(Received 8 January 2017; revised manuscript received 12 May 2017; published 11 October 2017)

We study the electrical conductivity in a nodal-line semimetal with charged impurities. The screening of the Coulomb potential in this system is qualitatively different from what is found in conventional metals or semiconductors, with the screened potential $\phi$ decaying as $\phi \propto 1/r^2$ over a wide interval of distances $r$. This unusual screening gives rise to a rich variety of conduction regimes as a function of temperature, doping level, and impurity concentration. In particular, nodal-line semimetals exhibit a diverging mobility $\alpha 1/|\mu|$ in the limit of vanishing chemical potential $\mu$, a linearly increasing dependence of the conductivity on temperature, $\sigma \propto T$, and a large weak-localization correction with a strongly anisotropic dependence on magnetic field.

We also assume that the dominant source of momentum scattering for quasiparticles is provided by Coulomb impurities, as is typical for semiconductors and semimetals. Due to the long-range nature of the potential of these impurities, they provide only small-momentum scattering relative to the radius of the tube (the Fermi momentum) is significantly smaller than the characteristic size of the nodal line, which is typically of order of the inverse lattice spacing.

The Hamiltonian for a quasiparticle near a short straight segment of the nodal line is given by

$$\hat{H}_0 = v(\hat{\sigma}_x k_x + \hat{\sigma}_y k_y) + \xi(k_z) + e\phi(r),$$

(1)

where $k_x$ and $k_y$ are the transverse momentum components and $\xi(k_z)$ is the contribution of the longitudinal motion to the kinetic energy; $\phi(r)$ is the electric potential created by charged impurities screened by electrons.

1 See Ref. [36] for a review.
For the small quasiparticle energies under consideration, the longitudinal quasiparticle velocity may be estimated as \( v_z \approx v k_z / p_0 \), and it is strongly suppressed compared to the transverse velocity \( v \), where \( p_0 \) is the local radius of curvature of the nodal line (in momentum space). As a result, the quasiparticle dynamics on sufficiently short length scales is effectively 2D and is confined to the plane perpendicular to the segment of the nodal line under consideration.

The strength of the Coulomb interaction in an NLS may be characterized by the effective fine structure constant \( \alpha = e^2 / \pi \epsilon_0 r_c \) (in Gaussian units), with \( \epsilon_0 \) being the dielectric constant. Usually, \( \alpha \lesssim 1 \) in semimetals (see, e.g., Refs. [21] and [22] for estimates). In this Rapid Communication, we make the usual weak-interaction assumption, \( \alpha \ll 1 \), which allows one to use the linear Poisson equation to describe the electrostatic potential \( \phi(r) \) created by screened charged impurities:

\[
\nabla^2 \phi(r) + 4\pi e^2 \int \Pi(r,r') \phi(r') \, dr' = -4\pi e \sum_j Z_j \delta(r-r_j).
\]

Here, \( r_j \) and \( Z_j \) are the location and the charge of the \( j \)th impurity (for donors and acceptors \( Z_j = \pm 1 \), respectively) and \( \Pi(r,r') = -i \int_{-\infty}^{0} [\hat{n}(0,r),\hat{n}(t',r')] dt' \) is the zero-frequency polarization operator, which describes the linear response of the local density of electrons \( \hat{n}(r) \) to the electrostatic potential \( \phi(r') \).

**Polarization operator.** Due to the effectively two-dimensional short-distance dynamics of the quasiparticles, the screening properties of electrons near a short segment of the nodal line are related to those in graphene [23,24], with the contribution to the polarization operator given by that of 2D Dirac electrons multiplied by \( g K_1 / (2\pi) \), where \( g \) indicates the spin and valley degeneracy and \( K_1 \) is the length of this segment in momentum space. The full polarization operator is given by a sum of all such straight-line-segment contributions, since the entire nodal line may be approximated as a chain of straight-line segments.

At low temperature and chemical potential, the polarization operator \( \Pi(q) \) is linear in the momentum \( |q| \) for any direction of \( q \). While the constant of proportionality between \( \Pi(q) \) and \( |q| \) for a given direction of \( q \) depends in general on the shape of the nodal line, below we assume for simplicity that the full polarization operator is isotropic in \( q \). For sufficiently high chemical potentials \( \mu \) or temperatures \( T \), \( \Pi(q) \) is momentum independent and is determined by the density of states (DoS) at energies \( \sim \max(\mu,|T|) \). Thus the behavior of the polarization operator in an NLS in the limits of high and low temperatures may be summarized as

\[
\Pi(q) = \begin{cases} 
-g CK_0 |q| / v, & |q| \gg T, |\mu|, \\
-g K_0 |\mu| / (4\pi^2 v^2), & |\mu| \gg T, v|q|, \\
-g K_0 T \ln 2 / (2\pi^2 v^2), & T \gg |\mu|, v|q|. 
\end{cases}
\]

Here, \( K_0 \) is the length of the nodal line and \( C \) is a constant of order unity, which accounts for the details of the geometry of the nodal line.

**Screened impurity potential.** At low temperature and chemical potential, the distance dependence of the screened Coulomb potential in an NLS is qualitatively different from that in conventional metals, dielectrics, or other semimetals. The Fourier transform of the screened interaction is given by \( \phi(q) = \phi_0(q) [1 - \Pi(q) \phi_0(q)]^{-1} \), where \( \phi_0(q) = 4\pi e^2 / (\pi q^2) \) describes the unscreened Coulomb interaction and the polarization operator \( \Pi(q) \) is given by Eq. (3). At short distances the interaction is unscreened, \( \phi(r) \sim e^2 / (\pi r) \). At distances of order of

\[
r_0 = (\alpha g K_0)^{-1},
\]

the interaction potential crosses over to the unconventional form

\[
\phi(r) = e^2 r_0 / 2\pi^2 e \alpha C r^2.
\]

Finally, at very large distances, exceeding the characteristic wavelength \( \max(|\mu|,T) / v \) of the quasiparticles in the conduction (valence) band, the polarization operator is effectively local, \( \Pi(r,r') \approx -4\pi e^2 \lambda_{TF}^2 / \alpha v \) \( \delta(r-r') \), resulting in the exponentially suppressed interaction \( \phi(r) \propto \exp(-r/\lambda_{TF}) \).

Here we have introduced the Thomas-Fermi (TF) screening length, given by

\[
\lambda_{TF}^{-2} = \begin{cases} 
(\alpha g / \pi) \cdot K_1 |\mu| / v, & |\mu| \gg T, \\
(2\alpha g / \pi) \ln 2 \cdot K_0 T / v, & T \gg |\mu|. 
\end{cases}
\]

The dependence of the screened interaction on distance is summarised in Fig. 2, assuming low temperature and chemical potential \( |\mu|,T \ll \alpha g v K_0 \).

For high temperatures or chemical potentials, \( \max(|\mu|,T) \gg \alpha g v K_0 \), the characteristic quasiparticle wavelength becomes shorter than the distance \( r_0 \), and the

\[\]

\footnote{These constants of proportionality between \( \Pi(q) \) and \( |q| \) are calculated for the case of a circular nodal line in Ref. [37].}
intermediate regime with $\phi(r) \propto 1/r^2$ (see Fig. 2) vanishes. In this case, the screened electrostatic potential is given by

$$\phi(r) = \frac{e^2}{kr} \exp(-r/\lambda_{TF})$$

across all distances, as in a conventional metal [25].

**Quasiparticle scattering.** As mentioned in Introduction, it is possible to approximate the nodal line by a chain of straight-line segments and to consider separately the quasiparticle transport near each segment. Due to the suppressed quasiparticle motion along the nodal line, the transverse conductivity $\sigma_t$ of a given segment with momentum length $K_\parallel$ significantly exceeds its longitudinal conductivity $\sigma_\parallel$. The sum of the conductivity from all segments, with their various orientations, is then of order of $\sigma_\parallel K_\parallel / K_\perp$.

The relaxation of the momentum of quasiparticles with energy $\epsilon$ (transverse momentum $v/\nu$) near a straight segment of the nodal line due to elastic scattering off impurities is characterised by the transport scattering time $\tau_\nu$. In the Born approximation,

$$\frac{1}{\tau_\epsilon(\epsilon)} = 2\pi n_{\text{imp}} \int \frac{d\mathbf{p}}{(2\pi)^3} \left| \phi(\mathbf{p} - \mathbf{k}) \langle \sigma_\epsilon | \sigma_\epsilon \rangle \right|^2 \times (1 - \cos \theta_{\mathbf{k},\mathbf{p}}) \delta(kv - pv),$$

where $n_{\text{imp}}$ is the total concentration of (donor and acceptor) impurities, $\mathbf{k}$ is a momentum with the transverse component $\epsilon/\nu$, $\phi(\mathbf{q})$ is the Fourier transform of the impurity potential, and $\langle \sigma_\epsilon | \sigma_\epsilon \rangle$ is the pseudospin state of a quasiparticle with momentum $\mathbf{p}$ in a given (conduction or valence) band; $\langle \sigma_\epsilon | \sigma_\epsilon \rangle = (1 + \cos \theta_{\mathbf{k},\mathbf{p}})/2$, with $\theta_{\mathbf{k},\mathbf{p}}$ being the angle between the transverse components of $\mathbf{k}$ and $\mathbf{p}$.

**Low-doping levels.** At low doping, $|\mu| \ll \alpha g v K_\perp$, and zero temperature, the Fermi wavelength $\sim \nu$ significantly exceeds the length scale $r_0$ [Eq. (4)]. Thus the scattering of quasiparticles at the Fermi surface is determined by the $\propto 1/r^2$ tail of the impurity potential rather than the $\propto 1/r^2$ core (see Fig. 2).

Using Eqs. (5) and (8), we find the transport scattering time in this regime to be (see Supplemental Material for details [26])

$$\tau_\nu = \gamma_\nu g^2 K_\parallel^2 / (n_{\text{imp}} v),$$

where $\gamma_\nu$ is a nonuniversal constant of order unity, which depends on the details of the geometry of the nodal line. We note that typical scattering events have large scattering angles $\theta_{\mathbf{k},\mathbf{p}} \sim 1$, and therefore the transport scattering time (9) is of the same order as the typical time $\tau_0$ between collisions (the elastic scattering time).

For weak disorder, such that $\tau_0 |\mu| \gg 1$, the DoS of quasiparticles at the Fermi energy is weakly affected by impurities, and the conductivity is dominated by the Drude contribution [25,27,28], which takes into account quasiparticle scattering processes not involving quasiparticle interference. The transverse Drude conductivity of the straight-nodal-line segment is given by

$$\sigma_t(\mu) = \frac{1}{2} \frac{K_\parallel}{2\pi} g^2 e^2 v^2 v_{2D}(\mu) \tau_\nu = \frac{\gamma_\nu}{8\pi^2} g^2 e^2 K_\parallel^2 K_\perp |\mu| n_{\text{imp}} v,$$

where $v_{2D} = |\mu/v|/2\pi$ is the quasiparticle DoS (per spin per valley) in the transverse 2D plane. As discussed above, the conductivity of the entire NLS is of order (10) with the replacement $K_\parallel \rightarrow K_\perp$.

Since the concentration of charge carriers depends quadratically on the chemical potential, $n(\mu) \propto \mu^2$, Eq. (10) implies that the quasiparticle mobility $\sigma_\epsilon(\mu) \propto 1/|\mu|$ diverges as the chemical potential approaches the nodal line, even for a fixed impurity concentration.

**Temperature dependence.** In the regime of low doping under consideration ($|\mu| \ll \alpha g v K_\perp$), the conductivity strongly depends on temperature when $T \gg |\mu|$ (here, we neglect electron-phonon scattering and the interaction between quasiparticles). In the limit of weak disorder, we find for the conductivity of a straight segment of the nodal line

$$\sigma_t = -\int n_F(\epsilon) \sigma_t(\epsilon) d\epsilon \approx \frac{\gamma_\nu}{4\pi^2} \frac{g^2 e^2 K_\parallel^2 K_\perp}{n_{\text{imp}} v} T, \quad (T \gg |\mu|),$$

where $n_F(\epsilon) = 1/|\exp(\epsilon/T) + 1|$ is the Fermi distribution function and $\sigma_t(\epsilon)$ is given by Eq. (10). The conductivity of the NLS is described approximately by Eq. (11) with the replacement $K_\parallel \rightarrow K_\perp$. The linear-in-$T$ dependency of the conductivity comes from thermally activated charge carriers with a linear density of states $v(\epsilon) \propto \epsilon$ and a constant scattered rate (9).

**High-doping regime.** When the NLS is so heavily doped that $|\mu| \gg \alpha g v K_\perp$, the TF screening radius becomes shorter than $r_0$ and the screened potential is equivalent to that in a conventional metal [Eq. (7)]. In this regime the transport properties of the NLS are also similar to those of a conventional metal and, in particular, weakly dependent on the temperature. Using Eqs. (7) and (8), we find the transport scattering rate in this regime

$$\frac{1}{\tau_\epsilon(\epsilon)} = \frac{2\alpha^2 g^2}{\epsilon^2} n_{\text{imp}} \ln \frac{|\epsilon| \lambda_{TF}}{v}.$$

At such high doping, the impurities typically scatter quasiparticle momenta by small angles $\theta \ll 1$, which leads to a significantly shorter elastic scattering time $\tau_0 = (4\pi\alpha^2 g^2 n_{\text{imp}} v \lambda_{TF})^{-1}$.

This transport scattering is equivalent to the scattering of electrons on the surface of a 3D topological-insulator with bulk impurities [38].
(see Ref. [26]). The Drude conductivity of a highly-doped NLS is then given by the segment contribution

\[ \sigma_{d}(\mu) = \frac{e^2 K_1 e^2}{8\pi^2 a^2 e^3 n_{\text{imp}} \ln |\mu|/(\alpha g K_1 v)}. \]  

with \( K_1 \) replaced by a quantity of order \( K_\sigma \).

**Weak localization.** For all doping levels, the quasiparticle dynamics on sufficiently short length scales is effectively 2D and is confined to the plane perpendicular to the nodal line. One can therefore expect significant quantum interference effects that are typical of 2D systems [27,29]. In order to estimate the characteristic length scale \( l_{\text{dim}} \) below which these interference effects are strong, we assume that the quasiparticles have a small longitudinal dispersion \( \xi(k_z) = v k_z^2/2p_0 \), e.g., due to the curvature of the nodal line (in which case \( p_0 \) is the local radius of curvature of the line).

To estimate \( l_{\text{dim}} \), let us consider a quasiparticle whose momentum \( k \) at time \( t = 0 \) lies in the \( x-y \) plane. Due to the small dispersion in the \( z \) direction and collisions with impurities, such a quasiparticle slowly drifts away from the \( x-y \) plane. During each collision with an impurity, the longitudinal velocity of the quasiparticles changes by an amount \( \delta v_z \sim \pm v k_z/K_\sigma \), where we have assumed that the local radius \( p_0 \) of the nodal line is of order \( K_\sigma \). After a long time \( t \gg t_0 \), the total change in \( z \) velocity is of order \( \Delta v_z \sim (v k_z)/\sqrt{\tau_0} \), and the quasiparticle travels a distance \( \Delta z \sim t \Delta v_z \sim v k_z/\sqrt{\tau_0} \) in the \( z \) direction. When this drift length exceeds the electron wavelength \( \sim k^{-1} = v/|\mu| \), the quasiparticle can be considered to have “escaped” its initial 2D plane of motion and no longer participates in the 2D interference effects in this plane. The characteristic time of 2D interference can thus be estimated as

\[ l_{\text{dim}} \sim (v^2 K_\sigma^2 \tau_0/\mu^3)^{1/2}, \]

which corresponds to the length

\[ l_{\text{dim}} = (v^4 K_\sigma/\mu^2)^{1/4} \tau_1^{1/4} \tau_0^{1/4}, \]  

(14)

of diffusion in the initial 2D plane.

Thus, quantum interference effects in an NLS on short distances \( L \ll l_{\text{dim}} \) are equivalent to those of 2D Dirac fermions, such as electrons in graphene in a single valley, which exhibit weak-antilocalization (WAL) corrections to conductivity [30,31]. On larger length scales \( L \gg l_{\text{dim}} \), the classical trajectories of the quasiparticles are essentially 3D and the interference between them is suppressed. Thus the conductivity of an NLS receives a WAL correction

\[ \delta \sigma_{WL} = \frac{e^2 K_\sigma}{2(\pi^2)} \times \left[ \ln[\min(l_{\phi},l_{\text{dim}})/(v \tau_0)], \quad B \ll B_0, \right. \]

\[ \left. \left( \tilde{\gamma}_B(n_B) \cdot \ln[l_{\text{B}}/(v \tau_0)], \quad B \gg B_0, \right) \right. \]

(15)

where \( B_0 = e \tau_0 \) is the characteristic value of magnetic field at which the WAL is affected by the field, \( \tilde{\gamma}_B(n_B) < 1 \) is a nonuniversal coefficient depending on the geometry of the nodal line and the direction \( n_B = \mathbf{B}/B \) of the magnetic field, \( l_{\phi} \) is the dephasing length, and \( l_{\text{B}} = e/c \times \tau_0 B \).

The first line in Eq. (15) describes the conventional WAL corrections due to the interference of 2D Dirac fermions [30,31]; the second line describes the partial suppression of WAL by the magnetic field. Because the correction is dominated by effectively 2D interference effects, the magnetic field \( B \) does not suppress the interference near parts of the nodal line perpendicular to \( B \) (here we neglect the much weaker effect of magnetic field on the motion along the nodal line), and therefore the suppression of the WAL correction by a magnetic field strongly depends on the direction of the field. In particular, if the entire nodal line lies in one plane, as, for example, in \( ZrSiS \) [see Fig. 1(a)], the in-plane magnetic field can partially suppress the WAL correction, while the field perpendicular to the plane has no significant effect. We note also that for sufficiently weak disorder \( (\mu v t_\mu \gg 1) \) the conductivity is dominated by the Drude contribution (10), and the interference correction (15) is negligible.

**Summary and discussion.** We have studied the conductivity in a weakly disordered NLS with charged impurities. At low temperature and chemical potential, the screened electrostatic interaction is qualitatively different from that in conventional semiconductors and semimetals and includes a broad regime of distances for which \( \phi(\mathbf{r}) \propto 1/r^3 \) (see Fig. 2). Such screening of impurities can potentially be probed using scanning tunneling microscopy, and it also manifests itself in the dependencies of the conductivity on temperature and doping level.

In particular, a low-doped NLS exhibits divergent quasiparticle mobility \( \propto |\mu|^{-1} \) at vanishing chemical potential \( \mu \), with conductivity given by Eq. (10). In this regime, the NLS also exhibits strong temperature dependence of the conductivity, \( \sigma(T) \propto T \), at \( T \gg |\mu| \). At larger doping, the impurities are strongly screened, and the transport properties of the NLS resemble those of a conventional metal.

In all of these regimes, the conductivity of an NLS receives large WAL corrections [Eq. (15)] due to the suppressed motion of the charge carriers along the nodal line, which makes electron dynamics effectively 2D on short scales and thus leads to strong single-particle interference effects.

For presently existing NLSs, which have \( K_\sigma \) of order 1 Å\(^{-1} \) and \( v \) of order 10\(^8\) cm/s, the energy scale \( \alpha g K_\sigma \) is as large as several eV for \( \alpha \sim 0.1 \). Existing NLS materials are therefore likely to fall in the “low-doping” regime of our analysis. Recent experiments on \( ZrSiS \) [32–35], for example, report \( \mu \) of order 100 meV. In this case, Eq. (10) implies a low-temperature resistivity on the order of tens of \( \Omega \) cm, assuming a charged impurity concentration of order \( 10^{17} \) cm\(^{-3} \) (as reported in Ref. [35]). This is consistent with the experimental measurements in Refs. [32,34]. In other NLSs, where the nodal line is not doped by additional pockets of states, it may be possible to achieve lower chemical potentials and significantly higher mobilities. For instance, impurity concentration \( n \sim n_{\text{imp}} \sim 10^{18} \) cm\(^{-3} \) (typical, for example, for Dirac semimetals) will lead to a chemical potential of order...
10 meV. Equation (10) then implies a huge mobility on the order of \(10^7 \text{cm}^2\text{V}^{-1}\text{s}^{-1}\) and a strong temperature dependence above \(T \sim 100\text{ K}\).

Finally, we note that current experiments correspond to the regime of weak disorder (\(\mu \tau_0 \gg 1\)), which is assumed throughout this paper and which requires \(n_{\text{imp}} \ll g^2 K^2 |\mu|/v \sim 10^{13} \text{cm}^{-2}\). Since there is no localization in systems of effectively-2D Dirac fermions (in the absence of scattering between opposite ends of the nodal line), one can expect that stronger disorder \((n_{\text{imp}} \gg g^2 K^2 |\mu|/v)\) may lead to a universal minimal conductivity \(\sigma \sim e^2 K_0\) in an NLS. However, this regime of strong disorder is left for a future study. Another question that deserves further investigation is the role of the interaction between quasiparticles in transport, as for sufficiently high temperatures the NLS resistivity will be dominated by the scattering of quasiparticles on each other rather than impurity scattering.
