Abstract: We demonstrate sub-10 nm transistor channel lengths by directed self-assembly patterning of monolayer MoS$_2$ in a periodic chain of homojunction semiconductor-(2H) and metallic-phase (1T') MoS$_2$ regions with half-pitch of 7.5 nm. The MoS$_2$ composite transistor possesses an off-state current of 100 pA/µm and an $I_{on}/I_{off}$ ratio in excess of 10$^6$. Modeling of the resulting current-voltage characteristics reveals that the 2H/1T' MoS$_2$ homojunction has a resistance of 75 Ω.µm while the 2H-MoS$_2$ exhibits low-field mobility of ~8 cm$^2$/V.s and carrier injection velocity of ~10$^6$ cm/s.

Introduction: 2D crystals of layered transition metal dichalcogenides (2D-TMDCs) such as MoS$_2$ are ideal candidates for aggressive miniaturization of field-effect transistors (FETs) to the single digit nanometer scale. In addition to large bandgap, chemical stability and compatibility with CMOS processes [1, 2], this class of materials can benefit from their atomically thin body with dangling-bond-free surfaces. Because of this and their ultra-small body thickness which leads to very small electrostatic characteristic scaling length, $\lambda \approx (\varepsilon_s/\varepsilon_{ox})(I_{on}/I_{off})$, transistor subthreshold swing (SS) and drain-induced barrier lowering (DIBL) coefficient in such films can be significantly smaller than for conventional thin-body semiconductors. In particular, monolayer-MoS$_2$ (ML-MoS$_2$), because of its bandgap of 1.8 eV yields high $I_{on}/I_{off}$ ratio MOSFETs, while its low dielectric constant, $\varepsilon_s = 4-7$, and atomically thin body, $t_s \approx 0.7$ nm, facilitate the reduction of $\lambda$. In our previous work [3], we reported a 15-nm channel length MoS$_2$ FET using monolayer graphene as the Source/Drain (S/D) contacts. In this work, by exploiting the semiconducting to metallic phase transition in MoS$_2$ [4], we demonstrate a sub-10-nm transistor channel length by patterning of MoS$_2$ in a periodic chain of homojunction semiconducting- (2H) and metallic-phase (1T') MoS$_2$ regions. The 2H- to 1T'-phase transition occurs by exposing 2H-MoS$_2$ to n-butyl lithium solution as confirmed by electrical and photoluminescence measurements (Fig.1). Sub-10 nm 1T'/2H MoS$_2$ patterning is achieved by directed self-assembly (DSA) of block copolymers (BCP) technique which is one of the most promising emerging technologies for cost-effective, nanoscale, and high-volume manufacturing [5].

Device Fabrication: The key steps for fabricating BCP patterned MoS$_2$ FETs, as well as a schematic of the devices are shown in Figs. 2 and 3, respectively. ML-MoS$_2$, grown by chemical vapor deposition (CVD), was transferred onto a [p$^+$ Si/native SiO$_2$] substrate coated with 10 nm of HfO$_2$ (EOT= 4 nm) serving as the back gate (BG). Subsequently, by means of electron beam lithography and Au metallization, end-contacts to the MoS$_2$ film and measurement pads were formed. Next the surface of the substrate is functionalized with hydroxyl terminated polystyrene (OH-PS), poly(styrene-b-dimethylsiloxane) (PS-b-PDMS) BCP solution is spun-on followed by a solvent vapor annealing step to promote microphase separation, and finally selective reactive ion etching (RIE) of PS matrix is done in a controlled O$_2$ plasma leaving behind oxidized-PDMS (ox-PDMS) lines parallel to the Au lines. Fig.4a shows the final ox-PDMS lines with half-pitch of 7.5 nm formed between Au lines contacting the MoS$_2$ film. Next, the phase transition treatment of the ox-PDMS-patterned MoS$_2$ is applied to selectively convert the uncovered underlying 2H-MoS$_2$ to 1T'-MoS$_2$, while the ox-PDMS-covered regions remain semiconducting. These alternating 2H-MoS$_2$/1T'-MoS$_2$ areas correspond to semiconducting and metallic regions with same length, and form a chain of transistors in series as shown in Fig.4b. The resulting transistor pitch is equal to the BCP period, 15 nm, with channel length of 7.5 nm. The minimum number of transistors-in-series thus formed between a pair of 120-nm-spaced Au electrodes was 8.

Results and discussion: Fig. 5a shows the $I_d$-$V_g$ evolution at three fabrication stages of an eventual chain of eight ML-Mo-S$_2$ FETs with 15 nm pitch. As can be seen, the ML-MoS$_2$ survives the PS etching step and still shows high $I_{on}/I_{off}$ modulation. However, current degradation of more than two orders of magnitude is observed as well as higher SS and shifted threshold voltage ($V_t$) compared with the as-fabricated MoS$_2$-FET. These changes are the consequences of the MoS$_2$ surface being affected by the plasma radicals. The unwanted degradation is nevertheless direct indication that the PS film is fully etched and the gaps between PDMS lines are fully opened. The last $I_d$-$V_g$ curve in Fig. 5a shows the same device characteristics after phase-transition treatment. Fig 5b shows the final device at different $V_g$ values highlighting the significant increase of $I_{on}$ at $V_g$=1 V, which can be attributed to direct source-drain tunneling in the individual FETs. Fig. 6a shows the model fit to the data using the MIT Virtual Source model [6]. The transfer curve below threshold is determined by the MoS$_2$ threshold voltage (~ -1V), gate capacitance (for 4 nm EOT) and carrier velocity (8x10$^5$ cm/s). Near and above threshold ($V_g$$\geq$0 V), the contact resistance (~20 kΩ.µm) dominates over the channel resistance until the Schottky contact resistance between the Au metal and MoS$_2$ is sufficiently low (~1 kΩ.µm for $V_g$$\geq$2 V). In this regime ($V_g$$\geq$2V), the channel resistance dominates again and the transport is determined by carrier mobility ($\mu \approx 8$ cm$^2$/V.s) and series resistance between 1T'/2H MoS$_2$ homojunction (~75 Ω.µm). Fig. 6b shows the predicted transfer characteristics of an idealized single 7.5 nm MoS$_2$ transistor assuming MoS$_2$-metal contact resistance of 100 Ω.µm, and double gate with appropriate work-function and EOT of 0.5 nm leading to a drastically improved SS (62 mV/dec), low DIBL (~20 mV/V) and higher ON current. The carrier velocity and mobility found here from the modeling of the experimental devices are comparable to previously estimated values [7-9]. With the current CVD growth technique, the $I_{on}$ is 0.1 mA/µm for $I_{off}$=10 pA/µm at $V_d$=0.5 V (Fig. 6b). Further improvement of carrier velocity is possible with improved film-growth method to meet ITRS requirements for future nodes. Conclusions: We have demonstrated the operation of MoS$_2$ FETs with the shortest and thinnest S/D channel, namely ~7.5 nm long and ~0.7 nm thick, reported to date. The transistor chain shows $I_{on}/I_{off}$ $\geq$10$^6$ with $I_{off}$ $\leq$100 pA/µm. Further improvement of $I_{on}$ current is possible by improved growth of MoS$_2$ and thus increased carrier velocity and mobility to meet the current requirement for high performance.
