Measurements of $\phi$ meson production in relativistic heavy-ion collisions at the BNL Relativistic Heavy Ion Collider (RHIC)

M. Bonnara,4 E. Bonne,36 J. Bouchet,49 E. Broida,28 A. V. Brindin,26 E. Brum,21 J. Bultmann,2
We present results for the measurement of φ meson production via its charged kaon decay channel $\phi \rightarrow K^+ K^-$ in Au + Au collisions at $\sqrt{s_{NN}} = 62.4$, 130, and 200 GeV, and in $p + p$ and $d + Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV from the STAR experiment at the BNL Relativistic Heavy Ion Collider (RHIC). The midrapidity ($|y| < 0.5$) φ meson transverse momentum ($p_T$) spectra in central Au + Au collisions are found to be well described by a single exponential distribution. On the other hand, the $p_T$ spectra from $p + p$, $d + Au$, and peripheral Au + Au collisions show power-law tails at intermediate and high $p_T$ and are described better by Levy distributions. The constant $\phi/K^-\pi^+$ yield ratio vs beam species, collision centrality, and colliding energy is in contradiction with expectations from models having kaon coalescence as the dominant mechanism for φ production at RHIC. The $\phi/\pi^0$ yield ratio as a function of $p_T$ is consistent with a model based on the recombination of thermal s quarks up to $p_T \sim 4$ GeV/$c$, but disagrees at higher transverse momenta. The measured nuclear modification factor, $R_{dAu}$, for the φ meson increases above unity at intermediate $p_T$, similar to that for pions and protons, while $R_{AA}$ is suppressed due to the energy loss effect in central Au + Au collisions. Number of constituent quark scaling of both $R_{cp}$ and $v_2$ for the φ meson with respect to other hadrons in Au + Au collisions
at $\sqrt{s_{NN}} = 200$ GeV at intermediate $p_T$ is observed. These observations support quark coalescence as being the dominant mechanism of hadronization in the intermediate $p_T$ region at RHIC.

I. INTRODUCTION

The $\phi(1020)$ vector meson’s properties and its transport in the nuclear medium have been of interest since its discovery [1]. The proper lifetime of the $\phi$ meson is about 45 fm/c, and it decays into charged kaons $K^+ K^-$ with a branching ratio of 49.2%, and more rarely into the dilepton pairs $e^+ e^-$ (B.R. of $2.97 \times 10^{-5}$) and $\mu^+ \mu^-$ (B.R. of $2.86 \times 10^{-4}$).

The mechanism for $\phi$ meson production in high energy collisions has remained an open issue. As the lightest bound state of strange quarks ($s\bar{s}$) with hidden strangeness, $\phi$ meson production is suppressed in elementary collisions because of the Okubo-Zweig-Iizuka (OZI) rule [2–4]. The OZI rule states that processes with disconnected quark lines in the initial and final state are suppressed. In an environment with many strange quarks, $\phi$ mesons can be produced readily through coalescence, bypassing the OZI rule [5]. The $\phi$ meson has been predicted to be a probe of the quark-gluon plasma (QGP) formed in ultrarelativistic heavy-ion collisions [6–11].

On the other hand, a naive interpretation of $\phi$ meson enhancement in heavy-ion collisions would be that the $\phi$ meson is produced via $K \bar{K} \rightarrow \phi$ in the hadronic rescattering stage. Models that include hadronic rescatterings such as RQMD [12] and UrQMD [13] have predicted an increase of the $\phi$ to $K^-$ production ratio at midrapidity as a function of the number of participant nucleons. This prediction was disproved in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV, from STAR year 2001 data [14]. With the higher statistics data newly recorded from the Solenoidal Tracker at RHIC (STAR) experiment [15], a precise measurement of the $\phi/K^-$ ratio as a function of beam energy and collision centrality is presented to confirm this finding in this paper.

The in-medium properties of vector mesons in the hot and dense environment are also interesting [11]. The mass and width of the $\phi$ meson were predicted to change because of the partial restoration of chiral symmetry in the nuclear medium. Asakawa and Ko [16] and Song [17] predicted that the $\phi$ mass decreases as a result of many-body effects in a hadronic medium. A double $\phi$ peak structure in the dilepton invariant mass spectrum from relativistic heavy-ion collisions was proposed as a signature of a phase transition from the QGP to hadronic matter [18]. Other calculations have predicted that the $\phi$ meson width can be widened significantly due to nuclear medium effects [19–21]. Recently, an interesting $\phi$ mass modification at normal nuclear density in 12 GeV $p + A$ interactions was observed in the dilepton channel ($e^+ e^-$) from the KEK experiment [22,23]. In STAR, we measure the $\phi$ meson mass and width to compare with these predictions/measurements, using the decay channel $\phi \rightarrow K^+ K^-$. From phenomenological analysis, it is suggested that the $\phi$ meson mean free path in hadronic matter is large because of its small cross section of scattering with hadrons [5]. Many other calculations also indicate that the $\phi$ meson has small rescattering cross sections with hadronic matter [19,20].

However, after including three- and four-vector meson vertices into their hidden local symmetry model, Alvarez-Ruso and Koch [24] found that the $\phi$ meson mean free path in nuclear media is smaller than that usually estimated. Ishikawa et al. [25] presented new data on near-threshold $\phi$ photoproduction on several nuclear targets. They found that the cross section between a $\phi$ meson and a nucleon, $\sigma_{\phi N}$, is equal to $35_{-11}^{+17}$ mb, which appears to be much larger than previous expectations, although the experimental uncertainty is very large [26]. Meanwhile, Sibirtsev et al. [27] presented a new analysis of existing $\phi$ photoproduction data and found $\sigma_{\phi N}$ heavy-ion collisions is still unclear.

The measurement of collective radial flow (represented by $\langle p_T \rangle$) probes the equation of state of matter produced in nuclear collisions [28,29]. Strong radial flow has been observed for many particles such as $\pi$, $K$, and $p(\bar{p})$ [30]. If the $\phi$ meson has indeed small hadronic rescattering cross sections and decouples early from the collision system, contributions to the radial flow of the $\phi$ meson will be mostly from the partonic stage instead of the hadronic stage. Thus the $\phi$ meson may have a significantly smaller radial flow than other hadrons with similar mass, such as the proton, especially in central heavy-ion collisions. Therefore, $\phi$ mesons may carry information about the conditions of nuclear collisions before chemical freeze-out. Thus it is important to experimentally measure and compare the freeze-out properties of the $\phi$ to other hadrons as a function of centrality and collision species. A comprehensive set of measurements will shed light on the characteristics of $\phi$ meson production and the evolution of the collision system.

The elliptic flow parameter $v_2$ is a good tool for studying the system formed in the early stages of high energy collisions at RHIC. It has been found that at low $p_T$ ($0 < p_T < 2$ GeV/$c$), the dependence of $v_2$ on particle mass [31–33] is consistent with hydrodynamic calculations in which local thermal equilibrium of partons is assumed [34–38]. This observation indicates that thermally equilibrated partonic matter may have been created at RHIC. However, at intermediate $p_T$ ($2 < p_T < 5$ GeV/$c$), the measured $v_2$ for various hadrons seems to depend on the number of constituent quarks in the hadron rather than its mass, consistent with the results from coalescence/recombination models [39–44]. Since $\phi$ is a meson but has a mass close to that of the proton and $\Lambda$, the measurement of the $\phi$ meson elliptic flow will provide a unique tool for testing the above statement.

Current measurements of various hadrons by STAR ($\Lambda, p, K^0_S, K^0_L, K^0, h^\pm$, etc.) show that the nuclear modification factor $R_{AA}$ for baryons differs from that of mesons $[45,46]$, consistent with the prediction of quark coalescence/recombination models [42,43,47,48]. Because of the value of the $\phi$ meson mass, a comparison of $R_{AA}$ for the $\phi$ with these previous measurements will conclusively determine if the observed difference is driven by particle mass or particle type.
In previous studies, the production of the $\phi$ meson has been measured in $\text{Au} + \text{Au}$ collisions at $\sqrt{s_{NN}} = 130$ GeV [49] and in $\text{Au} + \text{Au}$ and $p + p$ collisions at $\sqrt{s_{NN}} = 200$ GeV [14] at RHIC. The $\text{Au} + \text{Au}$ 200 GeV data presented in this paper were taken from the year 2004 run, where the number of events is approximately ten times larger than the previously reported number for the $\text{Au} + \text{Au}$ run in year 2001 [14]. The data from the year 2004 run contain the data reported in Refs. [50, 51]. It has been found that the results from the two runs are consistent with each other. In this paper, we present systematic measurements of $\phi$ meson production over a broad range of collision energies and system sizes, including $\text{Au} + \text{Au}$ collisions at $\sqrt{s_{NN}} = 62.4$, 130 [49], and 200 GeV, and $p + p$ [14] and $d + \text{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV from the STAR experiment. In Sec. II, we briefly introduce the STAR detector and discuss our analysis method (event-mixing technique) in detail. In Sec. III, we present the measurement of $\phi$ meson invariant mass distributions (III A), transverse mass $m_T$ spectra (III B), particle ratios (III C), nuclear modification factors (III D), and the elliptic flow parameter $v_2$ (III E); we also discuss the physics implication of each of these results. A summary and conclusions are presented in Sec. IV.

II. DATA ANALYSIS

A. Experimental setup

The STAR detector [15] consists of several subsystems in a large solenoidal analyzing magnet. We discuss here the subdetectors used in the analyses relevant to this paper. With its axis aligned along the beam direction, the time projection chamber (TPC) [52] is the main tracking device for charged particles, covering a pseudorapidity range $|\eta| \leq 1.8$ and providing complete azimuthal coverage. The entire TPC is located inside a solenoidal magnet, and data are taken at the maximum magnetic field $|B_z| = 0.5$ Tesla, where the $z$ axis is parallel to the beam direction. Radial-drift TPCs (FTPCs) [53] are also installed to extend particle tracking into the forward and backward regions ($2.5 < |\eta| < 4.0$). Surrounding the TPC is the central trigger barrel (CTB) [54], which is a scintillator counter array whose analog signal is sensitive to the total charged particle multiplicity with coverage $|\eta| \leq 1.0$. A pair of beam-beam counters (BBCs) at $3.3 < \eta < 5.0$ and a pair of zero degree calorimeters (ZDCs) [55] at $\theta < 2$ mrad are located on either side of the collision region along the beam line, and are used to provide event triggers for data taking. A more detailed description of the STAR detector can be found in Ref. [15] and references therein.

B. Event selection

1. Trigger selection

The $\text{Au} + \text{Au}$ data used in this analysis were taken under two different trigger conditions. One was a minimum-bias (MB) trigger requiring only a coincidence between both ZDCs. The other was a central trigger additionally requiring both a large analog signal in the CTB indicating a high charged particle multiplicity at midrapidity and a small ZDC signal. The ZDCs measure beam-velocity neutrons from the fragmentation of colliding nuclei and were used as the experimental level-0 trigger for selecting $d + \text{Au}$ and $\text{Au} + \text{Au}$ collisions for their respective runs. For $p + p$ data taking, the BBCs were used as trigger detectors. The central trigger corresponds to approximately the top 15% and 12% of the measured cross section for $\text{Au} + \text{Au}$ collisions at 130 GeV and 200 GeV, respectively. Data from both the MB and central triggers were used for this analysis. For the $\text{Au} + \text{Au}$ 62.4 GeV data set, only MB triggered events were used. For $p + p$ collisions at 200 GeV, the MB trigger was used in the analysis. It was based on a coincidence between the two BBCs. The BBCs are sensitive only to the non-single diffractive (NSD) part (30 mb) of the $p + p$ total inelastic cross section (42 mb) [14].

2. Vertex cuts and centrality selection

The longitudinal $z$ position of the interaction point is determined on-line by the measured time difference of the two ZDCs’s signals. A cut on the $z$ position of the interaction point is applied on-line for all data sets (except $p + p$) in order to maximize the amount of useful data for physics analysis, since events with primary vertices far away from the center of the TPC have a significant non-uniform acceptance. In the offline data analysis further cuts are applied on the $z$ position of the reconstructed primary vertex ($V_Z$), to ensure nearly uniform detector acceptance. These cuts are listed in Table I.

To define the collision centrality for the $\text{Au} + \text{Au}$ data, the raw charged hadron multiplicity distribution in the TPC within a pseudorapidity window $|\eta| \leq 0.5$ ($|\eta| \leq 0.75$ was used for the $\text{Au} + \text{Au}$ 130 GeV data) was divided into several bins. Each bin corresponds to a certain fraction of the total inelastic cross section [56]. For the $d + \text{Au}$ data, the raw charged hadron multiplicity in the east (Au-direction) FTPC ($-3.8 < \eta < -2.8$) was used for the centrality definition to avoid auto-correlation between centrality and the measurements of charged particles at midrapidity in the TPC [56]. We defined four centrality bins for the $\text{Au} + \text{Au}$ 62.4 GeV data (0–20%, 20–40%, 40–60%, 60–80%), three centrality bins for the $\text{Au} + \text{Au}$ 130 GeV data (0–11%, 11–26%, 26–85%), nine centrality bins for the $\text{Au} + \text{Au}$ 200 GeV data (0–5%, 5–10%, 10–20%, 20–30%, 30–40%, 40–50%, 50–60%, 60–70%, 70–80%) and three centrality bins for the $d + \text{Au}$ 200 GeV data (0–20%, 20–40%, 40–100%). The 80–100% most peripheral $\text{Au} + \text{Au}$ collision data were not used because of the rapidly decreasing trigger and vertex finding efficiencies.

| System | $\sqrt{s_{NN}}$ (GeV) | Trigger | $|V_Z|$ (cm) | Centrality | Events | Year |
|--------|-----------------------|---------|-------------|------------|--------|------|
| $\text{Au} + \text{Au}$ 62.4 | $\text{MB}$ | $\leq 30$ | 0–80% | $6.2 \times 10^6$ | 2004 |
| $\text{Au} + \text{Au}$ 130 | $\text{MB}$ | $\leq 80$ | 0–85% | $7.6 \times 10^6$ | 2000 |
| $\text{Au} + \text{Au}$ 130 | Central | $\leq 80$ | 0–11% | $8.8 \times 10^6$ | 2000 |
| $\text{Au} + \text{Au}$ 200 | $\text{MB}$ | $\leq 30$ | 0–80% | $1.4 \times 10^7$ | 2004 |
| $\text{Au} + \text{Au}$ 200 | Central | $\leq 30$ | 0–5% | $4.8 \times 10^6$ | 2004 |
| $p + p$ | $\text{MB}$ | $\leq 50$ | MB (NSD) | $6.5 \times 10^6$ | 2002 |
| $d + \text{Au}$ | $\text{MB}$ | $\leq 50$ | MB | $1.4 \times 10^7$ | 2003 |
MEASUREMENTS OF $\phi$ MESON PRODUCTION IN ... PHYSICAL REVIEW C 79, 064903 (2009)

for low multiplicity events. Table I lists the data sets used along with centrality selections and final numbers of events after these cuts. Note that the elliptic flow $v_2$ measurement only from 200 GeV MB Au + Au data is presented in this paper, as the statistics for the $v_2$ analysis is not sufficient for the 62.4 and 130 GeV Au + Au data.

### C. Track selection and particle identification

#### 1. Track selection

Several quality cuts were applied to ensure selection of good tracks. During the TPC track reconstruction, a charged track was extrapolated back to the beam line by using the reconstructed helix parameters. If the distance of closest approach (DCA) of the track to the event vertex was less than 3 cm and the track had at least ten hit points in the TPC, the reconstructed track was labeled as a primary track. The helix parameters for primary tracks were then refitted by requiring that the helix pass through the primary vertex position. Thus only primary tracks were used for the $\phi$ meson analysis. As a systematic check, the DCA selection for primary tracks was changed from 3 cm to 1 cm. The differences in the results were small and were included in the estimate of systematic uncertainties. Tracks with transverse momentum less than 0.1 GeV/c were not used, as their combined acceptance and efficiency becomes very small. Each track included in the $\phi$ analysis was required to have at least 15 hit points out of 45 used in the fitting of the tracks helix parameters. The ratio of the number of space points used in the track reconstruction to the maximum possible number of hit points was required to be greater than 55% to avoid split tracks where a real track is reconstructed in two or more segments. A pseudorapidity cut $|\eta| < 1.0$ ($|\eta| < 1.1$ for Au + Au 130 GeV data) was applied to select tracks that are well within the TPC acceptance.

#### 2. Kaon selection

Particle identification (PID) was achieved by correlating the ionization energy loss ($dE/dx$) of charged particles in the TPC gas with their measured momentum. The measurement of mean $dE/dx$ was achieved by averaging the measured $dE/dx$ samples along the track after truncating the top 30%. The measured $\langle dE/dx \rangle$ versus momentum curve is reasonably well described by the Bethe-Bloch function [57] smeared with the detector’s resolution (note that the Bichsel function was used to fit the $\langle dE/dx \rangle$ plot in Au + Au 200 GeV from the year 2004 run [58]). The $n_\sigma$ values for kaons are calculated via

$$n_\sigma = \frac{1}{R} \log \left( \frac{dE/dx}_{\text{measured}} / dE/dx_{\text{expected}} \right),$$

where $\langle dE/dx \rangle_{\text{measured}}$ and $dE/dx_{\text{expected}}$ are $dE/dx$ measured by TPC and calculated analytically, respectively, and $R$ denotes the $dE/dx$ resolution of the track which is found to range between 6% and 10%. $R$ is determined experimentally and depends on the event multiplicity and the number of $dE/dx$ samples from the track used to calculate the mean value. Tracks within $2\sigma$ of the kaon Bethe-Bloch curve were selected as kaon candidates. Figure 1 presents the measured $\langle dE/dx \rangle$ versus momentum × charge in Au + Au collisions at 62.4 GeV. Table II lists all the track cuts applied in the analysis.

Note that from the $\langle dE/dx \rangle$ measurement, kaons cannot be clearly separated from pions above $p \sim 0.6$ GeV/c and from protons/antiprotons above $p \sim 1.1$ GeV/c. Also note that the electron and positron $dE/dx$ bands cross the bands for pions, kaons, and protons/antiprotons. Therefore selected kaon candidates are contaminated by electrons/positrons, pions, and protons/antiprotons varying with $p$. Contamination by these charged particles in the kaon sample brings in additional real correlations (such as particle decays) which cannot be subtracted by the event-mixing method. We have varied the $n_\sigma$ cut for kaon to investigate the efficiency and combinatorial background dependence of the $\phi$ signal extraction on this cut. The resulting systematic uncertainties have been included in the estimate of the total systematic errors.

**TABLE II.** Track cuts used in the analysis, where $N_{\text{fit}}$ and $N_{\text{Max}}$ represent the number of fitted hits and the maximum number of hits for TPC tracks, respectively.

 FIG. 1. (Color online) Measured $\langle dE/dx \rangle$ vs momentum × charge of reconstructed tracks in the TPC. The figure is generated from Au + Au 62.4 GeV data.
D. Event mixing and raw yield extraction

The \( \phi \) meson signal was generated by pairing all \( K^+K^- \) tracks from the same event that passed the selection criteria and by then calculating the invariant mass \( m_{\text{inv}} \) for all possible \( K^+K^- \) pairs. As random combinations of \( K^+K^- \) pairs are dominant in this process, the resulting same-event invariant mass distribution contains the \( \phi \) meson signal on top of a large combinatorial background. An event-mixing technique [59,60] was applied to calculate the shape of the combinatorial background, where the invariant mass was calculated by pairing two kaons from two different events with same primary vertex and multiplicity bins (mixed event). Ideally, since it combines two different events, the mixed-event distribution contains everything except the real same-event correlations.

The STAR TPC has symmetric coverage about the center of the collision region. However, variations in the acceptance occur, since the collision vertex position may change considerably event-by-event. This variation in the collision vertex position gives rise to a nonstatistical variation in the collision region, since the collision vertex position may change event-by-event. This variation in the collision region in the subtracted invariant mass distribution. This is due to an imperfect description of the combinatorial background.

To reduce statistical uncertainty in the mixed event, each event was mixed with five to ten other events (depending on the collision system). To extract the \( \phi \) meson signal, the mixed-event and same-event \( K^+K^- \) invariant mass distributions were accumulated, and the mixed-event distribution normalized to the same-event distribution in the region above the \( \phi \) mass, \( 1.04 < m_{\text{inv}} < 1.06 \text{ GeV}/c^2 \), and subtracted in each \( p_T \) and \( y \) (rapidity) bin for every collision centrality. We varied the normalization region and normalization factor to estimate the systematic uncertainty on the normalization, and the estimated uncertainty was included in the quoted total systematic uncertainty.

Despite the requirements for mixing events described above, a residual background remains over a broad mass region in the subtracted invariant mass distribution. This is due to an imperfect description of the combinatorial background and the fact that the mixed event cannot account for the real correlated background from decay pairs due to Coulomb interactions, photon conversions (\( \gamma \rightarrow e^+e^- \)), and particle decays such as \( K^0_{\text{s}} \rightarrow K^+\pi^- \), \( \rho^0 \rightarrow \pi^+\pi^- \), \( K^0_{\text{s}} \rightarrow \pi^+\pi^- \), and \( \Lambda \rightarrow p\pi^- \) [61]. For example, when both pions from a \( K^0_{\text{s}} \) decay are misidentified as kaons, the real correlation from decay will remain in the same-event as a broad distribution but will not be reproduced by the event-mixing method.

Because of contamination of electrons/positrons in the selected kaon sample, the \( K^+K^- \) invariant mass distribution contains residual background near the threshold from correlated \( e^+e^- \) pairs, mainly from photon conversions (\( \gamma \rightarrow e^+e^- \)). The \( \delta \)-dip-angle between the photon converted electron and positron is usually quite small. The \( \delta \)-dip-angle is calculated from

\[
\delta \text{-dip-angle} = \cos^{-1} \left[ \frac{p_T1p_T2 + p_1p_2}{p_1p_2} \right],
\]

where \( p_1, p_2, p_{T1}, p_{T2}, p_1, p_2 \) are momentum and transverse and longitudinal momentum components of the two tracks; this represents the opening angle of a pair in the \( p_T \)-\( p_T \) plane. We required the \( \delta \)-dip-angle to be greater than 0.04 radians. This cut was found to be very effective in removing the photon conversion background while only reducing the \( \phi \) reconstruction efficiency by ~12%. Figure 2 shows two background-subtracted invariant mass distributions with and without the \( \delta \)-dip-angle cut. One can see that the peak from photon conversion \((m_{\text{inv}} \gtrsim 1.0 \text{ GeV}/c^2)\) is very effectively removed by this cut.

Figure 3 shows the \( K^+K^- \) invariant mass distributions for \( p + p \) collisions at 200 GeV [(a) and (b)], 60–80% \( Au + Au \) collisions at 62.4 GeV [(c) and (d)], and 0–10% \( Au + Au \) collisions at 200 GeV [(e) and (f)]. Solid circles in the upper panels are same-event pairs, whereas the histograms are from mixed-event pairs. The \( \phi \) meson peak is clearly visible for \( p + p \) 200 GeV and \( Au + Au \) 62.4 GeV (60–80%) in Figs. 3(a) and 3(c) before background subtraction, but not for \( Au + Au \) 200 GeV (0–10%) [Fig. 3(e)] due to its smaller signal significance. However, after background subtraction, the \( \phi \) mass peaks can be seen clearly for all data sets. The lower panels in Fig. 3 show the mixed-event background-subtracted \( \phi \) invariant mass distributions. Raw yields for the \( \phi \) meson
were determined by fitting the background-subtracted invariant mass distribution with a Breit-Wigner function superimposed on a linear (or polynomial) background function

\[
\frac{dN}{dm_{inv}} = \frac{A \Gamma}{(m_{inv} - m_0)^2 + \Gamma^2/4} + B(m_{inv}),
\]

where \(A\) is the area under the peak corresponding to the number of \(\phi\) mesons, \(\Gamma\) is the full width at half maximum (FWHM) of the peak, and \(m_0\) is the resonance mass position. \(B(m_{inv})\) denotes a linear \(B(m_{inv}) = p_0 + p_1 m_{inv}\), shown by a dashed line in Figs. 3(b), 3(d) and 3(f) or polynomial \(B(m_{inv}) = p_0 + p_1 m_{inv} + p_2 m_{inv}^2\), shown by a dot-dashed line in Fig. 3(f) residual background function. The parameters \(p_0, p_1, \) and \(p_2\) of \(B(m_{inv})\) and \(A, m_0, \) and \(\Gamma\) are free parameters.

### E. Efficiency correction

The \(\phi\) acceptance and reconstruction efficiency were calculated using an embedding technique, in which simulated tracks were embedded into real events. The number of embedded simulated tracks is approximately 5% of the measured multiplicity of the real event. The \(\phi\) meson decay (\(\phi \to K^+ K^-\)) and the detector responses were simulated by the GEANT program package [62] and the simulated output signals were embedded into real events before being processed by the standard STAR event reconstruction code. Embedded data were then analyzed to calculate tracking efficiencies and detector acceptance by dividing the number of reconstructed \(\phi\) by the number of input \(\phi\) in the desired kinematic regions. Figure 4 shows examples of correction factors (tracking efficiency \(\times\) acceptance) for our analysis as a function of \(\phi\) meson \(p_T\) for selected centrality bins for Au + Au, d + Au, and \(p + p\) 200 GeV collisions. It can be seen that the overall correction factors increase from a few percent at low \(p_T\) to over 30% at high \(p_T\). Low efficiency at low \(p_T\) is mainly due to poor acceptance of the daughter tracks. The efficiency is lower in more central collisions because of the increasing occupancy in the TPC [56].

### F. Vertex finding and trigger efficiency correction

For \(p + p\) and \(d + Au\) data, the trigger efficiency is less than 100% [63]. The MB trigger for \(p + p\) data was found to trigger \(~87\%\) of \(p + p\) NSD events. For \(d + Au\) data, the trigger efficiency was found to be \(~95\%\). These trigger efficiencies were used to normalize the measured yield, and the corresponding uncertainties are added to the total systematic.

FIG. 3. (Color online) Upper panels: same-event (full points) and mixed-event (solid line) \(K^+ K^-\) invariant mass distributions at \(0.6 < p_T < 1.4 \text{ GeV}/c\) in \(p + p\) 200 GeV collisions (a), \(0.8 < p_T < 1.2 \text{ GeV}/c\) in \(Au + Au\) 62.4 GeV collisions (60–80%) (c), and \(0.8 < p_T < 1.2 \text{ GeV}/c\) in \(Au + Au\) 200 GeV collisions (0–10%) (e). Lower panels: the corresponding \(\phi\) meson mass peaks after subtracting the background. Dashed curves show a Breit-Wigner + linear background function fit in (b), (d). In (f), both linear and quadratic backgrounds are shown as dashed and dot-dashed lines, respectively.

FIG. 4. (Color online) Reconstruction efficiency including acceptance of \(\phi\) meson as a function of \(p_T\) in several centrality bins of \(Au + Au, d + Au,\) and \(p + p\) 200 GeV collisions.
errors for $p + p$ and $d + Au$ data. The MB trigger efficiency for Au + Au data is essentially 100% [56].

It was found that the event vertex finding efficiency, which is the fraction of events having reconstructed vertices, drops rapidly for low multiplicity events [56]. For $d + Au$ collisions, the vertex efficiency was 88% for the most peripheral bin (40–100%), 93% for the MB events, and 100% for the central and middle central bins (0–20% and 20–40%). For Au + Au collisions, the vertex finding efficiency was 99.9% and $p_T$ independent [64] due to the increased track multiplicity in those collisions. However, the overall vertex finding efficiency was found to be 98.8% for the MB $p + p$ data by applying an additional BBC time difference selection (i.e., the NSD requirement), and the effect of correction was negligible in this analysis.

G. $v_2$ measurement

1. Reaction plane method

We employed the STAR standard reaction plane method as described in Refs. [65,66], which uses a Fourier expansion to describe particle emission with respect to the reaction plane angle, that is,

$$E \frac{d^3N}{d^3p} = \frac{1}{2\pi} \frac{d^2N}{dp_\perp dy} \left( 1 + \sum_{n=1}^{\infty} 2v_n \cos[n(\varphi - \Psi_r)] \right),$$

where $\Psi_r$ is the real reaction plane angle and $\varphi$ is the particle’s azimuthal angle. The coefficient $v_2$ in the second-order term of the expansion is the dominant part and is called the second harmonic anisotropic flow parameter, or elliptic flow.

The real reaction plane angle $\Psi_r$ is not known but can be estimated experimentally [67]. In our analysis, the estimated reaction plane angle from the second-order harmonic ($\Psi_2$) was used. This has a finite resolution due to a limited number of particles available in each event and a different event-by-event $v_2$, which is used for the estimation. The estimated reaction plane resolution was used to correct the observed $v_2^{obs}$ to obtain the final estimation of $v_2$.

The event plane angle $\Psi_2$ was calculated by the equation

$$\Psi_2 = \frac{1}{2} \tan^{-1} \left( \frac{\sum w_i \sin(2\varphi_i)}{\sum w_i \cos(2\varphi_i)} \right),$$

where the sums are over all charged particles used for reaction plane determination, and $w_i$ and $\varphi_i$ are the weight and azimuthal angle for the $i$th particle in a given event, respectively. The weights include both a $p_T$ weight and $\varphi$ weight. The $p_T$ weight was taken to be the particle $p_T$ up to 2.0 GeV/$c$ and constant (2.0) above that [66]. The $\varphi$ weight was taken to be the reciprocal of the $\varphi$ distribution (normalized by the average entries) for all selected tracks. The autocorrelations were eliminated by excluding all kaon tracks used in the $\psi$ invariant mass calculation from the reaction plane angle estimation [64].

The reaction plane resolution was then calculated by

$$\langle \cos[2(\Psi_2 - \Psi_r)] \rangle = C \langle \cos [2(\Psi_2^2 - \Psi_r)] \rangle,$$

where $\Psi_2^2$ is the calculated reaction plane angle of the subevent, and $C$ is a constant calculated from the known multiplicity dependence of the resolution [66]. This resolution was determined by dividing each event into two random subevents, a and b, with equal multiplicities. The reaction plane resolution therefore corresponds to how accurately the event plane angle represents the real reaction plane; due to its the definition in Eq. (6), a value of unity indicates ideal resolution. Figure 5 presents the reaction plane resolutions in different centrality bins for Au + Au 200 GeV collisions.

The combinatorial background in the $\psi$ invariant mass distribution was also calculated by an event-mixing technique as described above. To guarantee the mixed-event sample would represent the combinatorial background, an additional cut, the reaction plane angle difference between two mixed events, was required to be less than 0.1 rad in the event-mixing procedure. After background subtraction, the $\phi$ meson yield was extracted in each ($p_T, \varphi - \Psi_2$) bin. The yield distribution as a function of $\varphi - \Psi_2$ was fitted by the function

$$A \left( 1 + 2v_2^{obs} \cos[2(\varphi - \Psi_2)] \right),$$

where $\Psi_2^{obs}$ is the observed $v_2$ value, and $A$ is a constant. A typical result for the Au + Au data at 200 GeV is presented in Fig. 6.

The measured $v_2^{obs}$ was then divided by the reaction plane resolution to obtain the final $v_2$, i.e.,

$$v_2 = \frac{v_2^{obs}}{\langle \cos[2(\Psi_2 - \Psi_r)] \rangle}.$$

Simulation studies have found that the measured $v_2$ is about 7% (relative to the real $v_2$) lower than the real $v_2$ due to binning effects (five bins in $\varphi - \Psi_2$); a correction has been made to the measured $v_2$ to account for this effect.

2. Invariant mass method

A new method, namely, the invariant mass method, was also used to extract the elliptic flow $v_2$ of the $\phi$ meson. The method was proposed in Ref. [68], which decomposes the
anisotropic flow $v_n$ of a short-lived particle from that of all possible daughter pairs as a function of invariant mass. For extracting the $v_2$ of the $K^+K^-$ meson, it utilizes the fact that the $v_2$ of $K^+K^-$ pairs is composed of the $v_2$ of the combinatorial background and the $v_2$ of the $K^+K^-$ meson. Following the mixed-event background-subtraction procedure described in Sec. IID, the number of $K^+K^-$ pairs in each invariant-mass bin were counted, irrespective of the pair azimuth. Then

$$N_{K^+K^-}(m_{inv}) = N_{\phi}(m_{inv}) + N_{B}(m_{inv}),$$

where $N_{\phi}$ and $N_{B}$ are from the $\phi$ signal and the background, respectively. Once $N_{\phi}$ has been extracted via event-mixing and fitting the $\phi$ mass peak with Eq. (3) for each $p_T$ bin as discussed in Sec. IID, $N_K$ can be obtained from Eq. (9).

The same-event $v_2$ for $K^+K^-$ pairs vs invariant mass can be described by the function

$$v_2(m_{inv}) = a(m_{inv})v_{2S} + [1 - a(m_{inv})]v_{2B}(m_{inv}),$$

where $v_2(m_{inv})$ is the $v_2$ of same-event $K^+K^-$ pairs, $v_{2S} \equiv v_{2\phi}$ is the $v_2$ of the $\phi$ meson, $v_{2B}$ is the effective $v_2$ of the combinatorial background and $a(m_{inv}) = N_{\phi}(m_{inv})/N_{K^+K^-}(m_{inv})$ is the ratio of the $\phi$ signal to the sum of the background and $\phi$ signal. The reaction plane angle $\Psi_2$ was estimated in the same way as for the reaction plane method described in the previous section. Therefore the two methods are not completely independent. $v_2(m_{inv})$ can then be calculated from the following equation [66] for each $m_{inv}$ bin

$$v_2(m_{inv}) = \langle \cos[2(\phi_{K^+K^-} - \Psi_2)] \rangle,$$

where $\phi_{K^+K^-}$ is the azimuthal angle of the $K^+K^-$ pair.

Under the assumption that the background contribution to $v_2(m_{inv})$ [the second part on right side of Eq. (10)] is smooth as a function of $m_{inv}$ [68], a polynomial function, $p_0 + p_1m_{inv} + p_2m_{inv}^2$, can be used to parametrize the background $v_{2B}$ vs $m_{inv}$. $v_{2S}$ is then obtained by fitting $v_2$ by Eq. (10) in each $p_T$ bin, with $v_{2S}$ as a free parameter. Figure 7 shows $\langle \cos[2(\phi_{K^+K^-} - \Psi_2)] \rangle$ [i.e., $v_2$ in Eq. (11)] vs $m_{inv}$ for $0.5 < p_T < 1.0$ GeV/c in Au + Au 200 GeV collisions (0–80%), where the solid curve is the result of fitting by Eq. (10). The arrow shows the position of the $\phi$ invariant mass peak. The dashed line shows the zero horizontal line.

H. Systematic uncertainties

Major contributions to the systematic uncertainties come from variations in the procedure used for extracting the yields from the $K^+K^-$ invariant mass distributions and from variations in the determination of tracking and particle identification efficiencies. Different residual background functions (first-order vs third-order polynomial curves) were used to estimate the uncertainty of the raw yield extraction in each bin, and it was found to be of the order of $\sim 4.5\%$. The uncertainty due to different mixed-event normalization factors was estimated to be $\sim 2.1\%$ by varying the normalization region in the mixed-event background distribution. The uncertainty from tracking and PID efficiencies was estimated to be $\sim 8\%$, by varying the kinematic and PID cuts on the daughter tracks.

The overall systematic uncertainty was estimated to be approximately 10\% for the yield ($dN/dy$), and 10\% for $\langle p_T \rangle$ for the Au + Au and $d + Au$ data. It includes an additional contribution from the difference between exponential and Levy function fittings of the transverse mass or transverse momentum distributions. The systematic uncertainty in the overall normalization for the $p + p$ 200 GeV data was found to be 15\% for $dN/dy$ and 5\% for $\langle p_T \rangle$, including uncertainties due to vertex finding and trigger inefficiency for low multiplicity events.
Systematic uncertainties for the \(v_2\) measurement from the two different \(v_2\) extraction methods show \(p_T\) and centrality dependences, which mainly result from the determination of \(S/(S+B)\) ratios for the invariant mass method and from the removal of residual background in the reaction plane method, respectively. In our analysis, the point-to-point systematic errors included contributions from the following:

(i) Difference in finding the \(\phi\)-meson signal via bin-by-bin counting or Breit-Wigner function fitting methods;
(ii) Difference due to the residual background fitting function: first- or third-order polynomial functions;
(iii) Difference in combinatorial background determination: rotation of the background (the mixed event is from the azimuthal angle rotation of all tracks from the same event) or event-mixing (the current method);
(iv) Difference in \(v_2\) calculation: centrality-by-centrality \(v_2\) calculation and then weighting to get the final MB \(v_2\) or direct calculation of the \(v_2\) through MB raw yield fitting.

III. RESULTS

A. Mass and width

Figure 8 shows the \(\phi\) invariant mass peak position and width (FWHM) as a function of \(p_T\) for Au + Au 200 GeV (0–5\%), Au + Au 62.4 GeV (0–20\%), \(d + Au\) 200 GeV (0–20\%), and \(p + p\) 200 GeV (NSD) collisions. In the larger \(p_T\) region (>1 GeV/c), the measured mass and width for the \(\phi\) meson are consistent with those from Monte Carlo (MC) embedding simulations in various collision systems and at different energies. At low \(p_T\) (<1 GeV/c), the measured \(\phi\) meson mass is lower and the width is larger than from simulation. The drop of the \(\phi\) meson mass in both real data and simulation at low \(p_T\) is due to the multiple scattering energy loss of low \(p_T\) tracks in the detector, which is not fully corrected during track reconstruction.

Figure 9 shows shape comparisons between experimental and MC invariant mass distributions for the \(\phi\) meson at 0.6 < \(p_T\) < 1.0 GeV/c in \(p + p\) 200 GeV (NSD) and Au + Au 200 GeV (0–5\%) collisions. The real data \(\phi\) invariant mass peak (solid circles) is wider than that from standard MC data set (1) (open circles). If the momentum resolution for low \(p_T\) kaons used in the simulations is increased by 50\%, e.g., kaon momentum resolution at 350 MeV/c increases from ∼2\% [MC data set (1)] to ∼3\% [MC data set (2)], the \(\phi\) meson width from simulation reproduces the measured width from real data as shown by open diamonds. This decreased momentum resolution in MC could be possible considering uncertainties in simulations for the amount of material between the TPC active volume and the primary collision vertex and residual geometry alignment issues. These remaining issues for the differences in mass and width of \(\phi\) mesons between real data and simulations have limited our sensitivity to possible small modifications of \(\phi\) meson properties in the medium produced at RHIC collisions. It should also be noted that to really trace down the possible modification of the \(\phi\) meson mass and width in heavy-ion collisions, measurements through the dilepton decay channel are needed. An interesting excess on the low-mass side of the \(\phi\) meson invariant mass peak was observed by an \(e^+ + e^-\) channel in the low \(\beta\gamma\) region (\(\beta\gamma < 1.25\)) for 12 GeV \(p + Cu\) interactions from the recent KEK experiment [22,23]. This may indicate a vector meson mass modification at normal nuclear density. \(\phi\) measurements using the dilepton channel...
will hopefully be addressed in STAR in year 2010 with the time-of-flight detector upgrade under construction.

B. Spectra

φ meson invariant differential yields were calculated by correcting the extracted raw yield by tracking efficiency, detector acceptance, and the decay branching ratio. Figure 10 shows the φ meson transverse mass ($m_T = \sqrt{p_T^2 + m_\phi^2}$, where $m_\phi$ is the mass of φ meson) distributions from Au + Au collisions at $<p_T<$ 1000 MeV/c in $p + p$ and $p + p$ 200 GeV (NSD) and Au + Au 200 GeV (0–5%) collisions. Solid symbols: experimental data. Open symbols: MC simulation. Curves are the results of a Breit-Wigner function fit. Note: Two sets of MC data are shown for Au + Au collisions at 200 GeV, and see text for details.

The φ meson transverse mass spectra in central Au + Au collisions scales with that in peripheral Au + Au collisions to an exponential function shape $dN/dy = \exp(-m_T/m_\phi)$, while the Glauber model calculations use the number of binary collisions ($N_{\text{bin}}$) and number of participant pairs ($N_{\text{part}}/2$). $N_{\text{bin}}$ and $N_{\text{part}}$ were determined by Glauber model calculations [56]. We again point out that STAR only triggered on NSD $p + p$ events (measured $\sigma_{\text{NSD}} = 30.0 \pm 3.5$ mb) [71], while the Glauber model calculations use the $p + p$ inelastic cross section ($\sigma_{\text{inel}} = 42 \pm 1.0$ mb). Thus the NSD $p + p$ spectrum was normalized to the inelastic yield by a correction factor of 30/42.

A change in the shape of spectra from $p + p$, $d + Au$, and peripheral Au + Au collisions to central Au + Au collisions is clearly visible. In comparison with the fitting result for 200 GeV $p + p$ collisions in the high $p_T$ ($4.0 < p_T < 6.0$ GeV/c) region, the $N_{\text{bin}}$ normalized yield is suppressed in central Au + Au collisions at 200 GeV, while no suppression is observed for $d + Au$ collisions at 200 GeV. Since particles with high transverse momentum are mostly produced in hard scattering processes and modified by interactions with the medium in high energy heavy-ion collisions [72–74], the change of φ spectra from the Levy function shape in peripheral Au + Au collisions to an exponential function shape in central Au + Au collisions may indicate that different physics dominates the particle production in this $p_T$ region. In the low $p_T$ ($p_T < 1.0$ GeV/c) region, the $N_{\text{part}}/2$ normalized φ yield in $d + Au$ collisions scales with that in $p + p$ collisions, whereas it is enhanced significantly in central Au + Au collisions. This indicates that the hot environment created by central Au + Au collisions favors the production of soft φ mesons.

Theoretical calculations have shown that particles with different transverse momenta (or in different collision...
systems) are produced by or evolve with different mechanisms, such as hydrodynamics \cite{35-38}, coalescence/recombination \cite{39-44}, fragmentation \cite{75-77} and jet quenching \cite{72-74} mechanisms. The observed change of the $\phi$ $p_T$ systems) are produced by or evolve with different mechanisms, such as hydrodynamics \cite{35-38}, coalescence/recombination \cite{39-44}, fragmentation \cite{75-77} and jet quenching \cite{72-74} mechanisms. The observed change of the $\phi$ $p_T$ in different collision systems and collision systems. Further evidence of this will be discussed later, based on the measurements of different systems.

Figure 12 presents the $\phi$ meson midrapidity yield per participant pair $(dN/dy)/(0.5N_{\text{part}}$ as a function of $N_{\text{part}}$ (approximately proportional to the size of the collision system). The measured midrapidity yield per participant pair increases nonlinearly with $N_{\text{part}}$, except for the largest centrality bins and the Au + Au 130 GeV results where there are only three centrality bins with big error bars due to the limited statistics. For 200 GeV collisions, the yield increases rapidly from p + p and d + Au to peripheral Au + Au collisions and then saturates for midcentral Au + Au collisions. For the same $N_{\text{part}}, (dN/dy)/(0.5N_{\text{part}}$ increases with the collision energy of the Au + Au collisions. This is expected because of the increase of energy available to produce the $\phi$ mesons. The centrality and energy dependences of the enhancement of $\phi$ meson production can reflect the mechanism of strangeness enhancement in a dense medium formed in high energy heavy-ion collisions \cite{78}.

The upper panel of Fig. 13 shows the $N_{\text{part}}$ dependence of $\phi$ meson $\langle p_T \rangle$ in different collision systems, where $\langle p_T \rangle$ is extracted from the best fit to the $m_T$ spectra as described and shown in Table III. The measured $\langle p_T \rangle$ of the $\phi$ meson shows no significant centrality dependence within systematic errors. At the same $N_{\text{part}}$ value, the $\phi$ meson $\langle p_T \rangle$ increases slightly with collision energy from 62.4 to 200 GeV.

The mean values of transverse momentum $\langle p_T \rangle$ as a function of hadron mass from 62.4 and 200 GeV central Au + Au collisions are presented in the lower panel of Fig. 13. These data are taken from Refs. \cite{30,79}. The $\langle p_T \rangle$ of ordinary hadrons $\pi^-, K^-$, and $\tilde{p}$ follows a trend that is increasing with the mass of the hadron, as expected from the dynamics of these particles coming from a common radial velocity field shown as the hatched band \cite{Hydrodynamics model (1)} in the plot \cite{80,81}. However, heavy hyperons such as $\Xi$ and $\Omega$ show a deviation from the trend. Their values of $\langle p_T \rangle$ are lower than the expected ones. The observed $\langle p_T \rangle$ values for $\phi$ meson and $\Lambda$ are similar to those of $\Xi$ and $\Omega$. Meanwhile, another hydrodynamic model (2) shown by the curve \cite{82,83}, which considers possible different chemical freeze-out temperatures for ordinary and strange hadrons, gives a better description for strange particle $\langle p_T \rangle$. This behavior can be explained if strange hadrons have a smaller scattering cross section than ordinary hadrons in the later hadronic stage of the collisions. These strange particles would then decouple earlier from the system. The collective motion of the $\phi$ meson and multistrange hadrons $\Xi$ and $\Omega$ should have been developed at the early partonic stage in Au + Au collisions at RHIC. If radial flow is built up through the evolution of the system, the
particles with a smaller hadronic cross section would have smaller radial velocity and relatively smaller \( \langle p_T \rangle \).

### TABLE III. Results from fits to the transverse mass distributions of the \( \phi \) meson. The fit functions used to extract the results are also listed. All values are for midrapidity |\( y \)| < 0.5. The first error is statistical; the second is systematic.

### C. Ratios

The yield ratio \( \phi/\pi^- \) as a function of the center-of-mass energy per nucleon pair \( (\sqrt{s_{NN}}) \) is presented in the upper panel of Fig. 14. The \( \phi/\pi^- \) ratio increases with energy in both \( A + A \) [14,30,49,84–86] and \( p + p \) collisions [87–90], indicating that the yield of the \( \phi \) increases faster than that of the \( \pi^- \) in \( A + A \) and \( p + p \) collisions with increasing \( \sqrt{s_{NN}} \). The \( \phi/\pi^- \) ratio in \( A + A \) collisions is enhanced compared to that for \( p + p \) collisions, which indicates that \( A + A \) collisions may provide a more advantageous environment for the production of \( \phi \) mesons. In fact, an enhanced production of
The lower panel of Fig. 15 shows that the yield ratio of different collision systems. Bottom panel: Hadron mass dependence and energy from a few GeV up to 200 GeV [14,30,49,84–90].

relative enhancement from can be drawn from the experimental measurements, since the created by centrality. This is remarkable considering that the environment from our analysis is also almost constant as a function of occupancy factor [5]. However, no clear conclusion φ meson in a heavy-ion environment has been predicted to be a signal of QGP formation [5]. However, no clear conclusion can be drawn from the experimental measurements, since the relative enhancement from p + p to A + A collisions does not seem to change for $\sqrt{s_{NN}} > 10$ GeV. The bottom panel of Fig. 14 shows the $N_{\text{part}}$ dependence of the $\phi/\pi^- - \pi^0$ ratio in different collisions. The $\phi/\pi^-$ ratio first increases with $N_{\text{part}}$, and then seems to be saturated in the high $N_{\text{part}}$ region.

To further study whether $\phi$ meson production, or just that of strange particles, is enhanced in high energy $A + A$ collisions with respect to elementary collisions, we have plotted the yield ratio of $\phi/K^-$ as a function of $\sqrt{s_{NN}}$ in $A + A$, $e + e$, and $p + p$ collisions in the top panel of Fig. 15. For these collisions, at energies above the threshold for $\phi$ production, the $\phi/K^-$ ratio is essentially independent of collision species and energy from a few GeV up to 200 GeV [14,30,49,84–90].

The lower panel of Fig. 15 shows that the yield ratio $\phi/K^-$ from our analysis is also almost constant as a function of centrality. This is remarkable considering that the environment created by $p + p$ collisions is so drastically different from that of $Au + Au$ collisions that have both partonic and hadronic interactions.

The centrality dependence of the $\phi/K^-$ ratio provides another serious test for rescattering models based on the assumption that kaon coalescence is the dominant mechanism for $\phi$ production. The $K\bar{K}$ and $K$-hyperon modes are included in these rescattering models [12,13]. They predict an increasing $\phi/K^-$ ratio vs centrality (shown by the dashed line in the lower panel of Fig. 15), which is again in contradiction with the approximately flat trend of our measurements. Note also that the $\phi/K^-$ ratio from the UrQMD model is scaled by a factor of 3.4 to match the magnitude of our measurement for peripheral $Au + Au$ collisions. The comparisons of the data to predictions from these rescattering models including $\langle p_T \rangle$ and $\phi/K^-$ effectively rule out kaon coalescence as the dominant production mechanism for the $\phi$ meson. These measurements of the $\phi/K^-$ ratio may point to a common underlying production mechanism for $\phi$ and strange mesons in all collision systems.

In addition, statistical models [91–95] based on the assumption that the accessible phase space is fully saturated and thermalized can reproduce the STAR measurements of integrated hadron yield ratios (including $\phi/\pi^-$ and $\phi/K^-\bar{K}$) at midrapidity in $p + p$ and $Au + Au$ collisions at 200 GeV [34]. In these statistical models, the strangeness phase-space occupancy factor $\gamma$, approaches unity with increasing $N_{\text{part}}$, which indicates that strangeness approaches/reaches chemical equilibration for midcentral and central $Au + Au$ collisions at RHIC energies.

Because the mechanisms of (multi)strange particle production are predicted to be very sensitive to the early phase of
nuclear collisions, the ratio of $\Omega/\phi$ is expected to reflect the partonic nature of the thermal source that characterizes QGP [96] and the effects of the strong color field (SCF) [98]. In Fig. 16, the ratios of $\Omega/\phi$ vs $p_T$ are presented for different centralities. The $\Omega$ ($\Omega^- + \Omega^+$) data points are from Ref. [34] (for 0–12%) and from Ref. [100] for the other centralities. Also shown in the figure are three curves from two recombination model expectations for central collisions. A model by Ko et al., based on the dynamical recombination of quarks [97], is compared with the data and found to overpredict the ratio by a factor of about 3 over the whole $p_T$ region. (Note: the bumpy shape for this model is due to the limited statistics of their Monte Carlo simulation of the model.) Based on $\phi$ and $\Omega$ production from coalescence of thermal $s$ quarks in the medium [96], Hwa and Yang can describe the trend of the data up to $p_T \sim 4$ GeV/$c$ but fail at higher $p_T$ (solid line). In the alternative SCF scenario [98,99], a large string tension of $\kappa = 3$ GeV/fm can reproduce the data up to $p_T \sim 4.5$ GeV/$c$ in the framework of the HIJING/B$\overline{B}$ v2.0 model, but the effect of strong color electric fields remains an open issue and needs to be further investigated. With decreasing centrality, the observed $\Omega/\phi$ ratios seem to turn over at successively lower values of $p_T$, possibly indicating a smaller contribution from thermal quark coalescence in more peripheral collisions [96]. This is also reflected in the smooth evolution of the $p_T$ spectra shapes from the thermal-like exponentials to Levy-like curves.

**D. Nuclear modification factor**

The measurement of the nuclear modification factors $R_{cp}$ and $R_{AB}$ provides a sensitive tool to probe the production dynamics and hadronization process in relativistic heavy-ion collisions [39–44]. $R_{cp}$, which is the ratio of yields in central to peripheral heavy-ion collisions normalized by $N_{bin}$, is defined as

$$R_{cp}(p_T) = \frac{[dN/(N_{bin}dp_T)]_{\text{central}}}{[dN/(N_{bin}dp_T)]_{\text{peripheral}}},$$

and $R_{AB}$, which is the yield ratio of nucleus ($A$) + nucleus ($B$) collisions to inelastic $p + p$ collisions normalized by $N_{bin}$, is defined as

$$R_{AB}(p_T) = \frac{[dN/(N_{bin}dp_T)]_{A+B}}{[dN/(dN/dp_T)]_{p+p}}.$$  

where $N_{bin}$ is the number of binary inelastic nucleus-nucleon collisions determined from Glauber model calculations [71,101]. It is obvious that these two ratios will be unity if nucleus-nucleus collisions are just simple superpositions of nucleon-nucleon collisions. Deviation of these ratios from unity would imply contributions from nuclear or QGP effects. It should be mentioned that when using $p + p$ collisions in the $R_{AB}$ ratio, inelastic collisions should be used instead of the measured NSD collisions, therefore a correction factor 30/42, which was discussed in the above subsection B, was applied to correct the NSD yield to the inelastic yield in $p + p$ collisions.

There is a $p_T$-dependent correction to the NSD distribution from singly diffractive (SD) events, which is small in our measured $p_T$ range, being 1.05 at $p_T = 0.4$ GeV/$c$ and unity above 1.2 GeV/$c$ as determined from PYTHIA simulations [71].

Figure 17 presents the $p_T$ dependence of $R_{cp}$ for the $\phi$ with respect to midperipheral (top panel) and most-peripheral (bottom panel) bins in Au + Au collisions at 200 GeV. Results...
for the \( \Lambda + \bar{\Lambda} \), the \( K_S^0 \) [45], the \( \pi^+ + \pi^- \), and the \( p + \bar{p} \) [102] particles are also shown in the figure for comparison. Both statistical and systematic errors are included. Most of the systematic errors cancel in the ratios; however, the uncertainty due to particle identification from \( dE/dx \) remains as the dominant source and varies from point to point over the range \( \sim 7\% - 12\% \). In the measured \( p_T \) region, the \( R_{cp} \) of the \( \Phi \) meson is consistent with \( N_{\text{part}} \) scaling at lowest \( p_T \) (dot-dashed line), and is significantly suppressed relative to the binary collision scale (dashed horizontal line at unity) at all \( p_T \) in Au + Au collisions at 200 GeV. When compared to the STAR measured \( \Lambda + \bar{\Lambda} \) and \( K_S^0 \) data [45], the \( R_{cp} \) for \( \Phi \) follows that of \( K_S^0 \) rather than that of the similarly massive \( \Lambda \) (\( \bar{\Lambda} \)), especially for the case of 0–5%/40–60%. For 0–5%/60–80%, the \( R_{cp} \) of \( \Phi \) sits between that for the \( K_S^0 \) and the \( \Lambda \). This may be attributed to the shape change of the \( \Phi \) spectra from exponential at 40–60% centrality to Levy at 60–80% centrality as discussed above, which may be due to the change of the \( \Phi \) production mechanism at intermediate \( p_T \) in different environments with different degrees of strangeness equilibration.

Figure 18 presents the \( p_T \) dependence of \( R_{cp} \) for the \( \Phi \) meson for Au + Au 62.4 and 200 GeV and \( d + Au 200 GeV \) collisions. For the three collision systems, the \( R_{cp} \) factor follows \( N_{\text{part}} \) scaling at low \( p_T \). However, the \( R_{cp} \) at intermediate \( p_T \) is strongly suppressed in Au + Au collisions at 200 GeV, is weakly suppressed in Au + Au collisions at 62.4 GeV, and shows no suppression in \( d + Au \) collisions at 200 GeV.

Our measured \( R_{cp} \) for the \( \Phi \) meson further supports the proposed partonic coalescence/recombination scenario at intermediate \( p_T \) [42,43,47,48], where the centrality dependence of particle yield depends on the number of constituent quarks (NCQ) rather than on the mass of the particle. Das and Hwa [47] proposed a recombination scenario to explain the leading particle effect in \( p + p \) collisions, where the fragmenting partons would recombine with sea quarks to form hadrons. The resulting \( p_T \) distribution for the leading particle is therefore determined by the fragmenting quarks. In heavy-ion collisions, it is possible that \( q \bar{q} \) (\( q \bar{q}q \)) come together and form a meson (baryon) due to the high density of quarks (antiquarks) in the collision system. The abundant nearby partons give the recombination/coalescence mechanism a comparative advantage over the fragmentation mechanism for particle production in the intermediate \( p_T \) region, and this successfully explains the relative enhancement of baryons in the intermediate \( p_T \) region, such as the ratios \( p/\pi \) and \( \Lambda/K_S^0 \) [102–104]. Recently, Hwa and Yang used their recombination model to successfully describe the \( \Phi \) meson \( p_T \) spectra, but it fails to reproduce the \( p_T \) dependence of \( \Omega /\Phi \) at higher \( p_T \) as shown in the previous subsection. They assumed that for the production of \( \Phi \) this thermal component dominates over others involving jet shower contributions because of the suppression of shower s quarks in central Au + Au collisions [96]. However, the partonic medium, with an intrinsic temperature, may modify the recombination probability and momentum distribution for the \( \Phi \) [42,43,48].

Figure 19 presents the \( p_T \) dependence of the nuclear modification factor \( R_{AB} \) in Au + Au and \( d + Au \) collisions at 200 GeV. For comparison, data points for \( R_{dAu} \) of \( \pi^+ + \pi^- \) and \( p + \bar{p} \) are also shown in the figure. The \( R_{dAu} \) of \( \Phi \) mesons reveals a similar enhancement trend as those of \( \pi^+ + \pi^- \) and \( p + \bar{p} \) at the intermediate \( p_T \), which was attributed to be the Cronin effect [105–107]. The Cronin enhancement may result either from momentum broadening due to multiple soft [108] (or semihard [109–112]) scattering in the initial state or from final state interactions suggested in the recombination model [113]. These mechanisms lead to different particle type...
FIG. 19. (Color online) \(p_T\) dependence of the nuclear modification factor \(R_{AB}\) for \(\phi\) in \(Au+Au\) 200 GeV and \(d+Au\) 200 GeV collisions. For comparison, data points for \(\pi^+ + \pi^-\) in \(d+Au\) 200 GeV and \(p+\bar{p}\) in \(d+Au\) 200 GeV are also shown (see legend). Rectangular bands show the uncertainties of binary (solid line) and participant (dot-dash line) scalings. Systematic errors are included for \(\phi, \pi^+ + \pi^-\), and \(p+\bar{p}\).

and/or mass dependence in the nuclear modification factors as a function of \(p_T\). Our measurement of \(R_{dAu}\) of \(\phi\) mesons does not have the precision to differentiate particle dependence scenarios [114,115]. On the other hand, the \(R_{AA}\) in \(Au+Au\) 200 GeV is lower than that in \(d+Au\) 200 GeV and consistent with the binary collision scaling at intermediate \(p_T\). These features are consistent with the scenario that features the onset of parton-medium final state interactions in \(Au+Au\) collisions. The two \(R_{AB}\) observations in central \(d+Au\) and \(Au+Au\) collisions are consistent with the shape comparisons in Fig. 11 (top panel).

E. Elliptic flow

Figure 20 shows the elliptic flow \(v_2\) of the \(\phi\) meson as a function of \(p_T\) in MB (0–80%) \(Au+Au\) collisions at \(\sqrt{s_{NN}} = 200\) GeV. The \(v_2\) of the \(K^0_S\) and \(\Lambda\) measured by STAR [45] in \(Au+Au\) 200 GeV collisions are also shown for comparison. Measurements of \(v_2\) for the \(\phi\) meson from both reaction plane and invariant mass methods are presented, and they are consistent with each other.

The first interesting observation is that the \(\phi\) meson has significantly nonzero \(v_2\) in the measured \(p_T\) region. If the \(\phi\) meson has a small interaction cross section with the evolving hot-dense matter in \(A+\Lambda\) collisions, it would not participate in the late-stage hadronic interactions in contrast to hadrons such as \(\pi, K,\) and \(p(\bar{p})\) which freeze-out later. This indicates that the nonzero \(v_2\) of the \(\phi\) meson must have been developed in the earlier partonic stage. In the low \(p_T\) region (<2 GeV/c), the \(v_2\) value of \(\phi\) is between that for the \(K^0_S\) and the \(\Lambda\) in \(Au+Au\) 200 GeV collisions, consistent with the expectation of a mass ordering for \(v_2\) in hydrodynamic models. These observations support the hypothesis of the development of partonic collectivity and possible thermalization in the early stages of heavy-ion collisions at RHIC [34,100], although the underlying mechanism for the equilibration process remains an open issue.

FIG. 20. (Color online) \(p_T\) dependence of the elliptic flow \(v_2\) of \(\phi, \Lambda,\) and \(K^0_S\) in \(Au+Au\) collisions (0–80%) at 200 GeV. Data points for \(\phi\) are from the reaction plane method (full up-triangles) and invariant mass method (full circles), where data points from the reaction plane method are shifted slightly along the x axis for clarity. Vertical error bars represent statistical errors, while the square bands represent systematic uncertainties. The magenta curved band represents the \(v_2\) of the \(\phi\) meson from the AMPT model with a string melting mechanism [116]. The dash and dot curves represent parametrizations inspired by number-of-quark scaling ideas from Ref. [117] for \(NQ = 2\) and \(NQ = 3\), respectively.

In the intermediate \(p_T\) region (≈2–5 GeV/c), the \(v_2\) of the \(\phi\) meson is consistent with that for the \(K^0_S\) rather than for the \(\Lambda\). When we fit the \(v_2(p_T)\) of \(\phi\) mesons with the quark number scaling function [117], the resulting fit parameter NCQ (number of constituent quarks) = 2.3 ± 0.4. The fact that the \(v_2(p_T)\) of \(\phi\) is the same as that of other mesons indicates that the heavier s quarks flow as strongly as the lighter u and d quarks.

The AMPT model with string melting and parton coalescence mechanisms can reproduce the experimental results well up to 3 GeV/c, which favors the hadronization scenario of coalescence/recombination of quarks [116,118].

The \(v_2\) of the \(\phi\) meson from other centralities are shown in Fig. 21. The data are analyzed from the invariant mass

FIG. 21. (Color online) Elliptic flow \(v_2\) as a function of \(p_T\), \(v_2(p_T)\), for the \(\phi\) meson from different centralities. The vertical error bars represent the statistical errors, while the square bands represent the systematic uncertainties. For clarity, data points of 10–40% are shifted in the \(p_T\) direction slightly.

method only. As expected, $v_2(p_T)$ increases with increasing eccentricity (decreasing centrality) of the initial overlap region. This trend is also illustrated in Table IV, which presents the $p_T$-integrated values of $\phi$-meson elliptic flow, $\langle v_2 \rangle$, calculated by convoluting the $v_2(p_T)$ with the respective $p_T$ spectrum for four centrality bins. It should be noted that the centrality dependence of the $\langle v_2 \rangle$ of the $\phi$ meson is consistent with that of the charged hadrons [67].

IV. CONCLUSION

In conclusion, STAR has measured $\phi$ meson production for 62.4, 130, 200 GeV Au + Au, 200 GeV $d + Au$, and NSD $p + p$ collisions at RHIC. Details of the analysis method for $\phi$ meson are presented. The respective energy and $N_{\text{part}}$ dependence of the $\phi$ meson production, as well as the $p_T$ spectra for five collision systems, are reported.

The $\phi$ spectra in central Au + Au 200 GeV collisions are described well by an exponential function. The spectra for $p + p$, $d + Au$, and the most peripheral Au + Au 200 GeV collisions are better described by a Levy function due to the high-$p_T$ power-law tails. This change of spectra shape from $p + p$, $d + Au$, and peripheral Au + Au to central Au + Au collisions is most likely due to a change of the dominant $\phi$ production mechanism in the different collision environments. The yield of $\phi$ mesons per participant pair increases and saturates with the increase of $N_{\text{part}}$. It is found that the $\langle p_T \rangle$ of $\phi$, $\Lambda$, $\Xi$, and $\Omega$ does not follow the $\langle p_T \rangle$ vs hadron mass trend determined by the $\pi^\pm$, $K^\pm$, and $\bar{p}$. This may be due to their small hadronic cross sections, which indicates that the $\phi$ and strange hadrons can retain more information about the early state of the collision system.

The $\phi/K^-$ yield ratios from $p + p$ and $A + B$ collisions over a broad range of collision energies above the $\phi$ threshold are remarkably close to each other, indicating similar underlying hadronization processes for soft strange quark pairs in these collisions. The lack of a significant centrality dependence of the $\phi/K^-$ yield ratio and $\langle p_T \rangle_\phi$ effectively rules out kaon coalescence as a dominant production channel at RHIC. The trend of the $\Omega/\phi$ ratio is consistent with recombination models and a strong color field scenario up to $p_T \sim 4$ GeV/$c$ in central Au + Au collisions.

The measurement of the $\phi$ meson nuclear modification factor $R_{AB}$ is consistent with the Cronin effect in $d + Au$ 200 GeV collisions, and with the energy loss mechanism in Au + Au 200 GeV collisions. The $\phi$ meson was found to have nonzero $v_2$ in the measured $p_T$ range. When comparing the $\phi$ meson nuclear modification factor $R_{cp}$ (0–5%/40–60%) and elliptic flow $v_2$ to those of the similar mass $\Lambda$ baryon, and to the lighter $K^0_S$ meson, we see that the $\phi$ meson clearly behaves more like the $K^0_S$ meson than the $\Lambda$ baryon. Therefore, the processes relevant to $R_{cp}$ and $v_2$ at intermediate $p_T$ are driven not by the mass of the particle, but rather by the type of the particle, i.e., number of constituent quarks (NCQ) scaling. The coalescence/recombination model provides a fairly consistent picture to describe particle production in the intermediate $p_T$ region over a broad range of collision energies and system sizes at RHIC.
