Supporting Information Placeholder

ABSTRACT: Molecular catalysts offer tremendous advantages for stereoselective polymerization because their activity and selectivity can be optimized and understood mechanistically using the familiar tools of organometallic chemistry. Yet, this exquisite control over selectivity comes at an operational price that is generally not justifiable for the large-scale manufacture of polyolefins. In this report we identify Co-MFU-4l, prepared by cation exchange in a metal-organic framework, as a solid catalyst for the polymerization of 1,3-butadiene with high stereoselectivity (>99% 1,4-cis). To our knowledge, this is the highest stereoselectivity achieved with a heterogeneous catalyst for this transformation. The polymer's low polydispersity (PDI ~2) and the catalyst's ready recovery and low leaching indicate that our material is a structurally resilient single-site heterogeneous catalyst. Further characterization of Co-MFU-4l by X-ray absorption spectroscopy provided evidence for discrete, tris-pyrazolylborate-like coordination of Co(II). With this information, we identify a soluble cobalt complex that mimics the structure and reactivity of Co-MFU-4l, thus providing a well-defined platform for studying the catalytic mechanism in the solution phase. This work underscores the capacity for small-molecule like tunability and mechanistic tractability available to transition metal catalysis in metal-organic frameworks.

INTRODUCTION

The development of single-site heterogeneous catalysts promises great improvements in selectivity and efficiency for large-scale chemical processes. In particular, the industrial polymerization of olefins continues to largely rely on solid catalysts for continuous throughput and efficient separation on a large scale. Yet, conventional solid supports for polymerization are structurally inhomogeneous, which limits opportunities for catalyst design and optimization. By contrast, molecular polymerization catalysts are often capable of much finer catalytic selectivity. The utility of molecular catalysts is highlighted in the production of highly stereoregular polymers, which feature improved mechanical properties. Because stereoselective polymerization relies on small differences in transition state energies as the basis for kinetic selectivity, it is highly sensitive to variations in a catalyst’s steric and electronic environment. Consequently, soluble transition metal complexes with discrete and well-defined coordination structures have played a major role in the development of stereodefined polymers. Although stereoselective heterogeneous catalysts have been commercialized for a few polymers such as isotactic polypropylene, solid catalysts do not usually provide a sufficient degree of control.

Among stereodefined polymers, those of conjugated dienes represent one of the largest and most structurally diverse categories. These polymers offer both a commercially significant target and an important proving ground for new strategies in single-site heterogeneous catalysis. As a prototypical diene monomer, 1,3-butadiene inserts with either 1,2- or 1,4-regiochemistry; the 1,4-units have either cis- or trans-geometry (Figure 1). The configuration and stereopurity of polybutadienes define both their mechanical properties and their commercial applications. For instance, polymers featuring primarily 1,4-trans units are thermoplastics, whereas those featuring primarily 1,4-cis units are elastomers. The latter are desirable in high stereopurity (>98%) because they exhibit improved wear resistance and impact resilience. Interest in these high-performance elastomers has created a demand for catalysts with high stereoselectivity and molecular weight control (PDI ~2), typically achieved only by homogeneous catalysts. Transferring the high selectivity of these catalysts into the solid state remains challenging because insoluble metal halide-based precatalysts show a strong tendency to form soluble active catalysts in the presence of diene and alkylaluminum cocatalysts. Although more robust surface immobilization techniques have been proposed to address this challenge, none of these catalysts preserve the low PDI and high 1,4-cis selectivity of their soluble counterparts.
Because of their monodisperse and well-defined transition metal coordination environments, porous metal-organic frameworks (MOFs) offer unique opportunities for single-site heterogeneous catalysis. The inorganic nodes, or secondary building units (SBUs), are particularly attractive targets as site-isolated platforms for small-molecule like transition metal catalysis in a high surface area solid support. Many SBUs are capable of cation exchange, which occurs with preservation of local coordination structure and offers a predictable strategy to incorporate transition metals in a desired coordination geometry, an important design feature for organometallic catalysis.

Commercial stereoselective polymerization of 1,3-butadiene:

This study: Stereoselective diene polymerization in MOFs

Co-MFU-4\(l\) (1): a single-site heterogeneous catalyst

Figure 1. Design plan for stereoselective polymerization of 1,3-butadiene with a solid catalyst.

To address the challenge of designing a heterogeneous stereoselective butadiene polymerization catalyst, we were inspired by molecular cyclopentadienyl (Cp) catalysts. Based on the established isolobal analogy between Cp and tris-pyrazolylborate (Tp) complexes, we reasoned that the material known as MFU-4\(l\) (Zn\(5\)Cl\(4\)(BTDD)\(_3\)), H\(_2\)BTDD = bis(H-1,2,3-triazolo[4,5-b],[4',5'-i]dibenzo[1,4]dioxin), which features exchangeable Zn\(^{2+}\) cations in a Tp-like coordination environment would serve as an excellent support for addressing this challenge (Figure 1). Through this approach, we identified Co-MFU-4\(l\) (1) as a highly selective catalyst for the 1,4-cis-polymerization (>99 %) of 1,3-butadiene. To our knowledge, this stereoselectivity is the highest reported for 1,3-butadiene polymerization with a heterogeneous catalyst. We further present evidence for the single-site structure of 1 as well as a molecular model for interrogating the mechanistic basis for cis-selectivity in this catalyst.

RESULTS AND DISCUSSION

Stereoselective catalysis often relies upon systematic variation as a means to optimize small differences in activation energy, which can be difficult to anticipate a priori but nevertheless underlie significant differences in stereoselectivity. In analogy to metalloligand-based catalysis, cation exchange provides a unique opportunity to compare the reactivity of a range of transition metal cations with equivalent coordination geometry in the solid state. By contrast, conventional heterogeneous supports do not show equivalent support-catalyst interaction across a broad range of transition metals, highlighting the advantage that the well-defined, modular structure of MOFs hold for heterogeneous catalyst design.

Given the variety of transition metals used for stereoselective diene polymerization in Cp complexes, we initiated our catalyst development by evaluating a variety of 3d metals. Thus, MFU-4\(l\) samples exchanged with Ti, Cr, Fe, Co, and Ni\(^{10}\) were treated with 1,3-butadiene and modified methylaluminoxane-12 (MAAO-12) under semi-batch conditions. The results evidenced considerable variation in activity and selectivity based on both the choice of transition metal and its oxidation state (Table 1). In all cases, the exchanged transition metals were responsible for catalysis, the all-zinc MFU-4\(l\) parent MOF showing no background reactivity for this reaction. Surprisingly, the metal-exchanged MFU-4\(l\) catalysts previously reported to be most active for ethylene polymerization (i.e. Ti-, Cr-exchanged MFU-4\(l\))\(^{12}\) were found to be least effective for 1,3-butadiene polymerization (Table 1, entries 2–5, 8). Thus, although Ti(IV)-MFU-4\(l\) showed promising activity for 1,3-butadiene polymerization, the resulting polymer is predominantly trans and exhibits modest stereoregularity (Table 1, entry 2). This observation contrasts with the well documented 1,4-cis selectivity of CpTiCl\(_3\), underscoring the somewhat empirical nature of stereoselective catalysis. MFU-4\(l\) samples exchanged with late transition metals show contrasting reactivity with both olefins and dienes: whereas Fe(II)-MFU-4\(l\) is unreactive towards ethylene and produces polybutadiene with only modest stereoselectivity (68% 1,4-cis), Ni(II)-MFU-4\(l\) is a selective ethylene dimerization catalyst\(^{18}\) and a very active 1,3-butadiene polymerization catalyst, providing a polymer with promising stereoselectivity (96% 1,4-cis). However, Co(II)-MFU-4\(l\) (1) provides polybutadiene with the highest stereoselectivity, greater than 99% 1,4-cis content (Table 1, entry 7).

This selectivity is exceptional among heterogeneous catalysts and is relevant for high-performance elastomer applications, prompting a more in-depth study of the nature of the Co site in this catalyst.

Firstly, in order to determine the kinetic nature of our catalyst, the polymer’s molecular weight distribution was examined by gel permeation chromatography (GPC, section S4.1). For the Table 1. Evaluation of transition metal and activator for the heterogeneous polymerization of 1,3-butadiene.

Figure 4. Evaluating cocatalyst loading. Data points are from two-hour reactions performed at 21 °C.

polymers produced by both Ni(II)- and Co(II)-MFU-4l (1), the number-average molecular weights ($M_\text{n}$) were high, significant for elastomer applications, while the polydispersity index (PDI) was low, indicative of single-site activity. By both metrics, 1 displayed superior selectivity; while Ni(II)-MFU-4l provided a polymer with $M_\text{n} = 71,000 and
PDI = 2.12, that of Co(II)-MFU-4 displayed $M_N = 200,000$ and PDI = 1.26.

To further substantiate the single-site activity in 1, we evaluated the integrity of the catalyst under conditions relevant to polymerization. After treatment with MMAO-12 for 7 hours the powder X-ray diffraction (PXRD) pattern of 1 did not change noticeably, suggesting that the crystallinity of the material was preserved. Likewise, PXRD analysis indicated minimal decomposition for samples of 1 recovered after polymerization at 21 °C (Figure 2A) and at 60 °C (Figure S3.2). Moreover, scanning electron microscopy (SEM) analysis demonstrated that the block-shaped crystallite morphology of pristine 1 is retained in the recovered catalyst (Figure 2B and 2C). The lack of particle fracturing or surface restructuring suggests that polymerization largely takes place at or near the surface of the MOF particles.

To assess the heterogeneity of our catalyst system under reaction conditions, we evaluated possible leaching of soluble catalytically competent Co(II) species. Thus, the filtrate obtained by catalyst recovery after one hour of polymerization was treated with supplemental monomer. Negligible polymerization in the presence of this filtrate solution provides evidence against leaching of a soluble active catalyst (Figure S5.1). Indeed, elemental analysis of this filtrate solution confirmed low cobalt concentration corresponding to less than 1% leaching.

Having shown that 1 and MMAO-12 provide a highly stereoselective heterogeneous catalyst for 1,3-butadiene polymerization, we sought to further optimize its activity by systematically changing the nature of the cocatalyst and the reaction temperature. Among the various alkylaluminum cocatalysts explored in Table 1, MMAO-12 provides the best yield and stereoselectivity (entry 9). Although similar in activity, diethylaluminum chloride leads to a considerable reduction in stereoselectivity (entry 10). Trialkylaluminum reagents yielded the lowest reactivity (entries 11-13), likely due to reductive deactivation of 1, which occurs faster for Co(II) polymerization catalysts in combination with trialkylaluminum reagents than with methylaluminoxane.

Time and temperature studies showed that at 40 °C the catalyst is active for two hours, after which the yield remains constant even upon addition of excess monomer (Figure 3A). In contrast, $M_N$ levels off at ~700,000 g/mol after only one hour. Together, these data suggest that the polymerization occurs with rapid chain transfer and is therefore not likely to be a living polymerization, except possibly at short reaction times and reduced temperature. This is in line with what is observed for homogeneous transition metal catalysts for this reaction; living polymerization in this system is more characteristic of main group catalysts. Importantly, 1 exhibits good thermal stability: its catalytic activity increases with temperature up to 65 °C (Figure 3B), albeit at the expense of a slight reduction in stereoselectivity, which decreases to >96% at elevated temperatures. Stereoselectivity is optimized at low temperature and reaches 99.4% 1,4-cis at 0 °C.

Initial mechanistic insight into the activity of 1 came from systematic investigations of the Al:Co ratio. Thus, at constant loading of Co in 1, the activity correlated positively with increasing Al:Co ratio (Figure 4). In contrast, increasing the Co loading while keeping the Al:Co ratio constant had little effect on the overall turnover frequency or selectivity (Table S4.2). $M_N$ did not depend on the Al:Co ratio, remaining generally high (~700,000 g/mol). Together, these results indicate that MMAO-12 does not play a kinetically significant role in chain transfer. Nevertheless, both $M_N$ and turnover frequency have a first-order dependence on monomer concentration (Figure S6.37). This concentration effect represents a handle for molecular weight control and provides evidence for a unimolecular chain transfer or termination. By contrast, a weak or inverse dependence of $M_N$ on monomer concent-
tation would be expected in the case of chain transfer to monomer, observed for ethylene polymerization with Cr- and Ti-MFU-4l and for ethylene dimerization with Ni-MFU-4l. As a plausible explanation, we propose chain transfer by hydride elimination followed by monomer insertion, drawing a parallel with the reported behavior of single-site Ni(II) catalysts for 1,4-cis-selective polymerization.22

To elucidate the origin of stereoselectivity in 1, we took inspiration from mechanistic studies on single-site molecular catalysts. These reports have established the role of olefin back coordination and the stereospecific insertion of dienes to form η3-allyl intermediates (steps 6 and 5, respectively, in Scheme 1).3 In analogy to this work, we propose a mechanism for the 1,4-cis-selective polymerization with 1: alkylation of a cobalt site by MMAO-12 generates an allyl cobalt intermediate (3).34 Direct insertion of 1,3-butadiene forms η3-allyl complex 4, initiating the catalytic cycle. Stereospecific insertion of 1,3-butadiene through transition state 5 would provide an anti-η3-allyl 6, whose configuration gives rise to the cis-geometry of the resulting olefin. Continued insertion of butadiene would lead to chain growth, while chain transfer at this stage would furnish the 1,4-cis polymer. In contrast, isomerization of 6 to the syn-η3-allyl 7 would provide a trans-unit in the growing polymer. Consistent with this slow equilibrium, reduced monomer concentration leads to increased 1,4-trans content, which nevertheless remains low overall (Figure S6.38). Back-coordination of the previously inserted monomer unit would presumably stabilize intermediates such as 6 toward this isomerization, a unimolecular process that competes with bimolecular insertion.

Table 2. Fitting Results of the EXAFS Spectra. The average error in bond length is 0.02 Å and in σ2 is 0.003 Å². The fitting ranges for Tp2Co and Co-MFU-4l are Δk = 3.0–11.0 Å⁻¹ and ΔR = 1.0–2.0 Å. For CoCl2, the ranges are Δk = 3.2–10.6 Å⁻¹ and ΔR = 1.3–2.4 Å.

To evaluate the proposed mechanism in 1, we first sought to characterize the structure of our catalyst and the key reactive intermediates. First, the structure of precatalyst 1 was confirmed by X-ray absorption spectroscopy (XAS) in conjunction with an optimized structure under the Kohn-Sham density functional theory (DFT) construct. Consistent with the proposed Co2+ oxidation state, 1 displayed a Co K-edge energy similar to those of two Co2+ standards: Tp2Co and anhydrous CoCl2 (Table S1.1). Precatalyst 1 also exhibits a higher intensity pre-edge feature than the two standards, consistent with the lower symmetry pseudotetrahedral coordination environment of Co observed in the DFT-optimized structure of 1 (DFT-1, Figure 5). Fitting the X-ray absorption fine structure (EXAFS) data resulted in three N–Co (2.02 Å) and one Cl–Co (2.15 Å) bonds (Table 2). These bond lengths are in excellent agreement with those of DFT-1 (1.915 and 2.134 Å respectively). Moreover, all models with different coordination numbers or choice of scattering pairs provided quantitatively worse fits. Together with the kinetic observations, these data provide good evidence for the discrete, single-site structure of precatalyst 1.

We sought to examine the mechanistic basis for stereoselectivity and single-site reactivity in 1 with an analogous molecular complex, an attractive strategy for overcoming the inherent difficulty of characterizing reaction intermediates in the solid state that nevertheless suffers from the lack of reliable models for typical heterogeneous catalysts. By contrast, the single-site structure of 1 provided an excellent opportunity for structural modeling with Tp complexes. Although simple Tp ligands tend to form homoleptic complexes with Co(II) (e.g. Tp2Co3), we identified pyrazole-substituted Tp2CoCl (Tp2CoCl, Tp2Mes = HB(3-mesityl-1-pyrazolyl)3) as a close structural analogue accessible by metal metathesis with Tp2MesTl.26 Indeed, X-ray diffraction analysis of a single crystal of 9 indicated a primary coordination sphere nearly identical to that of DFT-1, with bond distances (Co–N = 2.032(2) Å; Co–Cl = 2.175(9) Å) that also agreed with those fit from the EXAFS analysis of 1.

The close structural homology between 9 and 1 suggested that the former would serve as an excellent molecular model for investigating the stereoinduction in 1,3-butadiene polymerization with 1 (Scheme 1). Toward this end, we chose symmetrical allyl complex 10, available by treating 9 with allylmagnesium bromide, as a stable, crystallizable model for proposed intermediates such as 4. Single-crystal diffraction analysis of 10 (Figure 6) showed near-symmetric η3-coordination of the allyl group, as would be required for the stereodefined diene insertion proposed in our mechanism (transition state 5 in Scheme 1). Notably, the crystal structure of 10 reveals a clear open coordination site at Co, as would be required for direct insertion into an η1-allyl or for olefin back coordination, the mechanistic bases for cis-selectivity in the proposed mechanism.

Finally, the validity of molecular complexes 9 and 10 as mechanistic models for 1 was verified by subjecting 1, 9, and 10 to analogous polymerization conditions (Table S4.6). All three precatalysts provided polymers with >98% 1,4-cis selectivity. This reinforces the concept that the proposed SBU-based reactivity is consistent with the close
correspondence in molecular selectivity between 1 and 9, with the 17-fold increase in activity for 9 versus 1 suggesting an increase in substrate accessibility in the solution phase.

CONCLUSION

We have shown that 1 is a robust heterogeneous single-site catalyst for 1,3-butadiene polymerization, whose mechanism of stereoinduction can be understood in fine detail by small molecule analogy. Both the control over the local structure of the catalyst and its stereoselectivity (>99% 1,4-cis) are exceptional among solid catalysts for olefin polymerization and highlight the utility of MOFs beyond reactions typically studied with these catalysts. Indeed, the results herein stand out among all heterogeneous catalysts and should stimulate interest for the manufacture of advanced polyolefins using heterogeneous catalysis.
