We study the quantum nonlinear Hall effect in two-dimensional (2D) materials with time-reversal symmetry. When only one mirror line exists, a transverse charge current occurs in the second-order response to an external electric field, as a result of the Berry curvature dipole in momentum space. Candidate 2D materials to observe this effect are two-dimensional transition metal dichalcogenides (TMDCs). First, we use an ab initio based tight-binding approach to demonstrate that monolayer Td-structure TMDCs exhibit a finite Berry curvature dipole. In the 1H and 1T′ phase of TMDCs, we show the emergence of a finite Berry curvature dipole with the application of strain and an electrical displacement field, respectively.

DOI: 10.1103/PhysRevB.98.121109

Transition metal dichalcogenides (TMDCs) [1–4] have lately attracted considerable attention because of their rich physics, such as charge density waves [5–7], a superconducting phase [8], two-dimensional (2D) quantum spin Hall (QSH) states [9–13], and Weyl semimetal states [14], among other phenomena. Recently, numerous studies have demonstrated new physical properties in a monolayer (ML) of TMDCs that may be different from those in the bulk. For example, molybdenum disulfide (MoS2) exhibits an induced indirect-to-direct band-gap transition from a 2H structure to its ML 1H structure, together with an enhancement of the luminescence quantum yield in comparison with the MoS2 bulk [15,16]. The 1H structure which does not possess a center of inversion, in contrast to the 2H structure, allows optical control of the valley degrees of freedom [17].

Generally, the electronic properties of monolayer TMDCs with a chemical composition MX2 (M = Mo, W and X = S, Se, Te) are directly related to their crystal structure, which includes the 1H (P62m), 1T (P3m1), 1T′ (P21/m), and Td (P1m1) crystal structures, shown in Fig. 1. 1H-MX2 is a semiconductor with a direct band gap in the range of visible light (1–2 eV) [1,18,19] and the 1T structure is metallic [20]. Topological phases occur in 1T′ structures since the global properties of electronic wave functions exhibit a nontrivial topology, theoretically predicted [9] and experimentally confirmed [10–13] to be a 2D quantum spin Hall state.

The local curvature of the wave function, defined as the Berry curvature (BC) [21,22], is a geometrical property of the Bloch energy band. The finite Berry curvature reveals a linear response, such as anomalous Hall conductivity [21], and a nonlinear response, such as the circular photogalvanic effect (CPGE) and the nonlinear Hall effect [23–34]. In TMDCs, the BC at the two valleys takes opposite values, giving rise to bulk topological charge neutral valley current [35–37], as a linear response. For a nonlinear response, the semiclassical approach has been used to describe the intraband contributions to transverse current at both zero frequency and second harmonic generation in terms of the dipole moment of the BC in momentum space [26]. In the dc limit, the photocurrent can remain finite as a transverse Hall-like current [26,32].

In this Rapid Communication, we study the emergence of the nonlinear Hall current induced by the BC dipole in various 2D TMDC structures, using ab initio calculations combined with a semiclassical approach. Monolayer TMDCs with low crystalline symmetry are expected to be excellent candidates for observing these quantum nonlinear effects [26]. Our study quantitatively reveals the finite BC dipole in the Td-structure monolayer TMDCs, where only one mirror line survives. For the 1H structure, uniaxial strain can break the underlying C3v symmetry which otherwise ensures a vanishing nonlinear response. In addition, we evaluate the Berry dipole of strained TMDC. Lastly, we show that application of an out-of-plane electrical displacement field induces a strong BC dipole which is absent in 1T′ monolayer TMDCs. Our results represent a numerical demonstration of nonlinear current in 2D TMDCs, which can be controlled by mechanical and/or electrical means. The proposed strategies of a tunable BC dipole also apply to a wide range of other two-dimensional materials, such as hexagonal boron nitride [38] and black phosphorus [39–41].

In the presence of an external electric field, the carrier velocity contains contributions from the group velocity of the electron wave and from the anomalous transverse term due to the BC, given by \(-\frac{e}{h} \mathbf{E} \times \mathbf{\Omega}^{\text{BC}}(\mathbf{k})\). Here, the BC for the electronic Bloch states of the nth band is defined

for a time-reversal-invariant system, since states at that transition metal dichalcogenides symmetry involves a 180◦ rotation about \( \hat{z} \), which prevents the inversion symmetry for the 1

The red solid line represents a screw rotate symmetry \( \hat{C}_{2z} \), axis which involves a 180◦ rotation about \( \hat{z} \) and a half lattice-constant translation along \( \hat{x} \). The dashed-dotted line represents the mirror symmetry \( M_x \). The combination of \( \hat{C}_{2z} \) and \( M_x \) symmetries leads to the inversion symmetry for the 1

The Hamiltonian \( \hat{H}_k \) and \( \hat{M}_x \) are eigenvalues and eigenfunctions of the Hamiltonian \( \hat{H}_k \), respectively, at the momentum \( \mathbf{k} \).

Within linear response theory, the integral of the BC over the entire Brillouin zone gives rise to a transverse conductivity, which is simply given by \( \sigma_{xy,n} = e^2/\hbar \int d^2 k f_0^{(n)}(\mathbf{k}) \Omega_x^{(n)}(\mathbf{k}) \), where \( f_0^{(n)}(\mathbf{k}) \) is the equilibrium Fermi-Dirac distribution function for the \( n \)-th band. The transverse conductivity is zero for a time-reversal-invariant system, since states at \( \mathbf{k} \) and \( -\mathbf{k} \) are equally occupied and time-reversal symmetry requires that \( \Omega_x^{(n)}(\mathbf{k}) = -\Omega_x^{(n)}(-\mathbf{k}) \). When the system is driven out of equilibrium, a net transverse current can survive as the second-order response to the electric field. The combination of time-reversal (TR) and inversion symmetry restricts \( \Omega_x^{(n)}(\mathbf{k}) = 0 \) over the entire Brillouin zone. Thus, for a TR-invariant system, inversion symmetry breaking is necessary to generate a finite BC.

We first examine the nature of the nonlinear current with a symmetry analysis. In the presence of a driving in-plane electric field, \( E_{k} = \text{Re}[\mathbf{E}_{k} e^{i\omega t}] \), the nonlinear current is written as \( j_i = j_i^{(0)} + j_i^{(2\omega)} e^{i2\omega t} \), where the dc and second harmonic generated currents are described by the second-order susceptibility tensor as \( j_i^{(0)} = \chi_{ijk} \mathbf{E}_{k,3} \mathbf{E}_{k,3} \) and \( j_i^{(2\omega)} = \chi_{ijk} \mathbf{E}_{k,3} \mathbf{E}_{k,3} \), respectively. The tensor indices \( i, j, k \) span the 2D sample coordinates \( x, y \). \( \chi_{ijk} \) respects the symmetry of the crystal lattice. The presence of \( M_x \) mirror symmetry forces \( \chi_{ijk} \) to be zero if any \( \chi_{ijk} \) contains an odd number of the index \( x \). All tensor components identically vanish in the presence of inversion symmetry. Thus, for a crystal breaking inversion but preserving the mirror symmetry \( M_x, \chi_{xyx} \neq 0 \), demonstrating that a Hall-like transverse current can occur in a second-order response to an external electric field \( \mathbf{E}_{k} \).

The expression of nonlinear currents has been theoretically obtained within the semiclassical Boltzmann transport theory for a single band [25,26]. Up to second order in the driving electric field, previous theoretical works showed that in the case involving only the intraband process, a nonlinear Hall-like current density is expressed as

\[
\begin{align*}
\mathbf{j}^{(0)} &= \frac{e^3 \tau}{2\hbar^2(1 + i\omega \tau)} \mathbf{\hat{z}} \times \mathbf{\hat{E}}^*(\mathbf{D} \cdot \mathbf{\hat{E}}), \quad (3) \\
\mathbf{j}^{(2\omega)} &= \frac{e^3 \tau}{2\hbar^2(1 + i\omega \tau)} \mathbf{\hat{z}} \times \mathbf{\hat{E}}(\mathbf{D} \cdot \mathbf{\hat{E}}), \quad (4)
\end{align*}
\]

with

\[
D_i = \sum_n \int d^2 k f_0^{(n)}(\mathbf{k}) \left[ \partial_k \Omega_x^{(n)}(\mathbf{k}) \right]
\]

\[
= - \sum_n \int d^2 k [\partial_k f_0^{(n)}(\mathbf{k})] \Omega_x^{(n)}(\mathbf{k}), \quad (5)
\]

where \( \tau \) is the relaxation time. The nonlinear dc current is proportional to the dipole moment of the BC over the occupied states. In fact, according to Eq. (5), the nonlinearity of these currents is associated with a “Fermi-surface” contribution, that is, only states near the Fermi surface can contribute to the integral in the low-temperature limit. The largest symmetry of a 2D crystal that allows for a nonvanishing BC dipole is a single mirror line [26]. Combining Eq. (5) with the fact that \( \Omega_x^{(n)}(k_x, k_y) = -\Omega_x^{(n)}(-k_x, k_y) \) enforced by the mirror plane \( M_x \), it is evident that \( D_x \neq 0 \) and \( D_y = 0 \). In what follows, we obtain \( D_x \) and \( D_y \), in units of Å. Consequently, according to Eqs. (3) and (4), when the driving electric field \( \mathbf{E}_k(t) = \mathbf{\hat{E}}_k \) is aligned with the direction of the Berry curvature dipole vector \( \mathbf{\hat{D}}_x \), we obtain the dc current density

\[
\mathbf{j}^{(0)} = 3698.1 \, (\text{A/m}^2) \times \mathbf{D}_x \sim 10^{-7} \, \text{(A/m)},
\]

where we choose \( \tau = 10^{-12} \, \text{s} \), \( \mathbf{D}_x = 1 \, \text{Å} \), and \( \mathbf{\hat{E}}_k = 100 \, \text{V/m} \).

The BC dipole is tied to the underlying crystal structure of monolayer TMDC. The most studied polymorphic structures of pristine monolayer TMDCs are 1\( H \), 1\( T \), and 1\( T' \) [44,45], shown in Fig. 1. The energetically favorable 1\( H \)-MX\(_2\) layer is built from two hexagonal lattices of \( X \) atoms and an intercalated hexagonal plane of \( M \) atoms forming a simple \( ABA \) Bernal stacking with \( P6m2 \) space-group symmetry. In a monolayer unit of \( H \) structure, the inversion symmetry is explicitly broken. The lack of an inversion center in TMDCs produces substantial local BCs near the \( K, K' \) valleys. Due to time-reversal symmetry, the curvature at the two valleys has
opposite sign, which implies counterpropagating currents that persist even when the system is in equilibrium. Due to exact cancellation from the two valleys, these transverse currents are charge neutral to a linear response in an applied external electric field. The nonlinear contribution could still exist when the samples have just one mirror symmetry. The 2D materials such as monolayer TMDCs in the $H$ structure do not have currents in a nonlinear response to the electric field because their $C_{3v}$ symmetry forces the BC dipole to vanish.

The $1T'-M\bar{X}_2$ layer forms a rhombohedral $ABC$ stacking phase with $P\bar{3}m2$ space group. In this structure, the transition metal atoms are octahedrally coordinated. Density functional theory (DFT) calculations show that the free-standing 1 atom forms one-dimensional (1D) zigzag chains [46], referred to as the $T'$ structure. Inversion symmetry is present in both the $T$ and $T'$ structure. The inversion-symmetric $1T'$ structure consists of two independent symmetries, the mirror symmetry $M_i$ and the twofold screw rotational symmetry $C_{2x}$. Due to the inversion symmetry and time-reversal symmetry, $\Omega^{(0)}(\vec{k}) = 0$ over the entire Brillouin zone for the $1T'$ structure.

A candidate material to observe the quantum nonlinear Hall effect is monolayer WTe$_2$, whose structure $T_d$ deviates slightly from the widely studied $1T'$ structure. In the $T_d$ phase, the $M_x$ mirror symmetry is preserved but the $C_{2x}$ symmetry is weakly broken. As a result, the $T_d$ structure with symmetry space group $P\bar{1}m1$ actually breaks inversion symmetry and allows a nonzero BC dipole to exist. We perform $ab$ initio DFT calculations using the Vienna $ab$ initio simulation package (VASP) [47,48] with a minimal basis based on a transformation of the Kohn-Sham density functional theory Hamiltonian to a basis of maximally localized Wannier functions [49] as implemented in the WANNIER90 code. A slab geometry is employed to model single or double layers with a 20-Å vacuum region between periodic images to minimize the interaction between slabs. For TMDC materials, the relevant states consist of seven valence bands and four conduction bands, which are hybrids of metal $d$ orbitals and chalcogen $p$ orbitals. Therefore, the Wannier projections to the $p/d$ orbitals provide us the $ab$ initio tight-binding Hamiltonian for computing the BC dipole [50,51].

In Fig. 2 we shows that the ML WTe$_2$ with spin-orbit coupling (SOC) exhibits a finite BC dipole. The SOC leads to an inverted, indirect quantum spin Hall gap. In the DFT calculation, we used the Heyd-Scuseria-Ernzerhof (HSE) method [52] with the hybrid parameter set at HSE = 0.4, which gives a global band gap of 50 meV. In the vicinity of the gap minimum, the BC for the lowest conduction band exhibits two hot spots of opposite sign, as shown in Fig. 2(c). Such a bipolar configuration of BC is due to the $M_x$ symmetry. It is worth noting that the distribution of BC near each hot spot is not uniform, leading to a nonzero BC dipole. To better understand the physics, we rewrite Eq. (5) as

$$ D_{\gamma} = \sum_n \int d^2k \delta(\epsilon_{\gamma}^{(n)} - \varepsilon_F)[\partial_{\vec{r}} \epsilon_{\gamma}^{(n)}] \Omega_n^0(\vec{k}), $$

where $\varepsilon_F$ is the Fermi energy and $\partial_{\vec{r}} \epsilon_{\gamma}^{(n)}$ is associated with the velocity along the $x$ direction. Let us first consider the case of one Dirac cone (one hot spot). If the BC is constant and the velocity is equal but opposite around a perfect Dirac cone, the BC dipole will vanish. However, for a tilted Dirac cone which has anisotropic BC and velocity around $E_F$, a finite BC dipole is allowed. In Fig. 2(c), the red (blue) hot spot shows more intense positive (negative) BC in the left (right) part of the Dirac cone, where the velocity is negative (positive) along the $x$ direction, leading to a negative BC dipole. For the highest valence band, the slope is negative along $\Gamma$ to $X$, as shown in Fig. 2(a). Thus, the configuration of BC in Fig. 2(d) gives a positive BC dipole.

The $H$-structure monolayer TMDCs do not have nonlinear currents due to their $C_{3v}$ symmetry, but applying uniaxial strain can reduce this symmetry, leaving only a single mirror operation, in which case the quantum nonlinear Hall effect can be observed [26]. The application of strain transforms the vector $\vec{r}_0$, which denotes an undistorted crystal coordinate, into the new position $\vec{r} = \vec{r}_0 + \vec{u}$, where $\vec{r}_0 = (x, y)$ and $\vec{u} = [u_x(x, y), u_y(x, y)]$ are the position and displacement deformation vector fields, respectively. Here, we are con-
considering only the acoustic part of the in-plane displacement vector. In general, the derivative of $\tilde{u}$ can be decomposed as

$$\tilde{u} = \varepsilon + \omega,$$

where $\varepsilon$ and $\omega$ are the strain and rotation tensors, respectively. The simplest way to incorporate the effect of strain is to vary the interatomic bond lengths $|\delta_{\alpha\beta}|$ between the $\alpha$ and $\beta$ sites, which is known as the central force approximation. At the linear order and under this approximation, the modified hopping terms in the presence of strain can be approximated as

$$t_{\alpha\beta} = t_{\alpha\beta}^{(0)} + \mu \delta_{\alpha\beta} \cdot (\tilde{\delta}_{\alpha\beta} \cdot \tilde{\nabla}) \tilde{u} + \frac{1}{|\delta_{\alpha\beta}|} \left[ \frac{dt_{\alpha\beta}}{d|\delta_{\alpha\beta}|} \right].$$

The central force approximation fails to capture the change in the hopping when the crystal is stretched along a direction perpendicular to the bond. The microscopic models based on the $ab$ initio derived Wannier functions describe up to linear order contributions in the strain ($u_{xx} + u_{yy}$), ($u_{xx} - u_{yy}$), and $u_{xy}$ with respect to the crystal symmetry and local crystal configuration, free from any empirical fitting procedures.

Based on the models of strained TMDCs [53], the BC dipole can be readily evaluated. Figure 3 shows that the $H$-structure WSe$_2$ with strain exhibits the BC dipole. The Brillouin zone of monolayer TMDC with Dirac points is shifted away from the $K$ and $K'$ by uniaxial strain. When the shear strain is applied along high-symmetry lines, one obtains finite $D_z$ but zero $D_x$.

The application of an out-of-plane electrical displacement field can be used to systematically control the magnitude of the nonlinear Hall current. This can be understood from a third-order susceptibility tensor $\chi^{(3)}_{ijj}$. In the presence of a static electrical displacement field $\varepsilon_{d,z}$ along the $z$ direction, the nonlinear dc current is written as

$$i_i = \chi^{(2)}_{ijj} |\varepsilon_j|^2 + \chi^{(3)}_{ijj} |\varepsilon_j|^3 \varepsilon_{d,z}.$$  

We obtain the effective second-order tensor containing the electrical displacement field effect as $\chi^{(2)}_{ijj} = \chi_{ijj}^{(2)} + \chi_{ijj}^{(3)} \varepsilon_{d,z}$. We choose $\chi^{(3)}_{ijj} = 0$ due to the intrinsic inversion symmetry, $\varepsilon_{d,z}$ makes it possible to produce the second response with a significant amplitude.

Finally, we consider the basic symmetry properties of the Hamiltonian for the TMDC family of materials in the presence of $\varepsilon_{d,z}$. The $1T'$ phase has inversion symmetry from the combination of twofold screw rotational symmetry $C_{2x}$ and the mirror symmetry $M_x$. Therefore the monolayer $1T'$ structure, which has zero BC dipole, can acquire a nonzero dipole if $\varepsilon_{d,z}$ is applied to break the $C_{2x}$ symmetry and thus inversion symmetry. This inversion symmetry-breaking scheme can be simply modeled with only an electrostatic on-site potential within each unit cell. We show the monolayer MoTe$_2$ with $1T'$ structure as a function of the electrical displacement $\tilde{\varepsilon}$ field in the $z$ direction which breaks the inversion symmetry. $D_z = 0$ in all cases.

In conclusion, we discussed the nonlinear current induced by the BC dipole in 2D materials of the TMDC family. The existence of only a single mirror symmetry line is needed to provide a finite BC dipole. Breaking of the crystal symmetry can be controlled by mechanical and/or electrical means.
Certainly, it would be desirable to explore if the proposed effect could be observed in other 2D materials subject to the same symmetry constraints. Such a tunable BC dipole can not only lead to the quantum nonlinear Hall effect but could also be relevant for the understanding of other quantum geometrical phenomena.

Note added. Recently, we became aware of an independent work by Zhang et al. [54] which also shows the nonlinear electric response in MoTe$_2$ and WTe$_2$ monolayers.

We thank Inti Sodemann, Qiong Ma, Bertrand I. Halperin, Philip Kim, and Jeroen van den Brink for useful discussions. J.-S.Y. thanks Ulrike Nitzsche for technical assistance. This work was supported by the STC Center for Integrated Quantum Materials, NSF Grant No. DMR-1231319 and by ARO MURI Award No. W911NF-14-0247. The computations in this work were run on the Odyssey cluster supported by the FAS Division of Science, Research Computing Group at Harvard University.

[51] Based on the tight-binding Hamiltonian, the BC is computed in the discretized Brillouin zone [50]. For the BC dipole, we sample the first Brillouin zone more than $500 \times 500k$ grids.
