The study of final states with an isolated high energy photon and an identified $b$-quark jet is a testing ground for quantum chromodynamics (QCD) predictions at the Tevatron. At photon transverse energies $E_T$ below 70 GeV Compton scattering processes $gb \rightarrow \gamma gb$ or $qb \rightarrow \gamma qb$ dominate production, while above that value the dominant process is quark annihilation $q\bar{q} \rightarrow b\bar{b}y$ [1]. A cross section measurement provides a probe of the hard scattering dynamics within the proton, and a cross-check of the predictions of its $b$-quark content, whose parton density function is indirectly extracted from constraints on the gluon density functions.

The first measurement of photon and heavy flavor jets (identified by the presence of a muon in the jet) was performed on 86 pb$^{-1}$ of integrated luminosity taken at $\sqrt{s} = 1.8$ TeV with the CDF I detector [2]. The results were interpreted as limits to new physics involving decays of techni-omega states [3], or supersymmetric particles [4]. Recently the D0 Collaboration has measured the cross section of heavy flavor jets and photons [5] using data collected at $\sqrt{s} = 1.96$ TeV. In this paper we exploit the improved CDF II detector to identify $b$ jets by a lifetime based secondary vertex tag, use a larger data set collected at a somewhat higher energy probe, explore lower photon transverse energies, and employ a superior analysis technique where all backgrounds are determined from data.

The CDF II detector is described in detail in [6]. It is composed of a central spectrometer inside a 1.4 T magnetic field, surrounded by electromagnetic and hadronic calorimetry and muon chambers. The inner spectrometer measures charged particle trajectories with a transverse momentum ($p_T$) precision of $\Delta p_T / p_T^2 = 0.07\% (\text{GeV}/c)^{-1}$, and an uncertainty on the transverse impact parameter of about 40 $\mu$m for tracks of $p_T$ above 1 GeV/c, which includes the intrinsic beam size of about 30 $\mu$m. Information from the central tracker can be sent to the hardware tracker silicon vertex tracker (SVT) [7] that compares hits from the tracking detectors with prefitted tracks stored in an associative memory to extract their parameters. An impact parameter resolution less than 50 $\mu$m, including the contribution from the beam, can be obtained in time to be used at the trigger level. Central calorimeters [8] cover the region $|\eta|<1.1$, with an electromagnetic (hadronic) energy resolution of $\sigma(E)/E = 13.5%/\sqrt{E} \oplus 2.0\%$ ($\sigma(E)/E = 50%/\sqrt{E} \oplus 3\%$). The endwall hadronic calorimeter extends this coverage to $|\eta|<1.3$ [9] with an energy resolution of $75%/\sqrt{E} \oplus 4\%$, while the region $1.3<|\eta|<3.6$ is covered by forward calorimeters [10], with hadronic and electromagnetic energy resolutions of $80%/\sqrt{E} \oplus 5\%$ and $16%/\sqrt{E} \oplus 1\%$, respectively.

To distinguish electromagnetic clusters from photons, electrons, and decays of neutral pions, the central electromagnetic calorimeter is equipped with a preshower detector (CPR) in front of the calorimeter to detect early photon conversions in the solenoid coil, and a shower maximum detector (CES) placed inside the calorimeter to measure the shower profile. For each electromagnetic cluster a weight related to its probability of being a photon is given by comparing signals from these detectors to the expected shapes.

We use data obtained by two triggers: one which requires a photonlike object with transverse energy larger than 25 GeV (‘‘high $E_T$ photon’’), and one (‘‘SVT photon’’) which requires a photonlike object with transverse energy larger than 12 GeV, a jet with transverse energy larger than 10 GeV, and a track, measured by the SVT [7], with transverse momentum larger than 2 GeV/c, and an impact parameter larger than 120 $\mu$m.

An integrated luminosity of 340 (208) pb$^{-1}$ of data was analyzed in the high $E_T$ photon (SVT photon) triggered data set.
The high $E_T^\gamma$ photon trigger has an efficiency close to 100% for events with $E_T^\gamma > 28$ GeV, while the SVT photon trigger has an efficiency of $(50 \pm 4\%)$ (estimated from data, in the overlap region with the $E_T^\gamma$ data set), for photons down to 12 GeV.

Selected events must pass at least one of the two photon triggers, contain an isolated central ($|\eta| < 1.1$) photon of $E_T^\gamma > 20$ GeV, and a $b$ jet of $E_T > 20$ GeV within $|\eta| < 1.5$.

Photon candidates must have a calorimeter cluster with hadronic energy fraction smaller than $0.055 + 0.00045 \cdot E_T^\gamma$, where $E_T^\gamma$ is the photon energy. The shower profile must also agree with that expected for an electromagnetic deposit. In order to reduce contamination from neutral mesons, photon candidates must be isolated from nearby calorimeter deposits and tracks. We require that the total transverse energy deposits for clusters in a cone of radius $R = \sqrt{\Delta \phi^2 + \Delta \eta^2} = 0.4$ around the photon candidate are smaller than $2.0 + 0.02(E_T^\gamma - 20)$, and the same quantity for tracks must be smaller than $<2.0 + E_T^\gamma * 0.005$ to ensure isolation in the tracking detectors. Events containing adjacent calorimeter clusters in the CES are rejected.

Jets are reconstructed using the JETCLU algorithm [11] with a cone radius 0.4 (0.7) for events containing photons of $E_T^\gamma < (>)26$ GeV. To recover the true hadronic energy, jets are corrected for instrumental effects [12]. We select events containing at least one jet with $E_T > 20$ GeV, with $\Delta R > 0.7$ to the photon candidate. Jets originating from $b$ hadrons are identified from displaced secondary vertices [13]. The secondary vertex must be more than 2 standard deviations away from the beam position, in the same direction as the jet momentum. At least one $b$ jet must be identified for each event. The efficiency of the $b$-tagging algorithm is 25% for $b$ jets of $E_T = 20$ GeV, increasing to 40% at $E_T = 50$ GeV.

The PYTHIA [14] Monte Carlo code is used to estimate the photon and jet selection efficiencies, using a $Q^2$ scale of the interaction of 225 GeV$^2$, and the CTEQ5L [15] parton distribution functions. A simulation of the underlying event is included [16]. Backgrounds to photons from high energy $\pi^0$'s, decaying to pairs of overlapping photons that cannot be distinguished, were estimated from data, using the signals from the CPR and CES detectors, following the procedure detailed in [17]. The fraction of correctly identified photons in the sample passing those selection criteria increases with $E_T$, going from about 50% at the lower end of the spectrum considered here (20 GeV) to around 80% at high $E_T^\gamma$. Backgrounds to $b$ jets can arise from $c$-quark jets (charm hadrons have a lifetime between a quarter and two-thirds that of $b$ hadrons), and light-quark jets where random combinations of tracks mimic a displaced vertex. The purity of the selected sample is determined from fitting the invariant mass of tracks composing the secondary vertex using Monte Carlo templates of the shapes expected for $b$-, charm ($c$-), and light-quark jets.

Figure 1 shows an example of the fit to the data. Here, about one-third of jets arise from $b$ quarks. This invariant mass is lower than the corresponding hadron mass due to misassigned tracks and unreconstructed neutral hadrons, but template shapes of the different quark jet types are sufficiently different to provide reasonable discriminating power.

To estimate the $b$ purity of the fake photon candidates, we assume that the composition of the tagged jet sample in $\pi^0 +$ tagged jet events is similar to $\pi^\pm +$ tagged jet events, so we use di-jet data. Events are required to contain two jets, one of which must be tagged and have similar transverse energy and pseudorapidity requirements to the $b$ jet, and a second which passes similar kinematic requirements to the photon in our analysis. The fraction of $b$ jets in this sample can be found by fitting the invariant mass at the secondary vertex of the tagged jets. The purity of the selected jets ranges from 50% for jets of $E_T$ around 20 GeV, to about 15% for jets of $E_T$ around 75 GeV, where the rate of light-quark jet tagging increases. This $b$ fraction is then normalized to the estimated number of misidentified photons, and subtracted from the estimated number of $b$ jets in the whole event sample.

Some $10,900$ ($55,800$) events pass the selection criteria in the high transverse energy photon (SVT photon) triggered data sets. Candidate events are divided into bins of photon transverse energy. The numbers of events in each bin are corrected for background, trigger, selection, and acceptance efficiency, and divided by the appropriate integrated luminosity. The results are given in Table I, which also lists the systematic uncertainties detailed later. The statistical uncertainty for the high $E_T^\gamma$ photon data set includes contributions from finite Monte Carlo statistics.
TABLE I. The measured differential cross section for central photon production in association with at least one b jet of $E_T > 20$ GeV, inside $| \eta | < 1.5$, tabulated as a function of the photon transverse energy $E_T^\gamma$. The first column is the energy range of each bin, the second is the measured cross section from data, and the third the prediction from NLO Monte Carlo. In data, the first (second) uncertainty quoted is statistical (systematic). For the Monte Carlo prediction the quoted uncertainty arises from the convolution of scale variation, parton distribution functions, and the numerical integration procedure [1]. Note that the first two measurements are made using the SVT data set, and the remainder with the high $E_T^\gamma$ data set. Systematics about luminosity, the secondary vertex tagging scale factor, and the effect of multiple vertices are correlated between all bins. The uncertainty due to the statistical precision of the SVT trigger efficiency is only fully correlated between the first two bins only. All other uncertainties are uncorrelated between bins.

*The overlap bin, is not used in the final results.

Sources of systematic uncertainty studied are photon identification, jet energy scale, b-jet identification, and luminosity. In the following only the largest contributions will be quantified.

The variables used in photon identification have been validated by comparing data and simulation in $Z \rightarrow e^+e^-$ decays [18], showing good agreement. Uncertainties in the fake photon estimate arise from assumed values of the hit rate in the preshower detector, backscattered showers rate, and the composition of fake photon backgrounds. The associated systematic uncertainty is about 6%.

The uncertainty on the jet energy scale has been studied in detail elsewhere [12] and the findings applied to this analysis. It decreases with increasing jet $E_T$, being about 5% for jets of 35 GeV $E_T$. Uncertainties have also been determined for multiple interactions overlapping in the same event, and the uncertainty on the b-jet scale. Uncertainties in the b-quark purity arise from imperfect modeling of the Monte Carlo template shapes. Differences in shape can arise between the secondary vertex invariant mass of jets containing one or two b quarks, or if track efficiency is incorrectly modeled. For the first effect we fit the data to templates composed of mixtures of single and double quark templates (ranging from 0% to 100%), and the $\chi^2$ of the resulting distributions with respect to the default is computed. We take as a $1-\sigma$ deviation the value for this mixture for which the $\chi^2$ increases by one unit with respect to its minimum, and recalculate the cross section using this mixed template. The systematic uncertainty is the difference between this value and the cross section obtained with the default diquark fraction. This is the largest single source of uncertainty and is about 17%.

Previous studies [19] suggest a difference in tracking efficiency between data and simulation which is a function of isolation, momentum, and position in the detector. We remake the invariant mass templates incorporating the inefficiency derived from data, and take the full difference (5%) as a systematic uncertainty.

Other systematic uncertainties on b-jet identification arise from the difference in tagging efficiency between data and simulation, between single and double b jets, and from $b$ hadron multiplicity. The difference in scale between tagging efficiency in data and simulation was found in [13] to be 0.91 ± 0.06. This results in a 6% uncertainty on the measured cross sections. The uncertainty on tagging efficiency for single and double $b$ jets is determined as the difference between results obtained using the fractions of single and double quark templates corresponding to ±1 standard deviation, as found earlier, and is about 7%. We have adopted the findings of previous studies [19] of the effect of assumed $b$ hadron multiplicity (a 1% effect on the measured cross section). The SVT-based analysis is also affected by the statistical precision of the trigger efficiency determination (about 10%). Finally, the luminosity is subject to a ±6% uncertainty [20].

The cross section for photons produced in association with $b$ jets is tabulated in Table I, separately for the two data sets. There is overlap in the high-$E_T$ range between the two data sets, and due to its greater statistical precision, the inclusive photon one is used in the final results. The measurements are corrected to the hadron level so that they can be directly compared to a next-to-leading order (NLO) calculation [1]. This prediction was derived analytically, using the CTEQ6.6M parton density functions [21], and a renormalization, factorization, and fragmentation scale set to the transverse momentum of the photon. It does not include nonperturbative effects (hadronization and underlying event), and is presented in terms of parton level jets.

The measured cross sections are compared with this prediction in Fig. 2. Also shown are the theoretical uncertainties due to choice of scale and uncertainty in parton density functions. Agreement with next-to-leading order is
In summary, the cross section for photon production in association with $b$ jets has been measured in proton anti-proton collisions at $\sqrt{s} = 1.96$ TeV with the CDF II detector. The measurement has been made for $b$ jets with $E_T > 20$ GeV inside $|\eta| < 1.5$, and for photons of at least $E_T > 20$ GeV inside $|\eta| < 1.1$, including the lowest photon transverse energies probed to date. The results are consistent with next-to-leading order perturbative QCD predictions, using CTEQ6.6M parton density functions, throughout the photon $E_T$ range measured, while leading-order calculations would predict a cross section smaller by about 30%. The level of accuracy of this measurement is therefore already sufficient to discriminate between the first orders of perturbative expansion and favor the most precise NLO predictions.
