environ-
mments with obstacles, different terrains properties, and other topological constraints. Current results for optimal control under heterogeneity, which include those in [1,16], are limited to particles describing straight paths. Furthermore, optimal control problems exhibiting such discontinuous/impulsive behavior cannot be solved using the classical Pontryagin’s Maximum Principle. Extensions of this principle to systems with discontinuous right-hand side appeared in [20] while extensions to hybrid systems include [21], [7], and [18]. These principles establish the existence of an adjoint function which, in addition to conditions that parallel the necessary optimality conditions in the principle by Pontryagin, satisfies certain conditions at times of discontinuous/jumping behavior. The applicability of these principles to relevant problems have been highlighted in [21,13,5]. These will be the key tools in deriving the results in this paper.

Building from preliminary results in [17] and exploiting recent principles of optimality for hybrid systems, we establish necessary conditions for optimality of paths of particles with bounded curvature traveling across a state space that is partitioned into multiple regions, each with a different velocity and minimum turning radius. Necessary conditions for optimality of these paths are derived to characterize the nature of optimal paths, both when the particle is inside a region and when it crosses boundaries between neighboring regions. A “refraction” law at the boundary of the regions that generalizes the so-called Snell’s law of refraction in optics to the case of paths with bounded curvature is also derived. The optimal control problem with a “refraction” law at the boundary can be viewed as an extension of optimal control problems in which the terminal time is governed by the boundary condition.

The organization of the paper is as follows. Section 2 presents the main results: necessary conditions for optimality of paths, refraction law at the boundary of the regions, and characterization of families of optimal and nonoptimal paths. The results are validated numerically in Section 4.

1.3 Notation

We use the following notation throughout the paper. \( \mathbb{R}^n \) denotes \( n \)-dimensional Euclidean space. \( \mathbb{R} \) denotes the real numbers. \( \mathbb{R}_{\geq 0} \) denotes the nonnegative real numbers, i.e., \( \mathbb{R}_{\geq 0} = [0, \infty) \). \( \mathbb{N} \) denotes the natural numbers including 0, i.e., \( \mathbb{N} = \{0, 1, \ldots\} \). Given \( k \in \mathbb{N}, \mathbb{N}_{\leq k} \) denotes \( \{0, 1, \ldots, k\} \) and, if \( k > 0 \), \( \mathbb{N}_{< k} \) denotes \( \{0, 1, \ldots, k-1\} \). Given a set \( S, \overline{S} \) denotes its closure, \( S^0 \) denotes its interior, and \( \partial S \) denotes its boundary.

Given a vector \( x \in \mathbb{R}^n \), \( |x| \) denotes the Euclidean vector norm. Given vectors \( x, y \), at times, we write \( [x^\top, y^\top]^\top \) with the shorthand notation \( (x, y) \). Given a function \( f \), its domain is denoted by \( \text{dom} f \). Given \( \overline{\mathbb{U}}_i > 0 \) defining \( U_i := [-\overline{\mathbb{U}}_i, \overline{\mathbb{U}}_i] \), \( U_i \) denotes the set of all piecewise-continuous functions \( u \) from subsets of \( \mathbb{R}_{\geq 0} \) to \( U_i \). The inner product between vectors \( u \) and \( v \) is denoted by \( \langle u, v \rangle \). A unit vector with angle \( \theta \) is denoted by \( \hat{\theta} \).

2 Problem Statement and Solution Approach

We are interested in deriving necessary conditions for a path \( \mathcal{X} \) describing the motion of a particle, which starts and ends at pre-established points with particular velocity vectors, through regions \( \mathcal{P}_q \) with different constant velocity \( v_q \) and minimum turning radius \( r_q \). The dynamics of a particle with position \( (x, y) \in \mathbb{R}^2 \) and orientation \( \theta \in \mathbb{R} \) (with respect to the vertical axis) are given by

\[
\dot{x} = v \sin \theta, \quad \dot{y} = v \cos \theta, \quad \dot{\theta} = u, \quad (2)
\]

where \( u \in U_q \) is the angular velocity input and satisfies \( |u| \leq \overline{\mathbb{U}}_i \). The velocity vector of the particle is given by the vector \([v \sin \theta, v \cos \theta]^\top\). More precisely, we are interested in the following problem:

**Problem 1** Given a connected set \( \mathcal{P} \subset \mathbb{R}^2 \), \( N \) disjoint polytopes \( \mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_N \), subsets of \( \mathcal{P} \), with nonempty interior and such that \( \mathcal{P} = \bigcup_{q \in \{1, \ldots, N\}} \mathcal{P}_q \), determine necessary conditions on the minimum-time path \( \mathcal{X} \subset \mathcal{P} \) of a particle starting at a point \( (x, y)^i \in \mathcal{P}_q^0 \), \( q^i \in \{1, 2, \ldots, N\} \), with initial velocity vector \( \nu^i \), traveling according to (2), and ending at a point \( (x, y)^f \in \mathcal{P}_q^0 \), \( q^f \in \{1, 2, \ldots, N\} \), with final velocity vector \( \nu^f \), where, for each \( q \in \{1, 2, \ldots, N\} \), \( v_q > 0 \) and \( r_q > 0 \) are the velocity of travel and the minimum turning radius in \( \mathcal{P}_q \), respectively.

In addition to Problem 1, we consider the special case when the angular velocity constraints on neighboring regions have common bounds \( \overline{\mathbb{U}}_i \). We refer to the resulting problem as Problem 1*.

The organization of the paper is as follows. Section 2 states the problem of interest and outlines the solution approach. Section 3 presents the main results: necessary conditions for optimality of paths, refraction law at the
Figure 1 depicts the general scenario in Problem 1. Neighboring regions are such that either their velocity of travel, their minimum turning radius, or both are different from each other. In this way, the number of regions with different characteristics is irreducible.

![Diagram](image)

Fig. 1. Initial point (x, y)\(^{i}\) and final point (x, y)\(^{f}\) with given velocity vectors on regions \(P_1\) and \(P_2\). The minimum turning radius in region \(P_1\) is smaller than the one in region \(P_2\), which is smaller than the one in region \(P_3\) as denoted by the depicted paths with minimum turning radius.

Our approach to derive a solution to Problem 1 is as follows. Given a continuously differentiable curve \(X \subset \mathcal{P}\) defining the path of a particle starting at a point \((x, y)^{i}\) \(\in \mathcal{P}^{q}_q\), \(q^{i} \in \{1, 2, \ldots, N\}\), with initial velocity vector \(v^{i}\) and ending at a point \((x, y)^{f}\) \(\in \mathcal{P}^{q}_f\), \(q^{f} \in \{1, 2, \ldots, N\}\), with final velocity vector \(v^{f}\), we partition the curve \(X\) into a finite number of curves \(X_j\), \(j \in \{0, 1, \ldots, J-1\}\) \((= \mathbb{N}_{<J})\), such that, for each \(j \in \mathbb{N}_{<J}\), \(X_j \in \mathcal{P}_q\) for some \(q_j \in \{1, 2, \ldots, N\}\), where, for each \(j \in \mathbb{N}_{<J}\), \(q_j \neq q_{j+1}\). This partition is such that the velocity of the particle along each curve \(X_j\) is constant and given by \(v_q\) while the minimum turning radius is also constant and given by \(r_q\). For each \(j \in \mathbb{N}_{<J}\), let \(t_j \geq 0\) denote the time at which the particle starts the path defined by the curve \(X_j\) and let \(t_j\) denote the time at which the particle reaches the end point \((x, y)^{f}\).

To formally define trajectories to (2) that are solutions to Problem 1, we conveniently parametrize \(x, y, \theta\), and \(q\) by functions defined for each \(j \in \mathbb{N}_{<J}\) on \([t_j, t_{j+1}] \times \{j\}\), where, if necessary, the value at the boundaries (left or right) of the interval \([t_j, t_{j+1}]\) are obtained by taking (right or left, respectively) limit of the functions. The second argument \(j\) specifies the number of crossings between regions. With this parametrization, the current region of the particle at time \(t\) and after \(j\) crossings is given by the value of \(q\) at \((t, j)\), that is, \(q(t, j)\). Hence, the domain of \(x, y, \theta,\) and \(q\) is given by the following subset of \(\mathbb{R}_{\geq 0} \times \mathbb{N}_{<J}\):

\[
E := \bigcup_{j \in \mathbb{N}_{<J}} ([t_j, t_{j+1}] \times \{j\})
\]

(3)

on which, for each \(j \in \mathbb{N}_{<J}\), the function \((t, j) \mapsto [x(t, j), y(t, j), \theta(t, j), q(t, j)]^\top\) is absolutely continuous and for each \((t, j) \in E, j \in \{1, 2, \ldots, J-1\}, [x(t_{j+1}, j + 1), y(t_{j+1}, j + 1), \theta(t_{j+1}, j + 1)]^\top = [x(t_{j+1}, j), y(t_{j+1}, j), \theta(t_{j+1}, j)]^\top\), i.e., the position and angle of the vehicle do not jump when changing regions, while \(q(t_{j+1}, j + 1)\) is equal to the new region’s index.

With this re-parametrization of the path \(X\), we employ the principle of optimality for hybrid systems in [21] (see also [22] and [13]) to derive necessary conditions for the curve \(X\) to be optimal. To this end, we associate the re-parametrized curve \(X\) with a solution to a hybrid system, which via results in [21], infer conditions for optimality. More precisely, \([x, y, \theta]^\top\) along with a function \(q\) with domain (3), which takes discrete values \(1, 2, \ldots, N\) when the velocity of the particle is equal to \(v_1, v_2, \ldots, v_N\) and the minimum turning radius is equal to \(r_1, r_2, \ldots, r_N\), respectively, define a solution to a hybrid system. The continuous evolution of \([x, y, \theta]^\top\) is given as in (2) with \(q\) being a function that is constant during periods of flow, but when the particle crosses from one region to another, \(q\) is updated to indicate the region associated with the current velocity and minimum turning radius. The angular velocity input \(u\) is designed to satisfy the constraint \(|u| \leq \pi_q\) for the value of \(q\) corresponding to the current region of travel.

The following assumptions are imposed on some of the results to follow. For notational simplicity in the following sections, we define \(\xi := [x, y, \theta]^\top\) and \(Q := \{1, 2, \ldots, N\}\).

**Assumption 2.1** Given a solution \((\xi, q)\) to Problem 1, the following holds:

1. The set of points \(\{t : (t, j) \in \text{dom}(\xi, q), (x(t, j), y(t, j)) \in \partial P_{q(t, j)}\}\) has zero Lebesgue measure.
2. For every \((t, j)\) such that \((t, j + 1) \in \text{dom}(\xi, q)\), there exists unique \(p, p' \in Q\) such that \((x(t, j), y(t, j)) \in \partial P_p \cap \partial P_{p'}\) and the boundaries \(\partial P_p\) and \(\partial P_{p'}\) are locally smooth at \((x(t, j), y(t, j))\).

A solution \((\xi, q)\) to Problem 1 satisfying condition 1 in Assumption 2.1 does not slide on the boundary of the regions while, if it satisfies condition 2, then it crosses at points where only two regions exist with their boundaries defined by a smooth curve.

### 3 Properties of Optimal Paths

#### 3.1 Necessary conditions for optimality

The following lemma establishes basic conditions that the state variables \(\xi\) and associated adjoint satisfy for the case of two regions \(P_1\) and \(P_2\). It employs [21, Theorem 1], which, under further technical assumptions, establishes that there exists an adjoint pair \((\lambda, \lambda_0)\), where

---

1 This particular construction of time domain is borrowed from [8], where it is called a (compact) hybrid time domain.
\( \lambda \) is a function and \( \lambda_0 \) is a constant, which, along optimal solutions to Problem 1, satisfies certain Hamiltonian maximization, nontriviality, transversality, and Hamiltonian value conditions. Note that the restriction that the boundary of the switching surfaces is a subset of \( \{ (x, y) \in \mathbb{R}^2 : y = 0 \} \) in the following lemma will be relaxed in the ensuing discussion.

**Lemma 3.1** For each optimal solution \((\xi, q)\) to Problem 1 with optimal control \(u\), minimum transfer time \(T\), number of jumps \(J = 1\), number of regions \(N = 2\), and \((\mathcal{P}_1 \cap \mathcal{P}_2) \cap \mathcal{P} \subset \{ (x, y) \in \mathbb{R}^2 : y = 0 \}\) satisfying Assumption 2.1, there exists a function \(\lambda : \text{dom} \lambda \to \mathbb{R}^3\), \(\lambda := [\alpha, \beta, \gamma]^T\), \(\text{dom} \lambda = \text{dom}(\xi, q)\), where \(t \mapsto \lambda(t, j)\) is absolutely continuous for each \(j, t, j \in \text{dom} \lambda\), and a constant \(\lambda_0 \in \mathbb{R}\) defining the adjoint pair \((\lambda, \lambda_0)\) satisfying

\[
\dot{\lambda}(t, j) = -\frac{\partial H_{q(t,j)}(\xi(t,j), \lambda(t,j), \lambda_0, u(t,j))}{\partial \xi} \quad \text{and} \quad \lambda_0 \geq 0 \text{ for almost every } t \in [t_j, t_{j+1}], (t, j) \in \text{dom} \lambda,
\]

where, for each \(q \in Q\), \(H_q(\xi, \lambda, \lambda_0, u) = \alpha v_\theta \sin \theta + \beta u_q \cos \theta + \gamma u - \lambda_0\).

a) There exist \(\overline{\pi}, \underline{\pi} \in \mathbb{R}\) such that \(\alpha(t, j) := \overline{\pi} \) for all \((t, j) \in \text{dom}(\xi, q), \beta(t, j) := \underline{\pi} + p_j\) for almost all \((t, j) \in [0, T], (t, j) \in \text{dom}(\xi, q),\) and \(\gamma(t, j) = \gamma(t, j + 1)\) for each \((t, j) \in \text{dom} \lambda\).

b) The control \(u\) is equal to \(u_q(t, j)\) when \(\gamma(t, j) < 0\), \(-u_q(t, j)\) when \(\gamma(t, j) > 0\), and 0 when \(\gamma(t, j) = 0\).

c) For every \(j\) such that there exists an interval \(I_j\) with nonempty interior, \(I_j \times \{ j \} \subset \text{dom}(\xi, q)\), such that \(\gamma(t, j) = 0\) for each \(t \in I_j\), then \(\beta(t, j) \tan \theta(t, j) = \alpha(t, j)\) for each \(t \in I_j\).

d) There exists \(c \in \mathbb{R}\) such that for every \((t, j) \in \text{dom}(\xi, q)\)

\[
H_{q(t,j)}(\xi(t,j), \lambda(t,j), \lambda_0, u(t,j)) = c.
\]

**Proof:** For each \(q \in Q := \{1, 2\}\), let \(\mathcal{M}_q := \mathbb{R}^3, J_q := \mathbb{R}\), and recall the definition of \(U_q = [-\pi_q, \pi_q]\) from Section 1.3, where \(U_q\) is the set of all piecewise-continuous functions from subsets of \(\mathbb{S}^2\) to \(U_q\). Let \(\mathcal{S}\) be a subset of \(\mathcal{M}^2 := (\cup_{q \in Q} (\{q\} \times \mathcal{M}_q)) \times (\cup_{q \in Q} (\{q\} \times \mathcal{M}_q))\) given by

\[
\mathcal{S} := \{ (q, \xi, q', \xi) : y = 0, (q, \xi, q', \xi) \in \mathcal{M}^2 \}.
\]

and, for each \(q, q' \in Q\), let

\[
\mathcal{S}_{q, q'} := \{ (\xi, \xi) : y = 0, \xi \in \mathbb{R}^3 \}.
\]  

Then, the above definitions determine a hybrid system following the framework in [21]. We denote this hybrid system by \(\mathcal{H}\). Its continuous dynamics are given by \(\dot{\xi} = f_q(\xi, u)\), where \(f_q(\xi, u) := \nabla_{\theta} \cos \theta + \nabla_{\theta} \sin \theta + \hat{u}\) and discrete dynamics given by the switching sets \(\mathcal{S}_{q, q'}\).

By [21, Theorem 1], there exist a piecewise absolutely continuous function \(\lambda : \text{dom} \lambda \to \mathbb{R}^3\), \(\lambda = [\alpha, \beta, \gamma]^T\), with domain \(E\) and a constant \(\lambda_0 \in \mathbb{R}\) defining the adjoint pair \((\lambda, \lambda_0)\) satisfying

\[
\dot{\lambda}(t, j) = -\frac{\partial H_{q(t,j)}(\xi(t,j), \lambda(t,j), \lambda_0, u(t,j))}{\partial \xi} \quad \text{and} \quad \lambda_0 \geq 0 \text{ for almost every } t \in [t_j, t_{j+1}], (t, j) \in \text{dom} \lambda,
\]

for almost every \(t \in [t_j, t_{j+1}], (t, j) \in E\), where, for each \(q\), \(H_q(\xi, \lambda, \lambda_0, u) = \alpha v_\theta \sin \theta + \beta u_q \cos \theta + \gamma u - \lambda_0\).

Then, \(\alpha, \beta, \gamma\) are piecewise constant. By [21, Theorem 1], for each \((t, j) \in E, j \in \{1, 2, \ldots, J - 1\}\), \(\lambda\) satisfies

\[
(-\lambda(t, j), \lambda(t, j + 1)) \in K_f^\perp,
\]
where \( K^+ \) is the polar of the Boltyanskii approximating cone to \( S_k(t_j, q(t_j+1)) \) at the jump at \((t_j, j)\). \( S_k := S_{1,2} \). The Boltyanskii approximating cone to the set \( S \) is the set itself. Then, for each \( j \in \{1, 2, \ldots, J-1\} \), \( K^+ \) is given by

\[
K^+ = \left\{ w \in \mathbb{R}^3 \times \mathbb{R}^3 : \langle w, v \rangle \leq 0 \ \forall v \in S \right\}.
\]

Note that \( w \in K^+ \) if and only if \( \langle w, v \rangle \leq 0 \) for all \( v := (v_1^a, v_2^a, v_3^a)^T, (v_1^b, v_2^b, v_3^b)^T \) \( \in \mathbb{R}^3 \times \mathbb{R}^3 \) such that \( v_2^a = v_2^b = 0 \). Hence, condition (11) implies that, for each \((t_j, j) \in E, j \in \{1, 2, \ldots, J-1\}\),

\[(-\lambda(t_j, j) + \lambda(t_j, j+1), v') = 0\]

for all \( v' := (v_1', v_2', v_3')^T \in \mathbb{R}^3 \) such that \( v_2' = 0 \). Then, for each such \((t_j, j), \alpha(t_j, j) = \alpha(t_j, j+1), \gamma(t_j, j) = \gamma(t_j, j+1)\), and only \( \beta \) can jump. This shows item b).

Claim c) follows directly from the Hamiltonian maximization condition guaranteed by [21, Theorem 1]. [21, Theorem 1] establishes that \( u \) satisfies

\[
H_{q(t,j)}(\xi(t,j), \lambda(t,j), \lambda_0, u(t,j)) = \max_{w' \in U} H_{q(t,j)}(\xi(t,j), \lambda(t,j), \lambda_0, w')
\]

for almost every \( t \in [t_j, t_{j+1}], (t, j) \in E \). Then, since \( H_{q}(\xi, \lambda, \lambda_0, u) = \alpha \eta_0 \sin \theta + \beta \eta_0 \cos \theta + \gamma u - \lambda \), for each \((t, j) \in E \) for which \( \gamma(t, j) \neq 0, u(t,j) = \text{sgn}(\gamma(t,j)) \pi q \in \{-\pi q, \pi q\}\). When \( \gamma(t,j) = 0 \), \( H_{q}(\xi, \lambda, \lambda_0, u) \) does not depend on \( u(t,j) \) and hence, the optimum value of \( u(t,j) \) is ambiguous. If the ambiguity exists over a time interval, we have the singular arc case.

In this case, differentiating \( \gamma(t, j) \) twice and setting it to zero yields \( \tau(t, j) = (\alpha \eta_0 \sin \theta + \beta \eta_0 \cos \theta) \pi q = 0 \), which leads to \( \tau(t, j) = 0 \) if \( \gamma(t, j) = 0 \). This implies item c).

Note that in optimal control, this is referred to as bang-singular control.

To establish item d), note that when \( \gamma(t, j) = 0 \) on \( I_j \times \{j\} \), since \( t \to \tau(t, j) \) is absolutely continuous, we have that \( \frac{d}{dt} \tau(t, j) = 0 \) for each \((t, j) \in I_j \times \{j\}\). Then, item d) follows from (10) and absolute continuity of \( t \to \theta(t, j) \).

Finally, to show item c) we use the Hamiltonian value condition guaranteed by [21, Theorem 1]. In fact, since

the jump condition in \( H \) is time independent, that is, \( J_1 = J_2 = \mathbb{R} \), the Hamiltonian value condition in [21, Theorem 1] establishes that there exists \( \epsilon \in \mathbb{R} \) such that (4) holds for almost every \( t \in [t_j, t_{j+1}], (t, j) \in \text{dom} E \).

Item a) determines the dynamics of the adjoint function \( \lambda \) while items b), c), and d) establish conditions that the components of \( \lambda, \xi, \) and \( u \) satisfy along the path. In particular, item c) indicates that the paths either describe a straight line or an arc with minimum turning radius, i.e., of radius \( r_p \), where \( p \) is equal to the corresponding entry in \( \{1, 2\} \).

The properties highlighted in Lemma 3.1 can be used to establish conditions for the functions \( x, y, \theta, \) and \( u \) in Problem 1, since at every crossing of the boundary between two arbitrary regions, a change of coordinates can be performed so that the geometry in Lemma 3.1 holds for the chosen boundary crossing. In fact, at every crossing of the boundary between two arbitrary regions occurring at a position \((x^*, y^*)\), a change to a coordinate system with vertical axis perpendicular to the tangent to the boundary of the two regions and vertical coordinate equal to zero when \( y = y^* \) can be defined via a rotation plus translation of the original coordinate system \((x, y, \theta)\). More precisely, a coordinate transformation performing this operation is given by

\[
\begin{pmatrix}
x' \\
y' \\
\theta'
\end{pmatrix} =
\begin{pmatrix}
\cos \varphi & \sin \varphi & 0 \\
-\sin \varphi & \cos \varphi & 0 \\
0 & 0 & 1
\end{pmatrix}
\begin{pmatrix}
x \\
y \\
\theta
\end{pmatrix} -
\begin{pmatrix}
x^* \cos \varphi + y^* \sin \varphi \\
-x^* \sin \varphi + y^* \cos \varphi \\
-\varphi
\end{pmatrix}
\]

where \( \varphi \) is the angle of the tangent line to the boundary of the regions where the crossing occurs. In this setting, as in Lemma 3.1, the optimal paths from given initial and terminal constraints can be characterized using the principle of optimality for hybrid systems in [21].

**Theorem 3.2** (optimality conditions of paths to Problem 1) Let the curve \( X \) describe a minimum-time path that solves Problem 1 and let \( x, y \) and \( \theta \) be its associated functions with input \( u \). Define the function \( q \) following the construction below (6). Suppose Assumption 2.1 holds. Then, the following properties hold:

a) The curve \( X \) is a smooth concatenation of finitely many pieces from the set \( \{C^+, C^-, \mathcal{L}\} \).

b) The angular velocity input \( u(t, j) \) is piecewise constant with finitely many pieces taking value in \( \{-\pi q(t,j), 0, \pi q(t,j)\} = \{-\pi q(t,j), 0, \pi q(t,j)\} \).

c) For each \( j \in \{0, 1, \ldots, J - 1\} \), each piece \( X_j \) of the curve \( X \) is Dubins optimal between the first and last point of such a piece, i.e., it is given as in (1).

d) For each \((t_j, j) \in E, j \in \{1, 2, \ldots, J - 1\} \), if the last path piece of \( X_{j-1} \) and the first path piece of \( X_j \) are
of type $\mathcal{L}$, and moreover, if $v_{q(t_j,j-1)} \neq v_{q(t_j,j)}$, then $\theta(t_j,j)$ is zero or any multiple of $\pi$. 

**Proof:** We apply Lemma 3.1 to the subpieces of the curve $X$, one at a time, after performing the coordinate transformation in (13) if needed. Consider the $j$-th piece $X_j$ of the curve $X$. By item c) in Lemma 3.1, for each $(t, j) \in \{t_j, t_{j+1}\} \times \{j\}$, $u(t, j)$ takes value $-\pi_v, 0, \text{or } \pi_v$. When $u(t, j) = \pm \pi_v$, the path at such $(t, j)$’s is of type $C$ (either $C^+$ or $C^-$), while when $u(t, j) = 0$, the path at such $(t, j)$’s is of type $L$. Then, the curve $X_j$ is a concatenation of paths of type $\{C^+, C^-, L\}$. Bellman’s principle of optimality implies that for $X$ to be optimal, each piece $X_j$ also has to be optimal. Then, by the original result by Dubins in [6], the concatenation of pieces that define $X_j$ is finite. Proceeding in this way for each piece of $X$, items a) c) hold true. To show item d), we apply Lemma 3.1.c), d), and e) to each pair of pieces $X_{j-1}, X_j$ for each $j \in \{1, 2, \ldots, J - 1\}$. Using the coordinate transformation (13) at the boundary of the $(j - 1)$-th region and the $j$-th region at which the pair of pieces $X_{j-1}, X_j$ connect, we have that $X_{j-1}, X_j$ connect at a point in the set $\{(x, y) \in \mathbb{R}^2 : y = 0\}$. The pair of pieces $X_{j-1}, X_j$ can be treated as the case of two regions considered in Lemma 3.1. Item b) in Lemma 3.1 indicates that the adjoin function component $\gamma$ remains constant at jumps, i.e., $\gamma(t_j, j - 1) = \gamma(t_j, j)$, which by the arguments above is equal to zero for $\mathcal{L}$-type paths. Since, by Lemma 3.1.c) the angular velocity input does not change when $\gamma$ is constant, then, at $(t_j, j - 1)$, we have that $u(t_j, j - 1) = \pm \pi_v$. It follows that $\theta(t_j, j - 1) = \theta(t_j, j)$. By Lemma 3.1.b), $\alpha(t_j, j) = \alpha(t_j, j + 1) = \pi_v$. Then, the Hamiltonian value condition guaranteed by Lemma 3.1.e) becomes 

$$\mathbf{w}_v \sin \theta(t_j, j) + \beta(t_j, j)v_q \cos \theta(t_j, j) = \mathbf{w}_v \sin \theta(t_j, j + 1) + \beta(t_j, j + 1)v_q \cos \theta(t_j, j + 1)$$

where we have used the shorthand notation $q = q(t_j, j)$ and $q' = q(t_j, j + 1)$. Item d) in Lemma 3.1 implies that $\beta(t_j, j) \tan \theta(t_j, j) = \pi_v$ and $\beta(t_j, j + 1) \tan \theta(t_j, j + 1) = \pi_v$. Substituting these expressions into (14), it follows that 

$$v_{q(t_j,j-1)} \sin \theta(t_j,j) = v_{q(t_j,j)} \sin \theta(t_j,j).$$

Since $v_{q(t_j,j-1)} \neq v_{q(t_j,j)}$, (15) holds if and only if $\theta(t_j,j) = 0$ or any multiple of $\pi$. Repeating this procedure for each piece concludes the proof. 

### 3.2 Refraction law at boundary

The necessary conditions of the Hamiltonian $H_q$ given in Lemma 3.1 relate the values of the state vector $\xi$, the angular velocity input $u$ and the adjoin vector $\lambda$ before and after crossing a boundary between regions. Using the properties of the adjoin vector and its relationship to the state vector $\xi$ in items b) d) in Lemma 3.1, it can be shown that an algebraic condition involving $\lambda, \xi$, and certain angles holds at the crossings points for optimal paths of type $\mathcal{L}_p \mathcal{C}_p \mathcal{L}_p'$ in Problem 1. More precisely, the condition on the Hamiltonian in item e) of Lemma 3.1 implies that for each $(t_j,j) \in \mathcal{E}$ 

$$\alpha v_p \sin \theta + \beta v_p \cos \theta + \gamma u = \alpha^+ v' \sin \theta^+ + \beta^+ v' \cos \theta^+ + \gamma^+ u^+ = c + \lambda_o,$$

where $p = q(t_j, j), p' = q(t_j, j + 1)$ and $c, \lambda_o \in \mathbb{R}$ are constants. For notational convenience, we dropped the $(t_j, j)$’s and denoted the valuation of the functions at $(t_j, j + 1)$ with $\gamma^+$. Moreover, for the path pieces of type $\mathcal{L}$, items b), c) and e) in Lemma 3.1 imply 

$$\alpha v_p \sin \theta + \beta v_p \cos \theta$$

$$= \alpha^+ v' \sin \theta' + \beta^+ v' \cos \theta' = c + \lambda_o,$$

where $\theta_p$ and $\theta'_p$ denote the initial and final angle, respectively, of a path piece intersecting the boundary between $\mathcal{P}_q$ and $\mathcal{P}_q^{-1}$, as shown in Figure 2. The algebraic conditions in (16) and (17) can be reduced to a refraction law as established in the following result.

**Theorem 3.3 (refraction law)** Let the curve $X$ describe a minimum-length curve that solves Problem 1 and let $x, y$ and $\theta, \theta'$ be its associated functions with input $u$. Consider partition pairs $X_{j-1}, X_j$ for all $j \in \{1, 2, \ldots, J - 1\}$ such that the path pieces across the boundary are of type $\mathcal{L}_p \mathcal{C}_p \mathcal{L}_p'$. For each of such pair of pieces, suppose the end points (opposite to the intersection with the boundary) of those path pieces are in $\mathcal{P}_q^0$ and $\mathcal{P}_q'^1$, respectively, and suppose Assumption 2.1 holds. Let $\Delta \theta_p, \Delta \theta'_p \in \mathbb{R}$ be given by $\Delta \theta_p := \theta^* - \theta_p, \Delta \theta'_p := \theta'_p - \theta^*$, where $\theta^*$ is the orientation of the vehicle at the boundary, i.e., it is the angle between the path and the boundary between $\mathcal{P}_p$ and $\mathcal{P}_p'$ at their intersection with respect to the normal to the boundary. If the path piece intersecting the boundary between $\mathcal{P}_p$ and $\mathcal{P}_p'$ is one of the type $\mathcal{C}_{p-p'}$ paths shown in Figure 2, then 

$$v_p = \frac{\sin \theta_p}{\sin \theta'_p},$$

$$r_p = \frac{v_p}{v'_p} \frac{1 - \cos \Delta \theta'_p}{1 - \cos \Delta \theta_p},$$

Moreover, if the path piece intersecting the boundary between $\mathcal{P}_p$ and $\mathcal{P}_p'$ is of type $\mathcal{L}$ and $v_p \neq v'_p$, then $\theta_p$ and $\theta'_p$ are equal to zero or any multiple of $\pi$.

---

5 To apply Lemma 3.1 to the paths of Problem 1, we proceed as in the proof of Theorem 3.2.
Lemma 3.1, we obtain $X_j$ which satisfy equations (18) and (19), which is a generalization of Snell’s law of refraction.

**Proof:** We first carry out the coordinate transformation (13) at the boundary of the $(j-1)$-th region and the $j$-th region in which the path pieces $X_i$ connect in order that $X_{i-1}, X_i$ connect at a point in the set $(x, y) \in \mathbb{R}^2 : y = 0$}. From items b) and c) of Lemma 3.1, we obtain $\alpha = \alpha^+, \beta = \beta^+, \beta^+=\beta^-, \gamma = \gamma^+, u = \text{sgn}(\gamma)\gamma p, u^+=\text{sgn}(\gamma)\gamma p$, and $\alpha^+=\alpha^-$. Moreover, at the boundary, we have $\theta = \theta^+ = \theta^-$. Thus, (16) and (17) become

\[
\begin{align*}
\pi v_p \sin \theta^+ + \beta^+ v_p \cos \theta^+ + \gamma |\frac{v_{r'}}{r_p'} &= c + \lambda_0, \quad (20) \\
\pi v_p \sin \theta^- + \beta^- v_p \cos \theta^- + |\gamma| \frac{v_{r'}}{r_p'} &= c + \lambda_0, \\
\pi v_p \sin \theta^+ + \beta^+ v_p \cos \theta^+ &= \pi v_p \sin \theta^+ + \beta^+ v_p \cos \theta^+ = c + \lambda_0, \quad (21)
\end{align*}
\]

respectively. Furthermore, for the path pieces of type $X, \beta^+$, $\tan \theta_p = \pi$ and $\beta^-$, $\tan \theta_p = \pi$ by item d) of Lemma 3.1. Substituting these into (21), we obtain (18) since

\[
\begin{align*}
\pi v_p \sin \theta_p + \beta^+ v_p \cos \theta_p &= \pi v_p \sin \theta_p + \beta^+ v_p \cos \theta_p \\
\pi v_p \sin \theta_p + \beta^+ v_p \cos \theta_p &= \pi v_p \sin \theta_p + \beta^+ v_p \cos \theta_p \\
\pi v_p \sin \theta_p + \beta^+ v_p \cos \theta_p &= \Delta \theta_p = \Delta \theta_p.
\end{align*}
\]

To finish the proof, we subtract (21) from (20) and substitute $\pi \tan \theta_p = \pi \tan \theta_p = \pi$ in it. We get

\[
\begin{align*}
\gamma |\frac{v_{r'}}{r_p'} &= -\pi v_p (\sin \theta^+ - \sin \theta^-) - \pi v_p \cos \theta^+ - \cos \theta^-) \\
|\gamma| \frac{v_{r'}}{r_p'} &= -\pi v_p (\sin \theta^+ - \sin \theta^-) - \pi v_p \cos \theta^+ - \cos \theta^-) \\
\end{align*}
\]

and

\[
\begin{align*}
\gamma |\frac{v_{r'}}{r_p'} &= -\pi v_p (\sin \theta^+ - \sin \theta^-) - \pi v_p \cos \theta^+ - \cos \theta^-) \\
\gamma |\frac{v_{r'}}{r_p'} &= -\pi v_p (\sin \theta^+ - \sin \theta^-) - \pi v_p \cos \theta^+ - \cos \theta^-) \\
\end{align*}
\]

Dividing the latter equation above with the former, using (18), and simplifying, we arrive at

\[
\begin{align*}
\frac{r_p}{r_p'} &= \frac{\sin \theta_p}{\sin \theta_p} (\sin \theta^+ - \sin \theta^-) + \cos \theta^-) + \cos \theta^-) \\
\end{align*}
\]

which is (19). When the type of the path intersecting the boundary between $P_p$ and $P_p'$ is $\pi$, by item d) of Theorem 3.2, $\theta_p = \theta_p' = 0$ (mod $\pi$).

**Corollary 3.4** Under the conditions of Theorem 3.3, if $\pi_p = \pi_p'$ (Problem 1*), then (19) reduces to $\Delta \theta_p = \Delta \theta_p'$.

**Proof:** The condition in Problem 1* is given by $\pi_p = \pi_p'$. Using this in (19), we get $\Delta \theta_p = \pm \Delta \theta_p$. To rule out the case $\Delta \theta_p = -\Delta \theta_p'$, suppose, by contradiction, that this relation holds. Using the definition of $\Delta \theta_p$ and $\Delta \theta_p'$, we get $\theta_p = \theta_p'$. Then, applying (18), the velocities $v_p$ and $v_p'$ in $P_p$ and $P_p'$, respectively, are equal. Replacing this in the condition in Problem 1* we get that $r_p = r_p'$. This leads to $P_p$ and $P_p'$ having the same properties, which is a contradiction.

Equations (18) and (19) can be interpreted as a refraction law at the boundary of the two regions for the angles (and their variations) $\theta_p, \theta_p'$ (and $\Delta \theta_p, \Delta \theta_p'$). In the case that the particle is allowed to instantaneously change its direction of travel, this refraction law simplifies to the so-called Snell’s law of refraction. Snell’s law of refraction in optics states a relationship between the angles of rays of light when passing through the boundary of two isotropic media with different refraction coefficients. More precisely, given two media defining two regions in the state space with different refraction indices $v_1$ and $v_2$, Snell’s law of refraction states that

\[
\begin{align*}
\frac{v_1}{v_2} = \frac{\sin \theta_1}{\sin \theta_2}, \\
\end{align*}
\]

where $\theta_1$ is the angle of incidence and $\theta_2$ is the angle of refraction. This law can be derived by solving a minimum-time problem between two points, one in each medium.
i.e. with instantaneous jumps in
law can be seen as a special case for refraction with the

Corollary 3.5

 Moreover, the dynamics of the rays of light can be associated to the differential equations \( \dot{\theta} \) with the

in Theorem 3.2 at the boundary between two regions with minimum turning radius \( r_p \) in region \( \mathcal{P}_p \) and with minimum turning radius \( r_{p'} \) in region \( \mathcal{P}_{p'} \), \( p, p' \in \{1, 2, \ldots, N\} \).

Fig. 3. Optimal paths satisfying the necessary conditions in Theorem 3.2 at the boundary between two regions with minimum turning radius \( r_p \) in region \( \mathcal{P}_p \) and with minimum turning radius \( r_{p'} \) in region \( \mathcal{P}_{p'} \), \( p, p' \in \{1, 2, \ldots, N\} \).

Moreover, the dynamics of the rays of light can be associated to the differential equations \( \dot{\theta} = v_i \), where \( v_i \) is the velocity in the \( i \)-th medium, \( i = 1, 2 \). In fact, Snell’s law can be seen as a special case for refraction with the dynamics given by (2) with a radius of curvature of zero, i.e. with instantaneous jumps in \( \theta \). In this case, (19) holds trivially for arbitrary values of \( \Delta \theta_1 \) and \( \Delta \theta_2 \), while the ratio of velocities in (18) is essentially (22). Thus, Theorem 3.3 generalizes Snell’s law to the case when the “dynamics” of the rays of light are given by (2). In the context of autonomous vehicles, the conditions given by (18) and (19) are a generalization of the refraction law for optimal steering of a point-mass vehicle, as in [1,16], to the Dubins vehicle case.

3.3 Optimal families of paths

Using Theorem 3.2, it is possible to determine optimal families of paths for a class of paths to Problem 1. The following statements follow directly from Dubins’ result and Theorem 3.2. Below, the subscript \( p, p' \) or \( p - p' \) on each path piece denotes that the path piece is in region \( p, p' \) or spans across both regions \( p \) and \( p' \), respectively. The numeric subscript on each path piece indicates the number of path piece.

Corollary 3.5 (optimal paths w/one jump) Let the curve \( \mathcal{X} \) describe a minimum-length path that solves

Fig. 4. Nonoptimal paths at the boundary determined by Corollary 3.6.

Problem 1 and let \( x, y \) and \( \theta \) be its associated functions with input \( u \). Define the function \( q \) following the construction below (6). Suppose Assumption 2.1 holds. If \( \mathcal{X} \) has no more than one boundary cross between two adjacent regions \( p \) and \( p' \), then it is a smooth concatenation of \( \mathcal{C}, \mathcal{L} \) paths pieces with at most three pieces in each region and is given by one of the following eight path types of paths:

\[
C_{1,p}C_{2,p}C_{3,p}C_{4,p'}C_{5,p'}C_{6,p'}, \quad C_{1,p}C_{2,p}C_{3,p}C_{4,p'}C_{5,p'}C_{6,p'},
C_{1,p}L_{2,p}C_{3,p}C_{4,p'}C_{5,p'}C_{6,p'}, \quad C_{1,p}L_{2,p}C_{3,p}C_{4,p'}C_{5,p'}C_{6,p'},
C_{1,p}C_{2,p}C_{3,p}C_{4,p}C_{5,p'}C_{6,p'}, \quad C_{1,p}C_{2,p}C_{3,p}C_{4,p}C_{5,p'}C_{6,p'},
C_{1,p}L_{2,p}C_{3,p}C_{4,p}C_{5,p'}C_{6,p'}, \quad C_{1,p}L_{2,p}C_{3,p}C_{4,p}C_{5,p'}C_{6,p'},
\]

where \( L_{2,p-p'} \) is perpendicular to the boundary, in addition to any such path obtained when some of the path pieces (but not all) have zero length.

Figure 3 depicts families of optimal paths across the boundary of two regions with minimum turning radius \( r_p \) in region \( \mathcal{P}_p \) and with minimum turning radius \( r_{p'} \) in region \( \mathcal{P}_{p'} \), \( p, p' \in \{1, 2, \ldots, N\} \). Item d) in Theorem 3.2 implies that \( \mathcal{L} \)-type paths at the boundary of regions with different velocity are optimal only if they are orthogonal to the boundary, depicted by Figure 3(a).

Another useful corollary is the following.
Corollary 3.6 (nonoptimal paths) Let the curve $X$ describe a minimum-length path that solves Problem 1 and let $x, y$ and $\theta$ be its associated functions with input $u$. Define the function $q$ following the construction below (6). Suppose Assumption 2.1 holds. For every one boundary crossing between two adjacent regions $p$ and $p'$, the minimum-time path cannot be a smooth concatenation of $C, L$ paths pieces with more than three pieces in each region and cannot belong to the following four types of paths:

$$
C_{1,p}L_{2,p-p'}C_{3,p}, C_{1,p}L_{2,p}C_{3,p}C_{4,p}C_{5,p'},
C_{1,p}L_{2,p}C_{3,p}L_{4,p'}C_{5,p'}, C_{1,p}L_{2,p}C_{3,p}C_{4,p'}L_{5,p'}C_{6,p'},
$$

where $L_{2,p-p'}$ is non-orthogonal to the boundary, in addition to any such path obtained when the first and/or last path pieces have zero length.

Proof: From the results in [6], any path with more than three path pieces in each region is nonoptimal. In addition, by item d) in Theorem 3.2, an $L_{p-p'}$-type of the path intersecting the boundary between $P_p$ and $P_{p'}$ must be orthogonal to the boundary. This rules out the first path in (24). The other three paths in (24) have segments of type $L_pC_pL_{p'}$, $L_pC_{p'}L_{p'}$ or $L_pC_{p'}C_{p'}$, which have a switch of the input $u$ at the boundary and correspond to a transition from or to a path of type $C$. This implies that $\gamma = 0$ at the boundary since, by item b) in Lemma 3.1, it is a continuous function. To reach a contradiction, suppose these path segments are optimal. Then, $\gamma = 0$ at the boundary implies that (16) becomes

$$
\overline{\alpha}v_p\sin\theta^* + \overline{\beta}_p v_p \cos\theta^* = \overline{\alpha}v_{p'} \sin\theta^* + \overline{\beta}_{p'} v_{p'} \cos\theta^* = c + \lambda_c.
$$

Then, by subtracting (21) from (25) and substituting $\overline{\beta}_p \tan\theta_p = \overline{\alpha}$ and $\overline{\beta}_{p'} \tan\theta_{p'} = \overline{\alpha}$ (by item d) in Lemma 3.1), we get

$$
\overline{\alpha}v_p\left(\sin\theta_p(\sin\theta^* - \sin\theta_p) + \cos\theta_p(\cos\theta^* - \cos\theta_p)\right) \overline{\alpha}v_{p'}\left(\sin\theta_{p'}(\sin\theta^* - \sin\theta_{p'}) + \cos\theta_{p'}(\cos\theta^* - \cos\theta_{p'})\right)
$$

$$
\sin\theta_p (1 - \cos \Delta \theta_p) = 0 \quad \sin\theta_{p'} (1 - \cos \Delta \theta_{p'}) = 0,
$$

which implies that $\Delta \theta_p = \Delta \theta_{p'} = 0$, i.e., no path piece of type $C$ is allowed before or after the boundary for optimal paths, which leads to a contradiction.

Figure 4 depicts the path types that Corollary 3.6 determines to be nonoptimal.

4 Numerical validation

4.1 Two Heterogeneous Regions

For the purposes of illustrating our main results, we first consider the case of two regions, $P_1$ and $P_2$, where $P_1 = \{(x, y) \in \mathbb{R}^2 : y > 0\}$ and $P_2 = \{(x, y) \in \mathbb{R}^2 : y \leq 0\}$, and choose initial and final configurations, given by $(x, y)^I \in P_1$ with initial velocity vector $\nu^I$ and $(x, y)^F \in P_2$ with final velocity vector $\nu^F$, respectively, so that optimal paths between the regions cross only once, that is, for every optimal path there exists a unique crossing point $(x^*, y^*) \in \overline{P_1} \cap \overline{P_2}$ with a unique velocity vector direction. We use the off-the-shelf software package GPOPS [15] to verify the necessary conditions for optimality as well as the refraction law at boundary derived in Section 3. The simulations were performed on a 2.2 GHz Intel Core i7 CPU with 15 mesh refinement iterations, a mesh tolerance of $10^{-5}$, and between 25 to 50 nodes per interval. The average CPU time for each simulation was 83.3 s.

Figure 5 shows optimal paths from a given initial point to a final point for different values of the velocities, $v_1$ and $v_2$ and minimum turning radii, $r_1$ and $r_2$, in regions $P_1$ and $P_2$, respectively. The path for velocity $v_1^{3(a)}$ in Figure 5(a) is the classical minimum-time Dubins path since $v_1^{3(a)} = v_2 = 1$ and $r_1^{3(a)} = r_2 = 1$.

Paths $v_1^{3(b)}$, $v_1^{3(c)}$ and $v_1^{3(d)}$ in Figures 5(b), 5(c) and 5(d) have equal velocities of travel in both regions, and are very similar to the classical Dubins path, as the path piece across the boundary can be of type $C$ and non-orthogonal to the boundary, i.e., with no refraction, resulting in paths of type $C^+ LC^-$. The only difference lies in the curvature constraint of the paths in the different regions.

Paths with smaller and larger velocities $v_1 \in \{1, 1, \frac{1}{2}, 2, 4\}$ are also depicted showing that the particle travels a larger distance in the region with the larger velocity of travel, as one would expect. Similarly, a larger minimum turning radius in each region leads to larger traveled distance. Turns of types $C^-$ and $C^+$ occur at points nearby the boundary between the regions for optimal paths $\{v_1^{1(a)}, v_1^{2(a)}, v_1^{4(a)}\}$, $\{v_1^{1(b)}, v_1^{2(b)}, v_1^{4(b)}\}$, $\{v_1^{1(c)}, v_1^{2(c)}, v_1^{4(c)}\}$, $\{v_1^{1(d)}, v_1^{2(d)}\}$ and $\{v_1^{5(a)}, v_1^{5(b)}, v_1^{5(c)}, v_1^{5(d)}\}$, respectively. With the exception of $\{v_1^{5(a)}, v_1^{5(b)}, v_1^{5(c)}, v_1^{5(d)}\}$, these paths have a subpath of type $C LC$ across the boundary and can be used to verify the derived refraction law given in (18) and (19). A comparison of the specified ratios of velocities, $\frac{v_1}{v_2}$, and minimum turning radii, $\frac{r_1}{r_2}$ with the computed values using the refraction law is shown in Table 1. This table demonstrates an agreement of the simulation results with theory, where the slight differences can be attributed to the numerical imprecision of the optimal control solver.
The symbols by $v_r$ of the bang-singular-bang controls, i.e., the locations where

Fig. 5. Optimal paths from a given initial point $(x, y)^{(1)}$, $(v^1, \nu^1)$ to a final point $(x, y)^{(2)}, (v^2, \nu^2)$ for different values of the velocity $v_1 = \{1, 2, 3, 4\}$ (from left to right) and minimum turning radii $r_1$ in region $P_1$, and a constant velocity given by $v_2 = 1$ and different minimum turning radii $r_2$ in region $P_2$. The path for velocity $v_1^{(a)} = 1$ is the classical minimum-time Dubins path. The symbols $\Delta$ mark the junctions of the bang-singular-bang controls, i.e., the locations where the path type changes.

4.2 Three Heterogeneous Regions

The same optimal control solver that was used to compute optimal paths when there is only one crossing can also be applied to the case of $N$ regions. For the general case of multiple crossings, computation is more involved, and the ability of the solver to find the global optimum strongly depends on having good initial guesses. We demonstrate this with an example with three regions, each with different velocities of travel and minimum turning radii, for a set of three different settings. The simulations were implemented on a 2.2 GHz Intel Core i7 CPU with 25 mesh refinement iterations, a mesh tolerance of $10^{-6}$, and 25 – 35 nodes per interval. The average CPU time for each simulation was 60.4 s.

In (a) $\gamma^{(b)} = (1, 2, 3, 4)$, and minimum turning radii, $r_1^{(b)}$, with computed values from (18) and (19).

Fig. 6 shows optimal paths from a given initial point $(x, y)^{(1)}, (v_1, \nu_1)$ in region $P_1$ to a final point $(x, y)^{(2)}, (v_2, \nu_2)$ in region $P_3$. In this case, the particle has the option of moving directly from region $P_1$ to $P_3$ or passing through region $P_2$ on the way to the final point in $P_3$. In fact, the setting in Figure 6(a) is equivalent to an instance of a lane changing problem, where there are two lanes with different coefficients of frictions and a driver needs to decide whether to stay on the slow lane or to take a detour on the fast lane. Regions $P_1$ and $P_3$ are identical in size, geometry, and properties, and the union of the two regions can be seen as the slow lane, whereas the region on the right, $P_2$ is the fast lane. For the setting in Figure 6(a), the particle travels through region $P_2$ because, although the traveled distance is increased, the travel time is decreased. The control input history also shows that the control $u$ is of the “bang-singular-bang” family as shown in The-
Theorem 3.2, while the states and adjoint states satisfy the properties stated in Lemma 3.1 and the refraction law shown given Theorem 3.3 (after taking the coordinate transformation given in (13) into consideration).

On the other hand, Figure 6(b) depicts the setting in which region $P_2$ is slower than both $P_1$ and $P_3$. Hence, the minimum-time path is also the minimum-distance path, passing directly from $P_1$ to $P_3$ in a straight path, orthogonal to the boundary, as necessitated by the refraction law in Theorem 3.3. The optimal path shown in Figure 6(c) is another instance in which region $P_2$ is a fast region. Hence, the minimum-time path takes advantage of this by traveling through $P_2$ on the way to $P_3$. Unlike the optimal path in Figure 6(a), there is an asymmetry about the $x$-axis because of the heterogeneous nature of travel in the various turning radii. In these two cases, the control input, the states and adjoint states also satisfy Theorem 3.2, Lemma 3.1, and Theorem 3.3.

Fig. 7. Optimal paths from a given initial point $(x, y)^{i}, \nu^{p} = ((-1, 2), (v_3, 2\pi/3))$ to a final point $(x, y)^{f}, \nu^{f} = ((-1, -2), (v_3, 2\pi/3))$ for various values of the velocity $v_2 = 0.475, 0.48, 0.75, 1.5, 5$ (from left to right) and a constant minimum turning radius $r_2 = 0.5$ in region $P_2$. The symbols $\Delta$ marks the junctions of the bang-singular-bang controls, i.e., the locations where the path type changes. Minimum times: (16.00e, 15.96e, 14.19e, 12.37e, 10.95e); Values of adjoints: $\mathbf{\lambda} = (0.00, 2.08, 1.33, 0.67, 0.20), \mathbf{\tau}_1 = (4.00, -3.41, -3.77, -3.94, -4.00), \mathbf{\tau}_2 = (4.00, -2.82 \times 10^{-5}, 3.59 \times 10^{-5}, -4.03, -9.92 \times 10^{-4}), \mathbf{\tau}_3 = (4.00, 3.41, 3.77, 3.94, 4.00), \tau_{\min} = (0.00, -0.18, -0.20, -0.16, -0.07), \tau_{\max} = (0.00, 0.96, 1.33, 1.67, 1.90).

It is also interesting to note that a phase transition can be observed with varying velocities of the regions. Figure 7 shows optimal paths from a given initial point $(x, y)^{i}, \nu^{p} = ((-1, 2), (v_3, 2\pi/3))$ to a final point $(x, y)^{f}, \nu^{f} = ((-1, -2), (v_3, 2\pi/3))$ for constant velocities given by $v_1 = v_3 = 0.25$ and minimum turning radii $r_1 = r_3 = 0.5$ in regions $P_1$ and $P_3$, respectively. In region $P_2$, the minimum turning radius is $r_2 = 0.5$, while the velocity is decreased from $v_2 = 5$ to zero. As expected, one can observe from Figure 7 (viewed from right to left) that the smaller the velocity of region $P_2$ is, the shorter the path the particle traverses in that region. In fact, a phase transition occurs when $v_2 \approx 0.476$.

For velocities below this value, the particle travels from $P_1$ to $P_3$ without going through $P_2$. 

5 Conclusion

We have derived necessary conditions for the optimality of paths with velocity and minimum turning constraints across $N$ regions. To establish our results, we formulated the problem as a hybrid optimal control problem and used optimality principles from the literature. Our results provide verifiable conditions for optimality of paths. These include conditions both in the interior of the regions and at their common boundary, as well as a refraction law for the angles which generalizes Snell’s law of refraction in optics to the current setting. Applications of our results include optimal motion planning tasks for autonomous vehicles with Dubins vehicle dynamics. By means of numerical examples, we verified the claims in this paper and illustrated the influence of the heterogeneous nature of the regions in state space on the resulting minimum-time paths of bounded curvature.
