**ABSTRACT:** The rapid detection and differentiation of chiral compounds is important to synthetic, medicinal, and biological chemistry. Palladium complexes with chiral pincer ligands are demonstrated to have utility in determining the chirality of various amines. The binding of enantiomeric amines induced distinct $^{19}$F NMR shifts of the fluorine atoms appended on the ligand that defines a chiral environment around palladium. It is further demonstrated that this method has the ability to evaluate the enantiomeric composition and discriminate between enantiomers with chiral centers several carbons away from the binding site. The wide detection window provided by optimized chiral chemosensors allows the simultaneous identification of as many as 12 chiral amines. The extraordinary discriminating ability of this method is demonstrated by the resolution of chiral aliphatic amines that are difficult to separate using chiral chromatography.

Rapid and facile methods to detect and discriminate chiral compounds are highly desirable to accelerate advances in synthetic and biological chemistry. The challenges in analysis stem from the obvious fact that enantiomeric molecules have the same physical properties. Chemosensory systems designed for chirality determination have attracted increasing attention as a result of the low cost and simplicity as alternatives to traditionally employed X-ray crystallography and chiral chromatography. For instance, on the basis of an intensity change of a fluorescence or circular dichroism (CD) signal, the enantiomeric excess (ee) value of a sample can be quickly evaluated. In addition to the speed of detection, other desirable attributes of a chirality sensing system include simplicity in the measurement, broad substrate applicability, and the ability to analyze complex mixtures. A limitation of optical methods for routine applications is that they usually require pure sample with known enantiomeric excess to construct a calibration curve. Herein, we introduce a $^{19}$F NMR chemosensing system that doesn’t suffer from these limitations in the differentiation of enantiomers. Specifically this method does not require enantiopure samples to determine the ee and is capable of predicting the absolute configuration. We also demonstrate for the first time that multiple chiral amines can be simultaneously identified in a single NMR experiment.

NMR is a useful tool to access chiral information by using chiral derivatizing or solvating agents to produce diastereomeric complexes that can be used to discriminate between enantiomers. As these methods typically rely on the NMR signals of the substrate, the analysis often requires pure samples and is complicated if the NMR signals overlap. One approach to address these limitations in NMR methods is to use a $^{19}$F chiral derivatizing agent as a probe to simplify the NMR signal. However, the discriminating ability of this approach is limited for aliphatic compounds. This is because aromatic rings are required to induce a pronounced shielding effect that facilitates the NMR signal splitting in a chiral environment (Scheme 1a). Furthermore, analytes with chirality centers remote to the derivatizing site are difficult to resolve through this approach. To achieve a chirality sensing method that addresses these limitations and eliminates the use of covalent derivatization, we targeted a $^{19}$F NMR chemosensory system that utilizes a chiral ligand-metal complex that reversibly binds to the analyte (Scheme 1b). The key elements that have led to the success of this chirality chemosensing platform are: (1) The dissociation of the chiral analyte and the metal is slow on the NMR time frame to generate “static complexes” with precise and characteristic $^{19}$F NMR shifts. (2) The ligand is capable of creating a chiral environment to host the analyte wherein the subtle interactions between the ligand and the chiral analyte are transduced by the nearby appended $^{19}$F probes (Scheme 1b).

**Scheme 1.** Comparison of Mosher Amide Based Approach and our Sensing Scheme for the Discrimination of Chiral Amines.

Previous approach (Mosher amide):

This work:

To examine the feasibility of our chemosensing scheme, we selected the amide-based palladium pincer complex 2 (Scheme 2) as a scaffold as a result of its easy preparation and well known coordination chemistry. The coordination site that undergoes facile ligand exchange is flanked by pendant groups that are sensitive to through-bond and through-space interactions with analyte enantiomers. The chiral ligands were constructed by reacting 2,6-pyridinedicarboxyl dichloride (1) with various chiral amines.
corresponding palladium complexes 2 were prepared with a weakly bound acetonitrile that is rapidly replaced by Lewis basic analytes. In addition to the C$_2$-symmetric complex (2a), we also prepared a nonsymmetric complex (2b) that is derived from (S)-$\alpha$-methylbenzylamine and 3,5-bis(trifluoromethyl)aniline with the aim to evaluate the influence of a remote chirality on the $^1$H NMR shifts in our sensing system. The nonsymmetric ligand of 2b was readily prepared by a sequential addition of the corresponding aniline and amine to a solution of 1 in toluene.

Scheme 2. The Preparation and Structures of Palladium Complexes with Chiral Pincer Ligands.

We began by exploring the $^19$F NMR chirality sensing potential of complex 2a. Initial studies revealed that the Lewis basic oxygens of amide groups act as ligands to produce insoluble oligomeric species. This oligomerization is prevented by the addition of 15 equivalent of CH$_3$CN to produce clear stable monomeric solutions of 2a. We then selected a series of readily available chiral amines and amino alcohols as the analytes to test the differentiation of enantiomers. The observation of discrete signals at precise chemical shifts that are not concentration dependent indicates the formation of “static” complexes on the NMR time scale (Figure S1 in SI). As a result, for a given solvent, each enantiomer can be correlated to a NMR signal with precise chemical shift. With amine binding, a new high field signal was observed that is indicative of an increased shielding effect caused by the analyte relative to the displaced acetonitrile ligand (Figure 1a). The shielding effect imposed by a pair of enantiomers to the chiral ligand is different and generates discrete NMR signals for identification. It is noteworthy that the association of 2a and amines is fast and the equilibrium is reached before the NMR analysis. Figure 1A illustrates the ability of 2a to resolve most of the enantiomers. One noteworthy feature of sensor 2a is the high sensitivity provided by 12 equivalent fluorine atoms, which allowed analysis to be performed at low concentrations (50 µg of analyte was adequate for the experiments in Figure 1 using a 400 MHz NMR spectrometer).

We next turned our attention to the nonsymmetric complex 2b, which positions the $^19$F probes closer to the analyte to create more pronounced changes in chemical shifts. The topology of 2b is interesting because the chiral moiety effecting the chirality discrimination is separated from the $^19$F probe by the analyte. We envisioned that this transduction mechanism could provide an orthogonal discriminatory ability relative to that of 2a. The data in Figure 1B confirm our designs and the chemical shift range induced by the bound analyte is larger for 2b in comparison to 2a. Specifically, in the case of (R)-$\alpha$-methylbenzylamine, we observed NMR shifts of 0.39 and 0.15

*NMR measurements were performed in CDCl$_3$/pentane (2:3) using 2b (5 mM) and analyte (ca. 2 mM)
SAMPLE TEXT: We have evaluated the potential of 2b to determine the enantiomeric excess values. Initial experiments showed that complexing 2b with racemic α-methylbenzylamines produced two new diastereomeric palladium species with the same 19F NMR resonance intensity. Therefore, we can determine the enantiomeric excess from 19F NMR integration under our experimental conditions. We have applied this method for the analysis of a series of nonracemic samples and Table 1 shows the calculated values are in excellent agreement with the actual enantiopurity (Table 1, right). In a similar way, the ee of nonracemic 2-phenylglycinol can be also accurately determined (Table 1, right). No calibration curve or derivatization is required, and this method has the potential to be adapted in routine asymmetric synthesis. Notably, nitriles and N-heterocycles are also potential analytes for this method (Figure S8 in SI), while secondary and tertiary amines generally do not coordinate to the palladium as a result of their steric hindrance.

To achieve a simultaneous resolution of multiple chiral analytes, we prepared complex 2c (1 mM in CDCl3) and different chiral amines. The replacement of the methyl group of 2a by a trifluoromethyl (CF3) group brings the fluorine probe closer to the analyte and extends the 19F NMR detection window. As a CF3 group is significantly bigger than a methyl group, the internal cleft flanked by this ligand becomes more confined than that of 2a and 2b, to promote intimate interactions between the ligand and analytes. A trifluoromethyl (OCF3) group was further introduced to increase the bulkiness of the phenyl group and to add an additional fluorine probe to 2c. Another benefit of this design is the self-aggregation that was observed previously is inhibited by 2c’s bulky ligand. Figure 2a illustrates that the wide detection window of 2c allows the simultaneous identification of as many as 12 chiral analytes (for the performance of a structurally similar sensor without OCF3 group, see Figure S7 in SI). Interestingly, a broader peak was observed in the experiment.
of the β-methylphenethylamine using the CF₃ probe, while the OCF₃ probe produced sharp signals and a good resolution (Figure 2b,c). Similar to the chirality sensing methods based on circular dichroism, empirical predictions of the absolute configuration can be made. For instance, we find that β-chiral amines of S configuration always appear at a lower field as compared to those of R configuration (Figure 2a). The extraordinary discriminating ability provided by 2c is further demonstrated by the resolution of aliphatic amines. Racemic samples were mixed with the chlorofluoroo solution of 2c and the ¹⁹F NMR spectrum was recorded. The discrimination of these amines is difficult because the alkyl groups connected to the chiral center differ solely in a single methylene unit (Figure 3a-c). One appealing feature of 2c is its orthogonal resolving ability provided by the CF₃ and OCF₃ probes which increases its success in resolving challenging analytes. This is revealed by inspection of the results illustrated in Figure 3, where one fluorine probe produced a better resolution than the other. In this way, all the aliphatic amines in Figure 3 can be differentiated. Proton-decoupled NMR experiments collapsed the doublet signal of the CF₃ group to a singlet, for further improved resolution (Figure 3c). In contrast to conventional chiral derivatizing methods, the current method is also capable of resolving the amines with chiral center several carbons away from the amino group (Figure 3d).

In summary, we have developed a new chirality chemosensor platform based on ¹⁹F NMR and chiral palladium pincer complexes. The bonding of enantiomers produced diastereomeric complexes with distinct and precise ¹⁹F NMR shifts. This approach provided a simple and robust differentiation of chiral amines that are not easily resolved with chiral HPLC. The key to the success of this approach is to bind enantiomers with an environment that is flanked by chiral ligands with fluorine probes optimally positioned. We expect the combination of the current strategy and diversified supramolecular scaffolds will produce a powerful sensing platform that addresses chirality differentiations relevant to chiral synthesis and biological chemistry.
