(Received 3 January 2009; published 18 May 2009)

We demonstrate a fiber-optical switch that is activated at tiny energies corresponding to a few hundred optical photons per pulse. This is achieved by simultaneously confining both photons and a small laser-cooled ensemble of atoms inside the microscopic hollow core of a single-mode photonic-crystal fiber and using quantum optical techniques for generating slow light propagation and large nonlinear interaction between light beams.

DOI: 10.1103/PhysRevLett.102.203902

In analogy with an electronic transistor, an all-optical switch is a device in which one light beam can fully control another. Realization of efficient all-optical switches is a long-standing goal in optical science and engineering [1]. If integrated with modern fiber-optical technologies, such devices may have important applications for optical communication and computation in telecommunication networks. Optical switches operating at a fundamental limit of one photon per switching event would further enable the realization of key protocols from quantum information science [2].

Typically, interactions of light beams in nonlinear media are very weak at low light levels. Strong interactions between few-photon pulses require a combination of large optical nonlinearity, long interaction time, low photon loss, and tight confinement of the light beams. Here, we present a fiber-optical switch that makes use of an optically dense medium containing a few hundred cold atoms trapped inside the hollow core of a photonic-crystal fiber (PCF) within dimensions d of a few micrometers. Near atomic resonance, the interaction probability p between a single atom and a single photon of wavelength λ, which scales as p ∝ λ^2/d^2, approaches a few percent. In this system, the properties of slowly propagating photons under conditions of electromagnetically induced transparency (EIT) [4–6] can be manipulated by pulses containing p−1 ∼ 100 photons [7–10].

Simultaneous implementation of all requirements for few-photon nonlinear optics has until now only been feasible in the context of cavity quantum electrodynamics (QED) [11–14]. However, these experiments remain technologically challenging and must compromise between cavity bandwidth, mirror transmission and atom-photon interaction strength. Consequently, large nonlinearities in these systems are accompanied by substantial input and output losses. Our alternative cavity-free approach uses propagating fields in a PCF. Hollow-core PCFs filled with molecular gas have been used for significant enhancements of efficiency in processes such as stimulated Raman scattering [15] and four-wave mixing [16], as well as observations of EIT [17]. Recently, both room-temperature and ultracold atoms have successfully been loaded into PCFs [18–21] and EIT with less than a micro-Watt field has been reported [18, 19].

Our apparatus [Fig. 1(a)] makes use of a 3 cm-long piece of single-mode hollow-core PCF vertically mounted inside an ultrahigh vacuum chamber. A laser-cooled cloud of 87Rb atoms is collected into a magneto-optical trap, focused with a magnetic guide, and loaded into the hollow core of the PCF. Once inside, the atoms are radially confined by a red-detuned dipole trap formed by a single beam guided by the fiber. The small mode diameter allows for strong transverse confinement (trapping frequencies ω_x/2π ∼ 50–100 kHz) and deep trapping potential (∼10 mK) at guiding light powers of a few milliwatts.

To probe the atoms in the fiber, we monitor the transmission of a very low power (~1 pW) probe beam through the PCF [Fig. 1(a)]. The signature of atoms inside the PCF are absorption profiles associated with atomic resonance lines. If the atoms are probed inside the dipole trap, we observe a unique profile shown in Fig. 1(d). The dipole trap introduces a power dependent, radially varying ac-Stark shift, which results in broadening and frequency shift of the absorption profile [red data points in Fig. 1(d)]. Comparison with the calculated profile based on the dipole trap parameters verifies that the atoms are loaded inside the fiber. For the experiments described below, we avoid the broadening of the atomic transition by synchronous square-wave modulation of the dipole trap and the probe beam with opposite phase [Fig. 1(e)] at a rate much higher than the trapping frequency. When using this technique and scanning the probe laser over a particular hyperfine transition, we observe a typical absorption profile as shown in Fig. 1(d) (black data points). The shape of this resonance is completely determined by the natural line profile of the transition T_{nat} = \exp(-\Omega D/[1 + 4(\Gamma_e)^2])], where \Gamma_e is the linewidth of the excited atomic state and \delta_p = \omega_p - \omega_0 is the detuning of the probe laser from resonance. The optical depth is defined as OD = 2N_{eff}(\sigma_g/A), where N_{eff} is the effective number of atoms in the fiber (corresponding to all...
ent population transfer in our mesoscopic atomic en-
vironment. The transmission of the probe beam, coupled to a cycling atomic transition, \( |2\rangle \rightarrow |4\rangle \), is controlled via an additional pump beam transferring atoms from an auxiliary state \( |1\rangle \) into \( |2\rangle \) [Fig. 2(a)]. Initially, the state \( |2\rangle \) is not populated, and the system is transparent for the probe beam. The incident pump beam, resonant with the \( |1\rangle \rightarrow |3\rangle \) transition, is fully absorbed by the optically dense atom cloud, thereby transferring atoms into the \( |2\rangle \) state, where they then affect the propagation of the probe beam. As demonstrated in Fig. 2(b), we achieve a 50% reduction of the probe transmission with only 300 pump photons. This corresponds to \( \sim 150 \) atoms being transferred into the \( |2\rangle \) state, which is sufficient to cause the observed absorption of the probe beam.

Next, we turn to coherent interaction between few atoms and photons in our system. First, we demonstrate EIT [4,5], where atomic coherence induced by a control beam changes the transmission of a probe beam. The essence of this phenomenon is the creation of a coupled excitation of probe photons and atomic spins (“dark-state polariton”) [22] that propagates through the atomic medium at greatly reduced group velocity [6]. We consider the three-state \( \Lambda \)-configuration shown in Fig. 3(a). In the absence of the control field, our medium is completely opaque at resonance [Fig. 3(c), black data points]. In contrast, when the copropagating control field is added, the atomic ensemble becomes transparent near the probe resonance [Fig. 3(c), red data points]. Figure 3(d) shows the profile of individual pulses and their transmission and delay due to reduced group velocity \( v_g \) inside the atomic medium. For probe pulses with rms width \( t_p \sim 150 \) ns we observe a group delay \( t_d \) approaching 100 ns, corresponding to a reduced group velocity of \( v_g = 3 \) km/s. Remarkably, Fig. 3(e) shows that control pulses containing as few as \( \sim 10^4 \) photons are sufficient to achieve almost complete transparency of the otherwise opaque system.

The sensitive nature of the quantum interference underlying EIT enables strong nonlinear coherent interaction between the dark-state polariton and additional light fields, which can be viewed as an effective photon-photon interaction [7,8,10]. An efficient nonlinear optical switch can be realized by adding to the EIT \( \Lambda \)-system a switch field

FIG. 1 (color online). (a) Schematic of the experimental setup. (b) Schematic detail of the fiber loading. Inside the fiber, the atoms are transversely trapped by an optical trap formed by a single beam guided by the fiber. After exiting the top end of the fiber the divergent beam creates a funnel potential guiding the atoms into the fiber core from a distance up to \( \sim 100 \) \( \mu \)m. The atomic cloud is moved into this region by a magnetic guide consisting of four current-carrying wires that fan out from the fiber tip. (c) Scanning electron microscope image of the fiber waist of guided light inside the fiber is \( w_0 = 1.9 \pm 0.2 \) \( \mu \)m. This means that \( \sim 100 \) atoms inside the fiber create an optically dense medium (OD = 1). The profile shown in Fig. 1(d) yields OD = 30, which corresponds to \( \sim 3000 \) atoms loaded into the fiber.

We now consider nonlinear saturation based on incoherent population transfer in our mesoscopic atomic en-
vironment. The transmission of the probe beam, coupled to a cycling atomic transition, \( |2\rangle \rightarrow |4\rangle \), is controlled via an additional pump beam transferring atoms from an auxiliary state \( |1\rangle \) into \( |2\rangle \) [Fig. 2(a)]. Initially, the state \( |2\rangle \) is not populated, and the system is transparent for the probe beam. The incident pump beam, resonant with the \( |1\rangle \rightarrow |3\rangle \) transition, is fully absorbed by the optically dense atom cloud, thereby transferring atoms into the \( |2\rangle \) state, where they then affect the propagation of the probe beam. As demonstrated in Fig. 2(b), we achieve a 50% reduction of the probe transmission with only 300 pump photons. This corresponds to \( \sim 150 \) atoms being transferred into the \( |2\rangle \) state, which is sufficient to cause the observed absorption of the probe beam.

Next, we turn to coherent interaction between few atoms and photons in our system. First, we demonstrate EIT [4,5], where atomic coherence induced by a control beam changes the transmission of a probe beam. The essence of this phenomenon is the creation of a coupled excitation of probe photons and atomic spins (“dark-state polariton”) [22] that propagates through the atomic medium at greatly reduced group velocity [6]. We consider the three-state \( \Lambda \)-configuration shown in Fig. 3(a). In the absence of the control field, our medium is completely opaque at resonance [Fig. 3(c), black data points]. In contrast, when the copropagating control field is added, the atomic ensemble becomes transparent near the probe resonance [Fig. 3(c), red data points]. Figure 3(d) shows the profile of individual pulses and their transmission and delay due to reduced group velocity \( v_g \) inside the atomic medium. For probe pulses with rms width \( t_p \sim 150 \) ns we observe a group delay \( t_d \) approaching 100 ns, corresponding to a reduced group velocity of \( v_g = 3 \) km/s. Remarkably, Fig. 3(e) shows that control pulses containing as few as \( \sim 10^4 \) photons are sufficient to achieve almost complete transparency of the otherwise opaque system.

The sensitive nature of the quantum interference underlying EIT enables strong nonlinear coherent interaction between the dark-state polariton and additional light fields, which can be viewed as an effective photon-photon interaction [7,8,10]. An efficient nonlinear optical switch can be realized by adding to the EIT \( \Lambda \)-system a switch field

FIG. 2 (color online). (a) Four-state atomic system for nonlinear saturation based on incoherent population transfer. (b) Transmission of the probe as a function of the number of incident pump photons with exponential fit. 50% reduction of probe transmission is achieved with \( \sim 300 \) pump photons.

atoms localized on the fiber axis), \( \sigma_{eg} \) is the atomic absorption cross section for the probed transition, and \( A = \pi w_0^2 \) is the beam area. Note that the optical depth for a given number of atoms inside the fiber does not depend upon the length of the atomic cloud. The measured beam waist of guided light inside the fiber is \( w_0 = 1.9 \pm 0.2 \) \( \mu \)m. This means that \( \sim 100 \) atoms inside the fiber create an optically dense medium (OD = 1). The profile shown in Fig. 1(d) yields OD = 30, which corresponds to \( \sim 3000 \) atoms loaded into the fiber.
coupling the state $|2\rangle$ to an excited state $|4\rangle$ [Fig. 4(a)] [9]. In this scheme, the switching photons interact with flipped atomic spins (state $|2\rangle$) within the dark-state polariton, causing a simultaneous absorption of a probe and a switch photon [23,24]. Switching is achieved when all three light fields involved (probe, control, and switching field) are overlapping within the atomic cloud [Fig. 4(b)]. In the absence of the switching field [red data in Fig. 4(c)], we observe high transmission of the probe beam on resonance due to EIT. When the switch field is turned on, this transmission is reduced. The strength of the reduction depends on the number of photons contained in the switch pulse [Fig. 4(d)]. Experimentally, we observe best switching results for switch pulses of length $t_s = t_p + t_d$. We find a 50% reduction of the initial transmission for a total number of $\sim 700$ switch photons per pulse. Figure 4(e) presents the truth table of our switch, where the system acts as a logic gate for the incoming probe and switch pulses. As seen from Fig. 4(d), a contrast of over 90% between the “on” and “off” state of the switch, desirable for practical applications, can be achieved with a moderate increase of the number of switch photons.

We now analyze the nonlinear behavior of our atomic medium. When the resonant control and switching pulses are longer than the weak probe pulse, the effect of the atomic medium on such probe pulses with carrier frequency $\omega_p$ is given by $\mathcal{E}_{\text{out}}(t) = \frac{1}{\sqrt{2\pi}} \int d\omega \mathcal{E}_{\text{in}}(\omega) \times e^{i\omega t_1} \sqrt{\frac{N_{\text{in}}}{2}} e^{-\frac{1}{2}(|\Delta(\omega)|^2 + |\Delta^*(\omega)|^2)}$, where $\mathcal{E}_{\text{in}}(\omega)$ is the Fourier transform of the slowly varying envelope $\mathcal{E}_{\text{in}}(t)$ of the probe pulse, normalized such that $N_{\text{in}} = \int dt |\mathcal{E}_{\text{in}}(t)|^2$, with $N_{\text{in}}$ being the number of input photons. The frequency dependent atomic response to probe light $f(\omega)$ is given by [8,9]

$$f(\omega) = \frac{\gamma_{13}(\Omega_{\text{in}})^2 - 4\delta_{12}\delta_{24}}{\delta_{24}(4\delta_{12}\delta_{13} - |\Omega_{\text{in}}|^2) - \delta_{13}|\Omega_{\text{in}}|^2},$$

where $\Omega_{x,e}$ are the Rabi frequencies of the switch and control fields. The complex detunings $\delta_i$ are defined as $\delta_i = \delta_i + i\gamma_i$, with $\gamma_{ij}$ being the coherence decay rates between levels $i,j$ and $\delta_i = \omega_p - \omega_{13}$, where $\omega_{13}$ is the frequency of the $|1\rangle \rightarrow |3\rangle$ transition. We consider input pulses with Gaussian envelope $\mathcal{E}_{\text{in}}(t) \sim e^{-t^2/(2\sigma^2)}$, in which case the transmission through our atomic medium is

$$T(\omega_p; \text{OD}) = \frac{N_{\text{out}}}{N_{\text{in}}} = \sqrt{\frac{2}{\pi}} t_p \int d\omega e^{-2t_p^2(\omega^2 + \text{OD})} \text{Im}(f(\omega)).$$

We fit expression (2) to observed absorption profiles such
as the ones shown in Fig. 3(c) and 4(c) to extract the control and switch Rabi frequencies, optical depth, and ground state decoherence rate. We next use these parameters to compare our observed EIT and nonlinear optical switch data to the theoretical prediction in Fig. 3(e) and 4(d). In both cases, we find excellent agreement between our experimental data and the theoretical model. In the relevant case of resonant probe field, Eq. (2) can be approximated by

\[
T = \exp\left(-N_s \frac{\mu_s^2}{\mu_p^2} \frac{3}{\pi} A^2 \frac{\tau_p}{\sqrt{2} \tau_d + \tau_p}\right)
\]

(3)

Here, \(N_s\) is the number of switch photons and \(\mu_{s,p}\) are switch and probe transition dipole matrix elements, respectively. Furthermore, we have assumed \(\Omega_s \ll \Omega_c, \gamma_{12} = 0, \gamma_{13} = \gamma_{24}\) and used \(\tau_d = L/v_g = \frac{OD_{\gamma_5}}{4\Omega_{\gamma_5}^2}\), with \(L\) being the length of the medium. For the investigated case of a relatively weak probe transition and resulting OD = 3, the delay time is small \((\tau_d \sim \tau_p)\) and the probe pulse is never fully stored inside the medium. If the OD is increased, \(\tau_d \gg \tau_p\) and the whole probe pulse is contained inside the medium as a dark-state-polariton in mostly atomic form. Then, a switch photon number \(N_s \sim \frac{A^2}{\Delta^2}\) causes \(1/e\) attenuation of the probe pulse. This ideal limit can be easily understood. In the case of a single slow probe photon, the polariton contains only a single atomic spin. Consequently, absorption of a single switch photon, which occurs with probability \(p \sim \frac{A^2}{\Delta^2}\), is required to destroy this coherent atomic excitation.

Our experimental demonstrations introduce a novel physical system that opens up unique prospects in quantum and nonlinear optics. Our system can be used to implement efficient photon counting [25,26] by combining photon storage with spin-flipped atom interrogation via a cycling transition. Further improvements in nonlinear optical efficiency are possible by either simultaneously slowing down a pair of pulses to enable long interaction time [27] or using stationary-pulse techniques [28,29]. In the former case, the threshold number of switch photons would be reduced to \(N_s \sim \frac{1}{\sqrt{OD}} \frac{A}{\Delta} [27]\), while in the latter case the probability of interaction between two single photons scales as \(\sim OD \frac{A^2}{\Lambda}\) [29]. Thus, with a relatively modest improvement of atom loading resulting in optical depth \(OD > 100\), achieving nonlinear interaction of two guided photons appears within reach. Finally, the present demonstration opens up the possibility to create strongly interacting many-body photon states [30], which may give new insights into the physics of nonequilibrium strongly correlated systems.
