(Received 2 May 2017; published 27 July 2017)

Finding the optimal encoding strategies can be challenging for communication using quantum channels, as classical and quantum capacities may be superadditive. Entanglement assistance can often simplify this task, as the entanglement-assisted classical capacity for any channel is additive, making entanglement across channel uses unnecessary. If the entanglement assistance is limited, the picture is much more unclear. Suppose the classical capacity is superadditive, then the classical capacity with limited entanglement assistance could retain superadditivity by continuity arguments. If the classical capacity is additive, it is unknown if superadditivity can still be developed with limited entanglement assistance. We show this is possible, by providing an example. We construct a channel for which the classical capacity is additive, but that with limited entanglement assistance can be superadditive. This shows entanglement plays a weird role in communication, and we still understand very little about it.

DOI: 10.1103/PhysRevLett.119.040503

In Shannon’s classical information theory [1], a classical (memoryless) channel is a probabilistic map from input states to output states. This has been extended to the quantum world. A (memoryless) quantum channel is a time-invariant completely positive trace preserving (CPTP) linear map from input quantum states to output quantum states [2]. A classical channel can only transmit classical information, and the maximum communication rate is fully characterized by its capacity. A quantum channel can be used to transmit not only classical information but also quantum information. Hence, there are different types of capacity, such as classical capacity $C$ for classical communication [3,4] and quantum capacity $Q$ for quantum communication [5–7].

Since quantum channels transmit quantum states, and quantum states can be entangled with other parties, it is natural to ask if entanglement can assist the communication. This was first considered by Bennett et al., who showed that unlimited preshared entanglement could improve the classical capacity of a noisy channel [8,9]. Shor examined the case where only finite preshared entanglement is available and obtained a trade-off curve that illustrates how the optimal rate of classical communication depends on the amount of entanglement assistance (CE trade-off) [10]. One can also consider how entanglement (E), classical communication (C), or quantum communication (Q) can trade-off against each other as resources. The trade-off capacity of almost any two resources was studied by Devetak et al. [11,12], such as entanglement-assisted quantum capacity (QE trade-off). Subsequently, the triple resource (CQE) trade-off capacity was also characterized [13–15].

However, almost all the capacity formulas above are given by regularized expressions. They are difficult to evaluate because they require an optimization over an infinite number of channel uses, which is typically intractable. The existence of this regularization is because entanglement across different channel uses can sometimes protect information against noise and improve the communication rate, a phenomenon often called superadditivity. Superadditivity has long been known to be the case for quantum capacity [16,17], but remained undiscovered for classical capacity until Hastings gave an example [18]. One exception is the entanglement-assisted classical capacity $C_E$ [9,19]. An intuitive understanding of the additivity of $C_E$ is that the best way to use entanglement is to preserve it to the receiver, but not across different channels. The need for regularization for various capacity formulas represents our incomplete understanding of quantum channels, as one cannot find the optimal transmission rate and best encoding strategies. Thus, an important goal in quantum Shannon theory is to characterize quantum channels with additive capacities. For classical capacity, many such channels are known, including unital qubit channels [21], entanglement-breaking channels [22], etc. For quantum capacity, there are also examples like degradable channels [11]. Additivity for the double or triple resource trade-off capacity has also been considered, but many fewer examples are known [23].

One can also ask if it is possible to characterize the additivity of a capacity region (e.g., CE trade-off) from some of its subregions (e.g., C). This has been shown to be possible for QE trade-off, as additivity of $Q$ implies the additivity of quantum capacity with any amount of entanglement assistance [12]. However, the same problem is
transmission achieved using tensor products of states. This is the maximal rate of reliable classical information classical capacity (i.e., Holevo capacity) \[3,4\] of information transmission through capacity and is the ultimate limit of reliable classical sends them through the channel hence the \"input states which are entangled across obtain the uses also does not help if we have unlimited entanglement assistance. This is always true regardless of the channel. The uses also does not help if we have unlimited entanglement assistance (this is always true regardless of the channel). The question addressed is case (b), whether entangled input states with additive classical capacity. We have the following three scenarios: (a) Entanglement across channel uses does not help if we have some entanglement assistance \[Fig. 1(c)\]. But with limited entanglement assistance \[Fig. 1(b)\]. We answer the above question affirmatively. We show that there exists a channel \(N\) such that the classical capacity is additive, but with some entanglement assistance \(P\), it becomes superadditive. We give a schematic plot of our CE trade-off curve in Fig. 2(a).

To describe our results precisely, we need to first review a few key notions and results in classical capacity. To transmit classical information, Alice picks a set of signal states \(\rho_i\) with probability \(p_i\) (denoted as \(\{p_i, \rho_i\}\)), and sends them through the channel \(\Phi\) to Bob. The 1-shot classical capacity (i.e., Holevo capacity) \[3,4\] of \(\Phi\) is

\[
C^{(1)}(\Phi) = \max_{\{p, \rho\}} S\left(\sum_i p_i \Phi(\rho_i)\right) - \sum_i p_i S(\Phi(\rho_i)),
\]

(1)

where \(S(\rho) = -\text{tr}[\rho \log(\rho)]\) is the von Neumann entropy. This is the maximal rate of reliable classical information transmission achieved using tensor products of states \(\rho_i\), hence the \"1-shot\" classical capacity \[25\]. If we can use input states which are entangled across \(n\) channel uses, we obtain the \(n\)-shot classical capacity \(C^{(n)}(\Phi) = C^{(1)}(\Phi^\otimes n)/n\). \(C(\Phi) = \lim_{n \to \infty} C^{(n)}(\Phi)\) denotes the (regularized) classical capacity and is the ultimate limit of reliable classical information transmission through \(\Phi\). If \(C(\Phi)\) is additive open for CE trade-off. This question has only been recently explored \[24\], where one can restrict the encoding and constraint on entanglement to make it additive.

In this work, we consider the implication of additivity of the classical capacity on the CE trade-off region. Suppose \(C\) is additive, this means we can look at each channel use in place of \(\Phi\) for our channel. \(C_p = C^{(1)}(\Phi)\) at \(P = 0\) and \(P_{\max}\), but not for all values in between. (b) QE trade-off curve for channels with additive quantum capacity. \(P_{\max}\) is the maximum amount of available entanglement assistance.

Suppose \(C\) is additive, this means we can look at each channel use separately, and entangled input states do not help [Fig. 1(a)]. The same is true if there is unlimited entanglement assistance [Fig. 1(c)]. But with limited entanglement assistance, it is unclear whether entangled input states could help [Fig. 1(b)].

Now consider the scenario where the purifications of the states \(\rho_i\) are preshared to Bob, who can use them together with the states he receives through \(\Phi\) for decoding. If we restrict the average amount of preshared entanglement to be \(P\) ebits per channel use, we arrive at the 1-shot classical capacity with entanglement assistance \(P\) \[10\], denoted as \(C_p^{(1)}(\Phi)\),

\[
C_p^{(1)}(\Phi) = \max_{\{\rho_1, \ldots, \rho_P\}} \sum_i p_i S(\rho_i) + S\left(\Phi\left(\sum_i p_i \rho_i\right)\right) - \sum_i p_i S(\Phi \otimes I(\rho_i));
\]

where \(\rho_i = |\phi_i\rangle \langle \phi_i|\) is the density matrix of \(\rho_i\) together with a purification. This is also achieved using inputs which are tensor products of states \(\rho_i\). Similar to classical capacity, there is \(C_{p,n}^{(n)}(\Phi) = C^{(1)}(\Phi^\otimes n)/n\) and \(C_p(\Phi)\). Note that the above formula works for any \(P\). In particular, when \(P = 0\), we get \(C^{(1)}(\Phi)\). When \(P\) is maximal, we get \(C_E(\Phi)\).

Now we are ready to state our main result.

**Theorem 1 (Main Theorem)** There exists a channel \(N\) such that

\[C(N) = C^{(1)}(N),\]

i.e., its classical capacity is additive. However, there exists \(P\) such that

\[C_p(N) > C^{(1)}_p(N),\]

i.e., its classical capacity with limited entanglement assistance can be superadditive.

This additivity to superadditivity transition in classical capacity is illustrated in Fig. 2(a). This is in sharp contrast to the QE trade-off curve [Fig. 2(b)], as \(Q_p^{(n)}\) grows linearly.
in $P$ with gradient 1. Additivity of $Q_p$ follows from the additivity of $Q$.

Our channel $N$ is a conditional quantum channel $N^{MA}_{A\rightarrow B}$ [26], where register $M$ determines whether $N^{A\rightarrow B}_0$ or $N^{A\rightarrow B}_1$ is used (see Fig. 3 for a diagrammatic representation). Explicitly, on any input state $\rho^{MA}$ [27],

$$
N(\rho^{MA}) = N_0(\langle 0|\rho^{MA}|0\rangle^M) + N_1(\langle 1|\rho^{MA}|1\rangle^M).
$$

(2)

This construction is similar to the one in Ref. [28]. However, their construction does not directly apply to our case since $M$ is kept and contains classical information.

The intuition why a channel like $N$ will work is that without entanglement, we are only using the classical channel $N_0$; hence, its classical capacity is additive. As one increases entanglement assistance, one starts using the quantum channel $N_1$, where superadditivity kicks in.

Our construction is generic and does not depend on the specific forms of $N_0$ and $N_1$. Hence, we give the properties of $N_0$ and $N_1$ that are required for our argument to work and will give a construction of $N_1$ later. An example of $N_0$ is given in the Supplemental Material [29].

We require the classical channel $N_0$ to have the following properties: (0.1) $C(N_0) = \log(|B|) - \min S(N_0(\rho))$. (0.2) It has a noise parameter $\eta$ which can be tuned, such that $C(N_0)$ varies from $0$ to $\log(|B|)$ continuously.

We require the quantum channel $N_1$ to have the following properties: (1.1) It has a superadditive classical capacity, i.e., $C(N_1) > C^{(1)}(N_1)$. (1.2) For any $n$ and $P$,

$$
C_p^{(n)}(N_1) = \log(|B|) - \min_{\rho \leq \rho^P} \frac{1}{n} S(\hat{N}_1^\otimes n(\mathcal{I}(\rho))) - S(\rho).
$$

(1.3) There exists $P > 0$ such that $C_p(N_1) > C_p^{(1)}(N_1)$, and $C_p(N_1)$ is strictly concave at $P$.

Here by saying a function $f$ is strictly concave at $y$, we mean $f(y) > (1 - p)f(y) + pf(w)$ for all $v < y < w$ satisfying $(1 - p)v + pw = y$, with $p \in (0, 1)$. It is clear that $C_p(\Phi)$ is always concave in $P$. If $P = (1 - p)P_1 + pP_2$, then $C_p(\Phi) \leq pC_{P_1}(\Phi) + (1 - p)C_{P_2}(\Phi)$, as one can always just use entanglement $P_1$ for the $p$ fraction of the channel uses and entanglement $P_2$ for the other fraction.

The rest of the paper is organized as follows. We first state Lemma 2 about the classical capacity with limited entanglement assistance, of partial cq channels (defined in Lemma 2). This lemma together with the properties above lead to the simplification of capacity formulas, as we show in Lemmas 3 and 4. We will prove our main theorem in the main text and leave the proofs of various lemmas to the Supplemental Material [29].

**Lemma 2** Suppose a channel $\Psi$ has an input Hilbert space $\mathcal{H}_R \otimes \mathcal{H}_C$. If there exists a noiseless classical channel $\Pi$ on $\mathcal{H}_R$ with orthonormal basis $\{|j\rangle\}$, such that

$$
\Psi = \Psi_0(\Pi \otimes \mathcal{I}_C),
$$

then $C_p^{(1)}(\Psi)$ can be achieved with an input ensemble $\{p_{ij}|j\rangle\langle j|\otimes \rho_{ij}\}$, where $\rho_{ij}$ are states of $C$.

By saying $\Pi$ is a noiseless classical channel with orthonormal basis $\{|j\rangle\}$, we mean $\Pi(\rho) = \sum_j |j\rangle\langle j| \rho |j\rangle\langle j|$.

This is very intuitive. Entanglement between $R$ and other parties is not useful, as $\Pi$ destroys it. Since we only have limited entanglement, it is better to use it on $C$.

Using Lemma 2 and properties of $N_0$ and $N_1$, we can simplify the various capacity formulas of $N$.

**Lemma 3**

$$
C^{(1)}(N) = \max \{C(N_0), C^{(1)}(N_1)\},
$$

$$
C(N) = \max \{C(N_0), C(N_1)\}.
$$

Lemma 2 ensures that for different uses of the channel, we can choose to use $N_0$ or $N_1$ only, without sacrificing the capacity. Lemma 3 simply states that, for all channel uses, we should use either $N_0$ or $N_1$.

**Lemma 4**

$$
C_p^{(1)}(N) = \max_{\{q_{ij}\}} q C(N_0) + (1 - q) C_p^{(1)}(N_1).
$$

$$
C_p(N) = \max_{\{q_{ij}\}} q C(N_0) + (1 - q) C_p(N_1).
$$

This lemma states that, for entanglement-assisted classical communication, the best strategy is to use $N_0$ for some fraction of the channel uses and $N_1$ for the other fractions of the channel uses (i.e., time sharing). Since using $N_0$ does not require entanglement assistance, we can allocate more of it to $N_1$.

Now we are ready to prove the main theorem.

**Proof of main theorem**— Choose $N_0$ such that

$$
C(N_0) = C(N_0) > C^{(1)}(N_1).
$$

By Lemma 3, the classical capacity of $N$ is additive, i.e.,

$$
C(N) = C(N_0) = C^{(1)}(N).
$$

From Eqs. (3), (4) and concavity of $C_p(N_1)$ with respect to $P$, we have $C_p(N) \leq C_p(N_1)$. Also, $C_p(N) \geq C_p(N_1)$ by choosing $q = 0$ in Eq. (3). So we have
\[ C_p(N) = C_p(N_1), \]  
(7)

Choose \( P > 0 \) according to property 1.3. By Lemma 4, suppose \( C_p^{(1)}(N) \) is achieved at some \( \{\tilde{q}, \tilde{P}\} \) with \( (1 - \tilde{q})\tilde{P} = P \), i.e.,

\[ C_p^{(1)}(N) = \tilde{q}C(N_0) + (1 - \tilde{q})C_p^{(1)}(N_1). \]  
(8)

If \( \tilde{P} = P \), we have

\[ C_p(N) = C_p(N_1) > C_p^{(1)}(N_1) = C_p^{(1)}(N), \]  
(9)

where the inequality follows from property 1.3.

If \( P > P \) and thus \( \tilde{q} > 0 \),

\[ C_p(N) = C_p(N_1) > \tilde{q}C(N_1) + (1 - \tilde{q})C_{\tilde{P}}(N_1) \geq \tilde{q}C(N_0) + (1 - \tilde{q})C_p^{(1)}(N_1) = C_p^{(1)}(N), \]  
(10)

where the first inequality follows from property 1.3.

**Construction of \( N_1 \).** — The first two properties for \( N_1 \) can be easily satisfied. One can take a channel with a subadditive minimum output entropy [18] and unitally extend it to a channel with a superadditive classical capacity, via Shor’s construction [30,31]. Unfortunately, such channels are poorly understood, and we do not know if it satisfies property 1.3. We argue that if it does not, we cannot tensor product a dephasing channel that will guarantee it is satisfied, without sacrificing the other properties.

We quote the following property about concave functions [32]: A concave function \( u(y) \) is continuous, differentiable from the left and from the right. The derivative is decreasing, i.e., for \( x < y \), we have \( u'(x-) \geq u'(x+) \geq u'(y-) \geq u'(y+) \). We use “\( \pm \)" to denote the right and left derivatives when needed.

Let \( \mathcal{E}^{C-C} \) be a random orthogonal channel with subadditive minimum output entropy [18] and \( \mathcal{F}^{RC-C} \) (with \( |R| = |C|^2 \)) be a conditional quantum channel of the form

\[ \mathcal{F}(\rho^{RC}) = \sum_{j=1}^{|C|^2} X_j \mathcal{E}(j|\rho^{RC}|j)^R X_j^†, \]  
(11)

where \( X_j \)'s are the Heisenberg-Weyl operators on \( C \) [6]. This ensures \( \mathcal{F} \) satisfies properties 1.1 and 1.2 [29].

Because of Lemma 2, the useful entanglement assistance is at most \( \log(|C|) \). Thus, we restrict to \( 0 \leq P \leq \log(|C|) \).

Let

\[ \epsilon = C(\mathcal{F}) - C^{(1)}(\mathcal{F}) > 0. \]  
(12)

Since

\[ C_p^{(1)}(\mathcal{F}) \leq C^{(1)}(\mathcal{F}) + P, \]  
(13)

\[ C_E(\mathcal{F}) \leq C(\mathcal{F}) + \log(|C|) - \epsilon. \]  
(14)

This implies \( dC_p(\mathcal{F})/dP \) cannot always be 1. Thus, there exists \( \bar{P} \in [0, \log(|C|)] \) such that

\[ dC_p(\mathcal{F})/dP = 1, \quad \forall \ 0 \leq P \leq \bar{P} \]  
(15)

and

\[ dC_p(\mathcal{F})/dP < 1, \quad \forall \ P > \bar{P}. \]  
(16)

Next, we discuss the few different cases. (1) \( P > 0 \). Then \( C_p(\mathcal{F}) \) is strictly concave at \( \bar{P} \) by definition. Note that \( C_p(\mathcal{F}) = C(\mathcal{F}) + \bar{P} \) but \( C_p^{(1)}(\mathcal{F}) \leq C^{(1)}(\mathcal{F}) + \bar{P} \), thus \( C_p(\mathcal{F}) - C_p^{(1)}(\mathcal{F}) \geq \epsilon \) and \( \mathcal{N}_1 \) is \( \mathcal{F} \) satisfies property 1.3.

(2) \( P = 0 \). Let \( \mathcal{N}_1 = \mathcal{F} \otimes \Delta_2^\epsilon \), where \( \Delta_2^\epsilon \) is the qubit dephasing channel \( \Delta_2^\epsilon(\rho) = (1 - \lambda)\rho + \lambda Z\rho Z \). The CQE trade-off region is additive for \( \Phi \otimes \Delta_2^\epsilon \), for any channel \( \Phi \); thus, \( \mathcal{N}_1 \) satisfies property 1.1. \( \Delta_2^\epsilon \) satisfies property 1.2, and by arguments similar to Appendix B of Ref. [23], one can show \( \mathcal{N}_1 \) also satisfies property 1.2.

Since \( dC_p(\mathcal{F})/dP |_{P=0} < 1 \), choose \( \lambda > 0 \) such that \( dC_p(\Delta_2^\epsilon)/dP |_{P=0} < dC_p(\mathcal{F})/dP |_{P=0} \). This ensures that when \( 0 < P \leq 1 \),

\[ C_p(\mathcal{N}_1) = C(\mathcal{F}) + C_p(\Delta_2^\epsilon). \]  
(17)

Since \( C_p(\Delta_2^\epsilon) \) is strictly concave with respect to \( P \) when \( \lambda < 1/2 \) [13], \( C_p(\mathcal{N}_1) \) is also strictly concave with respect to \( P \), for \( 0 < P \leq 1 \). Also, when \( P < \epsilon \),

\[ C_p(\mathcal{N}_1) \geq C(\mathcal{F}) + C(\Delta_2^\epsilon) \geq C^{(1)}(\mathcal{F}) + P \geq C_p^{(1)}(\mathcal{N}_1), \]  
where the first inequality comes from Eq. (16), the second one comes from our assumption \( P < \epsilon \) and Eq. (11), and the last one comes from Eq. (12).

This ensures that \( C_p(\mathcal{N}_1) \) is superadditive. Thus, when \( 0 < P < \min\{1, \epsilon\} \), \( C_p(\mathcal{N}_1) \) is strictly concave and superadditive, satisfying property 1.3.

**Conclusion.** — Our work unveils the complications in characterizing the additivity of the CE capacity region. In fact, the only known channels that admit an additive CE capacity region are the quantum erasure channels [13] and Hadamard channels [23], many fewer than the class of channels with an additive classical capacity. Coincidentally, these two classes of channels also admit an additive CQE trade-off capacity, suggesting a nontrivial connection [13,23,33].

Also, we do not know the number of shots at which the superadditivity occurs. However, it is very likely that our \( \mathcal{N}_1 \) only has superadditivity in classical capacity up to two shots [34]. In that case, the superadditivity in classical capacity with limited entanglement will appear at two shots.

*eltonzhu@mit.edu*

[19] Here, we are only talking about the case of a single sender and a single receiver. If there are multiple senders, then the entanglement-assisted classical capacity requires regularization [20].
[25] This is not to be confused with the $\epsilon$-1-shot classical capacity, which is the amount of information transmitted through a single use of the channel, with the average error probability less than $\epsilon$.
[27] One can also normalize the input states to $N_0$ and $N_1$.
