The engulfment of apoptotic cells is required for normal metazoan development and tissue remodeling. In Caenorhabditis elegans, two parallel and partially redundant conserved pathways act in cell-corpse engulfment. One pathway includes the adaptor protein CED-2 CrkII and the small GTPase CED-10 Rac, and acts to rearrange the cytoskeleton of the engulfing cell. The other pathway includes the receptor tyrosine kinase CED-1 and might recruit membranes to extend the surface of the engulfing cell. Although many components required for engulfment have been identified, little is known about inhibition of engulfment. The tyrosine kinase Abl regulates the actin cytoskeleton in mammals and Drosophila in multiple ways. For example, Abl inhibits cell migration via phosphorylation of CrkII. We tested whether ABL-1, the C. elegans ortholog of Abi, inhibits the CED-2 CrkII-dependent engulfment of apoptotic cells. Our genetic studies indicate that ABL-1 inhibits apoptotic cell engulfment, but not through CED-2 CrkII, and instead acts in parallel to the two known engulfment pathways. The CED-10 Rac pathway is also required for proper migration of the distal tip cells (DTCs) during the development of the C. elegans gonad. The loss of ABL-1 function partially restores normal DTC migration in the CED-10 Rac pathway mutants. We found that ABL-1 is the C. elegans homolog of mammalian Abi (Abi interactor) proteins, is required for engulfment of apoptotic cells and proper DTC migration. Like Abl, Abi proteins are cytoskeletal regulators. ABI-1 acts in parallel to the two known engulfment pathways, likely downstream of ABL-1. ABL-1 and ABI-1 interact physically in vitro. We propose that ABL-1 opposes the engulfment of apoptotic cells by inhibiting ABI-1 via a pathway that is distinct from the two known engulfment pathways.

Introduction

Regulated reorganization of the cytoskeleton is a fundamental process in tissue morphogenesis and physiologic cell migration [1]. Dysregulation of the cytoskeleton is a hallmark of pathologic processes, such as cancer cell invasion and metastasis [2]. The engulfment of apoptotic cells requires a major cytoskeletal reorganization within the engulfing cell, which must extend its plasma membrane completely around the dying cell. In C. elegans, neighboring cells engulf apoptotic cells. Eleven genes appear to act in two parallel pathways required for engulfment: ced-1, ced-6, ced-7, and dyn-1; and ced-2, ced-5, ced-10, ced-12, mig-2, unc-73, and psr-1 (Figure 1) [3]. These two pathways have been proposed to recruit membranes for cell surface extension and rearrange the cytoskeleton, respectively. The pathways together promote the extension of the engulfing cell around the apoptotic cell.

In the pathway for membrane recruitment, which we refer to as the CED-1 pathway (see below), four proteins have been identified (Figure 1). CED-7 is an ABC transporter required in both the engulfing cell and the engulfed cell and might expose a pro-engulfment signal on the surface of the apoptotic cell [4,5]. The role of CED-7 in the engulfing cell has not been defined. CED-7 is thought to signal through CED-1, a receptor on the engulfing cell surface homologous to Drosophila Draper and the mammalian EGF-like receptor MEGF10 [6]. CED-1, in turn, is proposed to signal through CED-6, a protein that contains a phosphotyrosine-binding domain [7]; CED-6 can bind a motif in the intracellular domain of CED-1 [8] and is thought to activate DYNT-1, a C. elegans dynamin homolog [9]. DYNT-1, by analogy to its role in vesicular transport in mammalian cells, might recruit membrane for the engulfment process. The CED-1 pathway also is involved in degrading apoptotic cells once they are engulfed [10,11].

The pathway for cytoskeletal rearrangement requires the small GTPase CED-10 Rac, and we refer to this pathway as the CED-10 Rac pathway. Two parallel pathways contribute to CED-10 Rac activation (Figure 1). CED-2, the C. elegans homolog of the oncoprotein CrkII, is an SH2 and SH3 domain-containing adaptor protein [12] that interacts with an atypical heterodimeric guanine nucleotide exchange factor (GEF) consisting of the proteins CED-5 [13] and CED-12 [14–16], homologs of mammalian DOCK180 and ELMO, respectively. In mammals, a signal from the apoptotic cell induces the functions of DOCK180 and ELMO, leading to the recruitment of dynamin of the pre-engulfment. Although these proteins might interact in Caenorhabditis elegans, Caenorhabditis elegans cells possibly recruit a different molecular complex for cytoskeletal rearrangement.

Abbreviations: Abl, Abi interactor; DIC, differential interference contrast; DTC, distal tip cell; GEF, guanine nucleotide exchange factor; SH, Src homology

Author Summary

Cell death or apoptosis is a normal part of animal development, as is the engulfment and removal of dead cells by other cells. In the nematode Caenorhabditis elegans, ten highly conserved proteins have been characterized previously for their roles in engulfment and cell migration, both of which involve the formation of cellular extensions. Little is known, however, about how engulfment is inhibited. In mammals, the tyrosine kinase Abl, which regulates the actin cytoskeleton and which when misexpressed causes two types of leukemia, prevents the Crkl protein from facilitating cell migration. Crkl functions in engulfment in C. elegans and mammals. We tested whether the C. elegans homolog of Abl, ABL-1, could inhibit engulfment. We found that ABL-1 functions as an inhibitor of apoptotic cell engulfment and cell migration. However, our analysis further showed that ABL-1 does not function by inhibiting other known engulfment proteins, including C. elegans Crkl. Our data indicate that ABL-1 blocks ABI-1, the C. elegans homolog of the mammalian and Drosophila Abl-interactor (Abi) cytoskeletal-regulatory proteins. We propose that ABL-1 acts via ABI-1 to inhibit a newly identified pathway during cell corpse engulfment and cell migration.

cell to the engulfing cell is transduced through CrkII to the DOCK180/ELMO heterodimer [17], and an analogous process is thought to occur between CED-2 and the CED-5/CED-12 heterodimer. The CED-5/CED-12 GEF activates the Rac1 homolog CED-10, and activated CED-10 rearranges the cytoskeleton [18,19]. Rac proteins are members of the Rh family of small GTPases that regulate the cytoskeleton and function in intracellular signaling [20]. The phosphatidylserine receptor PSR-1, which recognizes phosphatidylserine on the surface of the dying cell, has been proposed to act upstream of CED-2 [21].

MIG-2, the mammalian homolog of RhG, another Rh family GTPase also regulates the CED-10 Rac pathway [22]. MIG-2 acts on CED-5/CED-12 in parallel to CED-2 [23]. UNC-73, a RhGGEF homologous to the mammalian protein Trio, activates MIG-2 [23]. The MIG-2 branch of the CED-10 Rac pathway provides a minor input into the engulfment pathway: mutations in mig-2 and unc-73 enhance the defects of other engulfment mutants but do not cause engulfment defects on their own [23].

Although many of the proteins that act in these two engulfment pathways are known, how these pathways are regulated is poorly understood. In mammals, the Abl tyrosine kinase functions in multiple processes that regulate the actin cytoskeleton [24]. For example, Abl blocks cell migration by phosphorylating and inhibiting the CED-2 homolog Crkl [25]. In addition to its role in Rac-dependent cell migration, Abl has been implicated in multiple signaling pathways in both the cytoplasm and the nucleus [26]. Abl acts in numerous cell biological processes, including cytoskeletal rearrangement, cell migration, apoptosis, transcription, and the response to oxidative stress [24,26]. Dysregulation of Abl via fusion of the Abl gene to the BCR gene is the cause of chronic myelogenous leukemia (CML) and an aggressive subtype of acute lymphoblastic leukemia (ALL) [27,28]. Recently, Abl signaling has been implicated in the prevention of breast cancer tumorigenesis [29] and in pathological fibrosis caused by the chemotherapeutic agent bleomycin [30,31].

That Abl functions in multiple diverse biological processes is reflected by its complex domain structure. In addition to its tyrosine kinase and DNA-binding domains, Abl has several protein-binding domains: Src Homology 2 (SH2), SH3, and F- and G-actin binding domains. Over 70 Abl-interacting proteins have been identified, largely through biochemical studies and cell-culture experiments. The in vivo relevance of most of these interactions has not been conclusively determined.

The C. elegans genome encodes a single Abl homolog, ABL-1. As in other organisms, Abl in C. elegans has many functions. ABL-1 protects germline cells from programmed cell death in response to ionizing radiation by antagonizing a molecular pathway that contains cell cycle checkpoint proteins and the p53 homolog CEP-1 [32]. ABL-1 is required for Shigella flexneri pathogenesis through an unknown mechanism [33]. A function for ABL-1 in cytoskeletal regulation has also been described: ABL-1 regulates epidermal morphogenesis in the C. elegans embryo by opposing the Ena/VASP homolog UNC-34 [34].

We found that ABL-1 inhibits the engulfment of apoptotic cells. Our genetic studies indicate that ABL-1 acts independently of both known engulfment pathways, suggesting the
existence of another pathway for engulfment. We show that ABL-1, the C. elegans homolog of the Abi (Abl interactor) cytoskeletal and signaling family of proteins, is a member of this newly identified pathway.

Results

ABL-1 Inhibits the Engulfment of Apoptotic Cell Corpses

To test whether abl-1 has a role in engulfment, we counted the number of unengulfed apoptotic cell corpses in the heads of first larval stage (L1) animals harboring mutations in abl-1 and engulfment pathway genes. The number of unengulfed corpses varies with the strength of the engulfment defect and defines a quantitative assay of engulfment defects [35]. We used two presumptive null alleles of abl-1 in this study, n1963 and ok171. n1963 is a G-to-A transition at the splice acceptor of exon 10 (bp 16967 of the M79 cosmid sequence), resulting in removal of most of the kinase domain and the change of a conserved arginine to serine. ok171 is a deletion allele that removes the entire kinase domain, most of the SH2 domain, and results in a frameshift and an opal stop codon 52 bp later [32].

abl-1 mutation alone had no obvious effect on engulfment. However, mutation of abl-1 decreased the number of unengulfed corpses in the heads of ced-1, ced-6, and ced-7 mutants (alleles e1735, n2095, and n1892, respectively, all of which are nulls) (Table 1). dyn-1 mutants die as embryos and were not tested. ABL-1 function did not depend on the presence of functional CED-1, CED-6, or CED-7 and therefore ABL-1 acts independently or downstream of the CED-1 pathway. These data are consistent with a role for ABL-1 in the negative regulation of apoptotic cell engulfment. Experiments that address alternative explanations for the effect of ABL-1 on engulfment are presented in the next section.

We tested for interactions between abl-1 and the genes of the CED-10 Rac pathway. abl-1 mutation did not modify the engulfment defects of either ced-5(n1812) or ced-12(n3261) null mutants (Table 1). abl-1 mutation also did not modify the engulfment defect of ced-2(n1994); mig-2(gm38 mu133) null double mutants, in which both known inputs into the CED-10 Rac pathway are absent (Figure 1). However, abl-1 mutation did partially suppress the engulfment defect caused by ced-2(n1994) alone (the number of cell corpses decreased from 22.0 to 15.7, p < 0.0001) and by the partial loss-of-function allele ced-2(e1752) alone (a decrease from 18.9 to 13.2, p < 0.0001). mig-2 null mutations do not cause engulfment defects on their own so they were tested in combination with a CED-1 pathway mutant (see below). Animals completely lacking ced-10 die as embryos and were not tested, but the engulfment defect caused by a partial loss-of-function allele, ced-10(n1993), was suppressed by abl-1(ok171) (the number of cell corpses decreased from 20 to 8.7, p < 0.0001).

Table 1. abl-1 Mutations Suppress the Engulfment Defects of Engulfment ced Gene Mutations

First larval stage (L1) worms were anaesthetized and viewed using DIC microscopy. The numbers of cell corpses in the heads were counted. sd, standard deviation.

*This p-value refers to comparisons between the strain with the engulfment mutation alone and the strains with the engulfment mutation with either the abl-1(n1963) or the abl-1(ok171) mutation.

doi:10.1371/journal.pbio.1000099.e001
We also tested whether the engulfment defect of a ced-1(n1735); ced-2(n1994) double mutant could be suppressed. A mutation in abl-1 did not modify the engulfment defect of the double mutant, even though each single mutant was suppressed. This result is consistent with the possibility that ABL-1 acts upstream of both the CED-10 Rac and the CED-1 pathways. Alternatively, ABL-1 might suppress a pathway parallel to these two pathways, but its suppression might be too weak to modify an engulfment defect as severe as that of the ced-1(n1735); ced-2(n1994) double mutant. We present data below that support the latter model.

Because mig-2 and unc-73 mutations enhance the engulfment defects of other engulfment gene mutations but do not cause defects on their own [23], we tested whether ABL-1 acts through the MIG-2 branch of the CED-10 Rac pathway by testing whether an abl-1 mutation could suppress the mig-2 enhancement of ced-1(n2091). We observed fewer apoptotic cell corpses in the heads of ced-1(n2091); mig-2(gm38 mu133) animals when an abl-1 mutation was present (Table 1), demonstrating that ABL-1 can act in the absence of MIG-2 function. Therefore, ABL-1 does not act solely through either the CED-2 branch or the MIG-2 branch of the CED-10 Rac engulfment pathway.

In summary, abl-1(lf) suppressed partial but not complete loss of the CED-10 Rac pathway. The inability of abl-1(lf) to suppress the engulfment defects of the CED-10 Rac pathway when this pathway was completely nonfunctional (i.e., ced-5 null, ced-12 null, or ced-2; mig-2 double null mutants, Figure 1) suggests that the CED-10 Rac pathway genes do not function by blocking the action of ABL-1. Instead, ABL-1 might inhibit the CED-10 Rac pathway, or ABL-1 might signal in parallel to the CED-10 Rac pathway through another group of effectors that require CED-10 Rac pathway function to accomplish apoptotic cell engulfment.

Notably, the observation that abl-1(lf) suppressed the engulfment defect of mutants that completely lack CED-2 function indicates that the effect of ABL-1 on engulfment is at least partially independent of CED-2, i.e., ABL-1 does not act only by inhibiting CED-2. Therefore, C. elegans ABL-1 can act to inhibit CED-2 CrkII-dependent pathways via a mechanism distinct from the known mechanism in mammals, in which Abl phosphorylates the CED-2 homolog CrkII.

**ABL-1 Does Not Affect the Cell-Death Process Directly**

The effect of abl-1 mutation on the number of unengulfed corpses could be caused by mechanisms other than the direct inhibition of cell engulfment. abl-1 mutation might (1) suppress programmed cell death, resulting in fewer cell corpses; (2) alter the timing of corpse appearance during development, resulting in fewer corpses at the time of observation; or (3) change cell-corpuses so that they were not recognized as corpses or were unstable and were lost altogether.

To determine whether abl-1 acts in programmed cell death, we evaluated whether cells known to undergo programmed cell death did so normally. In wild-type animals, 16 cells undergo programmed cell death in the anterior pharynx during embryogenesis [36], and their deaths can be scored by direct observation of their nuclei using DIC microscopy [35]. Mutants defective in programmed cell death, such as mutants with null mutations in the caspase ced-3, have up to 14 extra recognizable cell nuclei in the anterior pharynx [35,37]. We observed no extra nuclei in either abl-1(n1963) or abl-1(ok171) animals (Table 2). We also used a more stringent test for cell-death defects: enhancement of the death defect of ced-3(n2427) mutants, which are partially defective in programmed cell death [38]. As shown in Table 2, ced-3(n2427) animals had an average of 1.7 extra cells, and abl-1 mutation did not enhance the ced-3(n2427) death defect.

In the ventral nerve cord, six Pn.aap cells (P1.aap, P2.aap, and P9–12.aap) undergo programmed cell death postembryonically in wild-type animals, but not in death-deficient mutants [38,39]. Defects in programmed cell death are easily detected and quantified for five of these cells (P2.aap, P9–P12.aap) using a lin-11::gfp transcripational reporter transgene, which is expressed by surviving Pn.aap cells [38]. As in the pharynx, in the ventral nerve cord abl-1 mutation neither caused excess cell survival on its own nor enhanced the death defect caused by the ced-3(n2427) mutation (Table 2). We conclude that ABL-1 did not promote programmed cell death of non-germline cells. ABL-1 does protect against programmed cell death in the germline, most notably after radiation exposure [32]. In the germline abl-1 loss-of-function therefore causes excess cell death, not suppression of cell death. If this function of ABL-1 were present in non-germline cells, we would expect increased numbers of corpses, not the reduction of unengulfed corpses that we observed.

To test whether ABL-1 affects the timing, persistence, or morphology of cell corpses, we used time-lapse DIC microscopy to observe wild-type and abl-1(n1963) embryos for 150 min after the first appearance of a cell corpse [9]. During this time, approximately 70 cell corpses appear in the wild-type animal. We observed no significant difference between wild-type animals and abl-1(lf) mutants with respect to the number of corpses that appeared or when they appeared (Figure 2A). Also, the length of time that corpses persisted was similar between wild-type and abl-1(n1963) animals (Figure 2B). In addition, apoptotic cell corpses in abl-1(n1963) animals looked identical to wild-type corpses (Figure 2C). We conclude that loss of ABL-1 did not affect the time of appearance or morphology of apoptotic cell corpses.

abl-1 Mutation Suppresses Other Defects Associated with Engagement Pathway Genes

Mutants defective in corpse engulfment are also partially defective in programmed cell death, indicating that cell-corpse engulfment promotes cell killing [38,40]. A role for engulfment genes in promoting programmed cell death has also been found in *Drosophila* [41], showing that the pro-apoptotic function of cell engulfment is evolutionarily conserved.

In *C. elegans* mutants partially defective in cell-killing (e.g., *ced-3* caspase partial loss-of-function mutants), some cells that are fated to die undergo some of the morphological changes that accompany programmed cell death but then recover and persist as normal cells [38,40]. Most cells fated to die will nonetheless die. In *C. elegans* mutants with a partial loss of *ced-3* function and a mutation in an engulfment gene, a much larger number of cells fated to die will survive.

We tested whether *abl-1* mutations suppress the cell-death defect caused by engulfment gene mutations. The anterior pharynges of animals doubly mutant for *ced-3(n2427)*, a partial loss-of-function mutation, and a mutation in an engulfment gene, a much larger number of cells fated to die will survive.

The anterior pharynges of animals doubly mutant for *ced-3(n2427)*, a partial loss-of-function mutation, and a mutation in an engulfment gene, a much larger number of cells fated to die will survive.
example, ced-1(e1735); ced-3(n2427) animals had an average of 5.9 extra cells in their pharynxes, whereas ced-1(e1735); ced-3(n2427); abl-1(n1963) animals had an average of 4.2 extra cells (p < 0.001). However, abl-1 mutation did not affect the number of extra cells seen in ced-12(n3261); ced-3(n2427) animals. These findings are consistent with our observations concerning the role of ABL-1 in engulfment: abl-1 mutation suppressed the death defect of a null mutation in the CED-1 pathway but did not suppress the death defect of a null mutation in the CED-10 Rac pathway (ced-12(n3261)).

We also examined the effect of an abl-1 mutation on engulfment gene-related death defects in the ventral nerve
Figure 4. abl-1 Mutation Suppresses the DTC Migration Defects of all CED-10 Rac Pathway Gene Mutations

The gonads of animals mutant for an engulfment gene with or without abl-1 mutation were observed and scored for morphology using DIC microscopy. Scoring was as described in Materials and Methods. Percentages of abnormal gonad arms are shown. At least 50 gonad arms were scored for the wild-type and abl-1(n1963) mutants. More than 100 gonad arms were scored for all other genotypes. All mutant abl-1 strains used the abl-1(n1693) allele except for ced-10(n3417), which used abl-1(ok171). Statistical analysis used Fisher’s exact test, *, p < 1x10\(^{-5}\); **, p < 0.005. doi:10.1371/journal.pbio.1000099.g004

cord using the lin-11::gfp transgene and the n2424 partial loss-of-function allele of cel-3. In the anterior pharynx, the death defects of weak alleles of cel-1 and cel-12 were suppressed by loss of abl-1, but a null cel-12 allele was not strikingly suppressed (Figure 3B). Loss of abl-1 also suppressed the death defect of the partial loss-of-function allele ced-10(n1993) in this assay. However, unlike what was seen in the pharynx, abl-1 loss did not suppress the ced-1 null defect appreciably in the ventral nerve cord (Figure 3A). While it is possible that this disparity is caused by differences in the role of abl-1 in the ventral nerve cord and the pharynx, we prefer the hypothesis that the lack of suppression results from a relative insensitivity of the assay for ventral cord survival, i.e., loss of abl-1 is insufficient to suppress the effect of the loss of cel-1 function in this assay.

Mutants of the CED-10 Rac pathway have defects in cell migration. The two distal tip cells (DTCs) each migrate along a U-shaped trajectory during the development of the animal, guiding the formation of the gonads [42]. The gonads of CED-10 Rac pathway mutants often have an extra turn or have extra arms caused by abnormalities in DTC migration [43]. We tested whether abl-1 mutation could reduce the percentage of gonadal abnormalities in CED-10 Rac pathway mutants. We observed no effect of abl-1 mutation alone on DTC migration. Notably, abl-1 mutation suppressed the gonadal morphology defects of all CED-10 Rac pathway mutants tested, including those caused by null cel-5 and cel-12 mutations (Figure 4). The percentage of defective gonadal arms in ced-5(n1812) animals decreased from 40.8% to 21.7% in ced-5(n1812); abl-1(n1963) animals (p < 1x10\(^{-5}\)), and the percentage in ced-12(n3261) animals decreased from 45.2% to 24.2% in ced-12(n3261); abl-1(n1963) animals (p < 1x10\(^{-5}\)). This analysis indicates that ABL-1 negatively regulates DTC migration and does not act through the genes of the CED-10 Rac pathway to do so.

We also examined the effect of a loss of abl-1 function on the DTC migration defect of an animal harboring the ced-10(n3417) deletion mutation, a putative ced-10 null allele [22]. Because the ced-10(n3417) mutation causes maternal-effect lethality (i.e., homozygous null animals produce no live progeny), we analyzed the homozygous progeny of ced-10 heterozygotes (ced-10(n3417)/lin-1(e1275) dpy-13(e184sd)) with or without the abl-1(ok171) deletion mutation. These ced-10(n3417) homozygous animals presumably survived because they have CED-10 protein derived from maternally provided ced-10 mRNA. As with ced-2, ced-5, and ced-12 null mutants, the DTC defect of these ced-10 null mutants was suppressed by an abl-1 loss-of-function mutation: the percentage of defective gonadal arms in ced-10(n3417) animals decreased from 20.7% to 7.6% in ced-10(n3417); abl-1(ok171) animals (p < 0.005) (Figure 4). We note that these ced-10 animals are unlikely to totally lack ced-10 function, since the ced-10 null phenotype is maternal-effect lethal, indicating that ced-10 homozygotes derived from ced-10+ heterozygotes have some ced-10 function; that ced-10+ heterozygotes indeed have some ced-10 function is supported by the observation that only 20.7% of the DTCs of the ced-10(n3417) animals migrated inappropriately, which is far less than that seen in ced-5(n1812), ced-12(n3261), or ced-10(n1993) animals. Therefore, no compelling conclusion about whether ABL-1 acts in parallel to or downstream of the CED-10 pathway can be made on the basis of this experiment.

Notably, ced-10(n3417); abl-1(ok171) animals produced a small number of live progeny (unlike ced-10(n3417) animals), some of which achieved adulthood; none of these was fertile. This suppression of the maternal-effect lethality caused by ced-10(n3417) might well reflect an effect of the abl-1(ok171) mutation in the complete absence of ced-10 function. If so, at least in this case, abl-1 acts in parallel to or downstream of ced-10. We suggest it is simplest to postulate that abl-1 also acts in parallel to or downstream of ced-10 for engulfment, engulfment-mediated programmed cell death, and DTC migration.

Our findings concerning engulfment and gonadal migration are consistent with two models of ABL-1 function. In one model, ABL-1 acts through different molecular pathways to inhibit the morphological changes that drive engulfment of apoptotic cells and to inhibit the migration of DTCs, i.e., ABL-1 acts directly on CED-10 or another protein in the CED-10 Rac pathway to do so. This common pathway is more important in DTC migration than in engulfment. For example, in gonadal cell migration, either the CED-10 Rac pathway or a second ABL-1-inhibited pathway might be sufficient for normal DTC migration. If this were the case, loss of ABL-1 function would derepress the ABL-1-regulated pathway and suppress DTC migration defects even in the absence of any CED-10 Rac pathway function, as we observed. In engulfment, the requirement for the CED-10 Rac pathway might not be able to be overcome by derepression of the ABL-1-regulated pathway. We present data below supporting the second model, namely that ABL-1 acts in a common pathway distinct from the CED-10 Rac and CED-1 pathways in engulfment and gonadal cell migration.
levels of ABL-1 protein might have nonphysiologic activity that allows ABL-1 to bypass the requirement for its kinase activity. Alternatively, the K340R substitution might destabilize the ABL-1 protein, resulting in lower ABL-1 protein levels, and a consequent decrease in the rescuing activity of the abl-1(K340R) transgene.

**ABI-1 Acts in Engulfment and DTC Migration**

We tested whether ABI-1, the only *C. elegans* homolog of the Abi cytoskeletal regulatory gene family (Figure 5A), affects engulfment and gonadal cell migration. The Abi proteins (Abi-1/E3b1, Abi-2, and Abi-3/NESH in humans) were discovered as Abi interactors in yeast two-hybrid screens [48–50]. In different contexts, Abi and Abl proteins have been shown either to activate or suppress each other [48,49,51–57]. Abi proteins are part of the Scar/WAVE complex [58] and can interact with Formins [59], N-WASP [60], and Ena [52], all important regulators of the actin cytoskeleton. In addition, Abi proteins interact with signaling proteins that are important for cytoskeletal regulation, such as Ep8, Sos-1, and c-Cbl [50,55,61].

The Abi proteins have an N-terminal wave-binding domain [62], proline-rich repeats, and a C-terminal SH3 domain (Figure 5A). *C. elegans* ABI-1 is 31% identical to its closest human homolog, Abi-1 (Figure 5B), and has higher conservation in predicted functional domains. Our determination of *abi-1* transcript structures is described in Text S1.

We tested ABI-1 function using the deletion mutation tm494, which removes a 66-amino acid region just before the SH3 domain and changes the frame of the remaining sequence, resulting in a C-terminal truncation just before the SH3 domain. We also used abi-1 RNAi by feeding to reduce abi-1 expression [63,64], because RNAi by injection [65] causes embryonic lethality [66]. We showed that *abi-1(tm494)* and feeding *abi-1* RNAi probably caused a very weak loss of function, given that animals were viable and fertile. *abi-1(tm494)* or *abi-1* RNAi in wild-type animals caused a weak engulfment defect (Table 4). Also, the tm494 mutation or *abi-1* RNAi significantly enhanced the engulfment defects of all engulfment mutants tested (in both the CED-10 Rac and CED-1 pathways) (Table 4). In addition, *abi-1* RNAi significantly enhanced the engulfment defect of a *ced-1(e1735); ced-5(n1812)* double mutant, in which both engulfment pathways are nonfunctional. To determine whether ABI-1 function requires ABL-1, we assayed the effect of *abi-1* RNAi in strains doubly mutant for engulfment genes and *abl-1*. Loss of *abi-1* function enhanced the engulfment defects of these strains to the same degree, whether *abl-1* mutation was present or absent. Therefore, ABI-1 does not act by modulating ABL-1 function.

We also assayed the effect of *abi-1* RNAi on gonadal migration. *abi-1* RNAi enhanced the *ced-5* defect in gonadal cell migration (from 47.5% to 58.8%, p < 0.04) (Figure 6). Strikingly, *abi-1(II)* completely abrogated the effect of *abl-1* mutation on gonadal cell migration in *ced-5* and *ced-12* animals.

Because Abi proteins are in the Scar/WAVE complex and other Scar/WAVE complex members have been implicated in engulfment (GEX-2 and GEX-3, the *C. elegans* homologs of Sra-1 and Nap, respectively) [67], we asked whether the localization of GEX-3 is altered in animals with a loss of *abi-1* function. We assessed the localization of a rescuing

GFP::GEX-3 fusion protein (kindly provided by M. Soto) in embryos of animals that contain a gex-3 null mutation (zu196) with either a wild-type abl-1 allele or abl-1(ok171). We found no localization of the fusion protein around embryonic cell corpses and no apparent difference in the pattern of fluorescence in both strains (Figure S1). Therefore, Scar/WAVE complexes do not appear to localize around apoptotic cell corpses at least at the time that corpses become visible by DIC optics. Furthermore, the absence of ABL-1 protein does not appear to alter the localization of Scar/WAVE complexes. However, ABL-1 probably only interacts with a fraction of the Scar/WAVE complexes present, and this fraction might not be sufficiently large to detect a difference in the overall localization of Scar/WAVE complexes using this method. Moreover, the rescuing GFP::GEX-3 fusion transgene is located on an extrachromosomal array and might be expressed at much higher levels than wild-type GEX-3. For these reasons, we cannot unambiguously interpret these results.

In summary, loss of ABI-1 function enhanced the engulfment defects caused by the inactivation of either the CED-10 Rac pathway or the CED-1 pathway or both together and enhanced the DTC migration defects of the CED-10 Rac pathway (Figure 5).

Moreover, the rescuing GFP::GEX-3 fusion transgene is located on an extrachromosomal array and might be expressed at much higher levels than wild-type GEX-3. For these reasons, we cannot unambiguously interpret these results.

In summary, loss of ABI-1 function enhanced the engulfment defects caused by the inactivation of either the CED-10 Rac pathway or the CED-1 pathway or both together and enhanced the DTC migration defects of the CED-10 Rac pathway.
in the ABI-1 lane than in the GST lane despite a much smaller amount of ABI-1 than GST loaded on the gel (note Coomassie Blue-stained gel next to the autoradiograph) (Figure 7). ABL-1 did not bind to the control Luciferase; we also failed to observe ABL-1(606–1,224) binding. ABL-1(112–611) contains the SH3, SH2, and tyrosine kinase domains of ABL-1. ABL-1(606–1,224) contains the entire C-terminal half of ABL-1, including the region homologous to mammalian Abl where the Abl-2 SH3 domain binds. However, the polyproline stretch is within the first 60 amino acids of ABL-1(606–1,224) and might not have folded appropriately to bind to the ABL-1 SH3 domain. The direct binding of the N-terminal half of ABL-1 to ABI-1 strengthens the hypothesis that a direct interaction between these proteins exists in vivo and suggests that ABL-1 directly inhibits ABI-1 in its role in the engulfment of apoptotic cells and DTC migration.

We also tested whether ABL-1 binds to the product of the abi-1(tm494) allele, which contains only the first 350 amino acids of the 470 amino acid protein. We called this protein ABI-1. As described above, we made an N-terminal GST fusion to ABI-1 and tested whether it bound to ABL-1. Like ABL-1, ABI-1 bound to ABL-1(112–611) but not to ABL-1(606–1,224) or to Luciferase (Figure 7). This result is consistent with the fact that the region of ABL-1 thought to bind to the N terminus of ABL-1 on the basis of mammalian Abl/Abi interactions is intact in ABI-1A [49]. Although the amount of ABL-1(112–611) bound by ABI-1A was approximately 3-fold less than that bound by ABI-1, it is difficult to know how much ABI-1A was loaded onto the gel, because ABI-1A comigrates with a nonspecific band. Alternatively, truncation of ABI-1 might cause changes in folding that decrease its ability to bind substrates, which might reflect decreased binding to ABI-1 in vivo and possibly explain the decreased function of the abi-1(tm494) allele.

**Figure 6. Loss of abi-1 Function Enhances the DTC Migration Defects of Engagement Pathway Genes**

The gonads of animals mutant for an engulfment gene with or without abi-1(tm493) were treated with abi-1 RNAi or a control RNAi, observed, and scored for morphology using DIC microscopy. Scoring was as described in Materials and Methods. Percentages of abnormal gonad arms are shown. At least 50 gonad arms were scored for the wild-type and abi-1(tm493) mutants. More than 100 gonad arms were scored for all other genotypes. Statistical analysis used Fisher’s exact test, *, p < 0.04; **, p < 1 × 10⁻².

*p-Value refers to comparison between wild type and abi-1 RNAi. Comparison between wild type and abi-1(tm494) did not reach statistical significance.

doi:10.1371/journal.pbio.1000099.t004

pathway. ABI-1 action was not modified by ABL-1 inactivation. These data suggest that ABL-1 acts through ABI-1 to inhibit engulfment and DTC migration.

abi-1 is expressed broadly throughout embryogenesis [32]. To determine where abi-1 is expressed, we created an abi-1::gfp reporter transgene and observed expression of the abi-1 reporter broadly throughout embryogenesis (unpublished data).

**ABL-1 and ABI-1 Interact In Vitro**

In mammals, Abl and Abi-2 interact in vitro in two ways. The SH3 domain of Abl binds to a site in the first 157 amino acids of Abl-2, likely a proline-rich site. The SH3 domain of Abi-2 binds to a proline-rich region near the center of Abl (amino acids 593–730) [49]. To test whether C. elegans ABL-1 and ABI-1 interact directly, we performed in vitro binding experiments with glutathione-S-transferase fused to the N terminus of ABI-1 and in vitro translated portions of ABL-1. We made two ABL-1 constructs, an N-terminal fragment (amino acids 112–611) and a C-terminal fragment (amino acids 606–1,224). ABL-1(112–611) bound to ABI-1, but to a small degree also bound to GST alone. Quantitation of the bands using phosphorimager revealed 8-fold higher binding
Discussion

We have demonstrated that the C. elegans Abl ortholog ABL-1 negatively regulates the engulfment of apoptotic cells. abl-1 inhibits the engulfment process as well as the engulfment-related cell-killing process and the migration of DTCs during gonadogenesis. Our genetic analysis suggests that ABL-1 acts in a manner that does not require the known engulfment pathways. Ectopic expression experiments indicate that ABL-1 acts in engulfing cells and that its function at least partially depends on its kinase activity. Moreover, our studies show that the Abi ortholog ABI-1 acts in engulfment and DTC migration. Finally, our genetic and biochemical studies both suggest that ABL-1 directly inhibits ABI-1 in a pathway distinct from the known engulfment gene pathways.

How Do ABL-1 and ABI-1 Interact In Vivo?

Our genetic analysis indicates that either abl-1 could inhibit abi-1 or the two genes could act in separate molecular pathways. We favor the former hypothesis, both because ABL-1 and ABI-1 interact directly in vitro and because in mammalian cell culture and cultured neurons the homologs of these proteins interact and function in processes that regulate the cytoskeleton [55,56].

Our findings establish that an Abl protein and an Abi protein interact functionally in vivo. In some in vitro studies Abi activated Abl [49,51–54], in others Abi activated Abi [56,57], and in still others Abi appeared to block Abl function [48–50,55]. We found that abl-1 and abi-1 have opposing functions in vivo. Given the large number of proteins with which Abl and Abi interact and the multiple cellular contexts in which they function, in vivo analyses will be critical to distinguish which interactions are relevant for a particular cell biological process.

ABL-1/ABI-1 Likely Act in Parallel to the CED-10 Rac and CED-1 Pathways

The inhibition of engulfment by ABL-1 occurred in the absence of functional CED-2 CrkII, indicating that the effect of ABL-1 on engulfment and DTC migration is not mediated by CED-2 CrkII inhibition. In mammals, Abl phosphorylates tyrosine 221 of CrkII between its SH3 domains, resulting in inhibition of CrkII function and suppression of cell migration [25,68]. This tyrosine is not conserved in C. elegans. We conclude that C. elegans ABL-1 blocks the CED-10 Rac pathway by a novel mechanism.

Our analysis of genetic interactions between abl-1 and the engulfment genes suggests the existence of a new pathway involved in both cell-corpse engulfment and DTC migration. Loss of ABL-1 function suppressed the engulfment and cell-death defects of all CED-1 pathway genes tested. abl-1 mutation did not suppress the engulfment defects of ced-5 or ced-12 nulls but did suppress their DTC migration defects. Since abl-1 mutation modulated DTC migration in the absence of ced-5 or ced-12 function (i.e., when the CED-10 Rac pathway was inactive), ABL-1 can signal through another pathway. We propose that ABL-1 acts in a third pathway not only for DTC migration but also for engulfment. If so, this pathway cannot promote engulfment in the absence of CED-10 Rac activation. Although it is formally possible that the function of ABL-1 in engulfment is mediated through the CED-10 Rac pathway while its effect on DTC migration is mediated through a different pathway, we prefer a simpler model in which ABL-1 acts through a single pathway to oppose the engulfment genes. This pathway might act in parallel to CED-10 or it might act on CED-10 Rac (see below).

We found that ABI-1 is required for the function of ABL-1 in engulfment and DTC migration. ABL-1 promoted engulfment and migration independently of the known engulfment pathways downstream of or in parallel to ABL-1. We propose that ABL-1 inhibits ABI-1 and that these two proteins define a new molecular pathway required for cell-corpse engulfment and DTC migration. Interestingly, loss of abl-1 did not suppress the engulfment defects of CED-10 Rac pathway null mutants, whereas loss of abi-1 did enhance those engulfment defects. At least three models can explain these findings. ABL-1 might not be a sufficiently potent inhibitor of ABI-1 to
Figure 8. ABL-1 and ABI-1 Likely Function in Parallel to the CED-10 Rac and CED-1 Engulfment Pathways

We suggest that ABL-1 inhibits ABI-1, which acts to promote the engulfment of apoptotic cells. ABL-1 might signal either independently of the CED-10 Rac pathway (Arrow 1) or through CED-10 Rac, in parallel to the CED-10 GEF CED-5/CED-12 (Arrow 2). This model also applies to the roles of ABL-1 and ABI-1 in the regulation of DTC migration, but we do not show DTC migration in the figure, because the CED-1 pathway does not act in this process. Since ABL-1 and ABI-1 act in DTC migration, ABL-1/ABI-1 cannot act solely through the CED-1 pathway since the proteins of the CED-1 pathway have no role in DTC migration.

doi:10.1371/journal.pbio.1000099.g008

affect engulfment in the absence of CED-10 Rac pathway activity. Second, the CED-10 Rac pathway might be absolutely required for engulfment, so that derepressing the ABL-1/ABI-1 pathway does not suppress the CED-10 Rac pathway engulfment defect. Third, loss of abl-1 function might increase engulfment activity in the absence of the CED-10 Rac pathway insufficiently to detect in the engulfment assay.

Loss of abl-1 function suppressed the DTC migration defect of a null ced-10 mutant. However, these animals were the progeny of heterozygotes and probably contained some functional CED-10 protein. Loss of abl-1 function suppressed the maternal-effect lethality of a ced-10 null mutation. This observation provides stronger evidence that abl-1 can act in parallel to or downstream of ced-10. We were unable to test the effects of abl-1 or abi-1 mutations on a null mutant of dyn-1, because this mutant arrests development during embryogenesis and, unlike in the case of a null ced-10 mutant, DTC migration is not affected in dyn-1 mutants. Therefore, we do not know whether ABL-1 or ABI-1 can act independently of CED-10 or DYN-1 for engulfment or engulfment-mediated programmed cell death (or DTC migration in the case of CED-10) and hence whether ABL-1 and ABI-1 act through either of these genes or in a parallel molecular pathway. We think it unlikely that ABL-1 and ABI-1 act through DYN-1, since the CED-1 pathway has no known role in DTC migration, and ABL-1 and ABI-1 modulate DTC migration defects.

There are at least three models for how the ABL-1 and ABI-1 proteins act in engulfment and DTC migration. First, ABL-1 might directly inhibit ABI-1 from promoting engulfment of apoptotic cells and inappropriate DTC migration through a molecular pathway that acts in parallel to the known engulfment gene pathways (Figure 8). Second, ABL-1 might act on CED-10 Rac in parallel to the CED-5/CED-12 heterodimer (Figure 8). These models are not mutually exclusive. In a third model, the CED-10 Rac pathway and ABL-1 both act on ABI-1 in parallel to each other, with CED-10 Rac activating ABL-1 and ABL-1 inhibiting it. Studies of mammalian Abl proteins are consistent with the first two models. For example, Abl proteins are found in complexes with N-WASP [60] and the Formins [59]. Both N-WASP and formins act in actin cytoskeletal rearrangements independently of the CED-10 homolog Rac. C. elegans Abl-1 might act similarly in our first model. Abl proteins also form a complex with Eps8 and Sos-1. Formation of the Abl-1/Eps8/Sos-1 complex activates the RacGEF activity of Sos-1 in response to tyrosine kinase signaling [50,61]. ABI-1 might act this way in our second model. In mammals, Rac and Abl proteins both act on the Scar/WAVE complex through interactions with Abl proteins [53,69]. However, in these cases Abl activates Abl. By contrast, we found that ABL-1 inhibits ABI-1. For this reason we do not favor a model in which ABL-1 and CED-10 Rac act on ABI-1 in parallel.

Why Negatively Regulate Engulfment?

Despite the large number of genes known to be involved in engulfment, only a few negatively regulate the process. Loss of SWAN-1, a CED-10-binding protein, suppresses the engulfment and DTC migration defects caused by ced-10 loss of function, and SWAN-1 thus might be a negative regulator of these processes [70]. In mammalian macrophages and macrophage cell lines, the small GTPase Rac and one of its effectors, Rho-kinase, negatively regulate engulfment of apoptotic cells [71,72]. Rho, like Rac, regulates the cytoskeleton, and in many contexts the two proteins act in opposition to each other [20]. All Rac proteins are down-regulated by Rac-specific GTPases (RacGAPs) [73]. No RacGAPs have been identified that function in engulfment, though presumably one or more will be found.

Pathways that inhibit engulfment might prevent the inappropriate engulfment of healthy cells that are not programmed to die. There are examples of inappropriate engulfment of mammalian cells. In eosin, cells engulf and eventually kill neighboring cells that have lost their attachments to the extracellular matrix [74]. Also, the glycosylated surface protein SIRPα is found on engulfing cells and interacts with the integrin-associated protein CD47 on other viable cells. When that interaction is disrupted, inappropriate engulfment occurs [75]. Notably, the intracellular cascades that transduce these signaling events have not been discovered. Possibly abl-1 transduces these types of signals.

Perhaps there are conditions that cause cells to be particularly sensitive to engulfment, and without such negative regulatory pathways cells would be inappropriately killed. Since engulfment promotes the cell-killing process, several of the situations in which engulfment occurs could be severely affected by such excess cell death: organismal development, wound healing and infection control.

Targeting signaling pathways that negatively regulate engulfment might have therapeutic benefits. For example, inducing professional engulfing cells, such as macrophages, to engulf diseased cells, such as cancerous cells or those infected with viruses or bacteria, could aid in combating these disease processes. Also, in humans impaired engulfment of apoptotic cells or in viral or bacterial infections, targeting these pathways might aid in combating these diseases.
cells has been associated with systemic lupus erythematosus (SLE) [76] and in mice, ineffective engulfment of apoptotic cells can cause an SLE-like syndrome [77]. Enhancing the engulfment of apoptotic cells might aid in treating or preventing certain autoimmune disorders. Extremely effective and specific small molecule inhibitors of Abl, such as Imatinib [78] (Gleevec) and Nilotinib [79], exist so this idea could be tested.

Materials and Methods

Strains and genetics. C. elegans strains were maintained at 20 °C as described [80]. The N2 Bristol strain was used as the wild-type strain. Animals were grown on NGM plates and fed OP50 bacteria [42]. The mutations and integrants used were: LGI, ced-1(t1725), n2091; LGII, ab-1(tm494); LGIII, ced-1(n1813, n2095); LGV, ced-1(n1892); LGIV, ced-1(n1993, n3417), dpy-13(184sd), ges-3(nu1693), lin-1(1275), unc-24(e138), n1812, ced-10(n1993, n3417), dpy-13(184sd), ges-3(nu1693), lin-1(1275), unc-24(e138); LGV, unc-34(e566), gnt-116, unc-961, n1963, n1964 [all this study; see below], ok171, mgi-2738 m2013), n1306 [58]. Mutant allelic for which no citation is given were described previously [81]. Information about the two transgenic 100p alleles kindly provided by S. Kindt (University of Women’s Medical University, Japan) can be found at www.wormbase.org. The following balancer chromosomes were used: LGI; LGII, h2[flp[58]; LGIII, mhi-1[58]; LGIV, LGV, n1715[51].

Isolation of abl-1 alleles. abl-1 alleles (gm327, gm332, n1961, n1963, n1964) were isolated by separate genetic screens for mutations that suppressed the Unc locomotion phenotype of unc-34 mutants. unc-34 mutant C. elegans were mutagenized with ethyl methanesulfonate (EMS) as described [80]. The F2 progeny of mutagenized unc-34(e666) hermaphrodites representing 17,500 haploid genomes were inspected for the presence of animals with normal locomotion. Three strains were identified as containing candidate suppressors (n1961, n1963, n1964) [82], gm327 and gm332 were isolated in an F1 flonal screen. unc-34(e514) P0 hermaphrodites were mutagenized and allowed to lay eggs. Single F1 animals were transferred onto fresh plates daily. Two transgenes were screened as a non-unc phenotype: 10,952 haploid genomes were screened this way.

In addition to the five alleles of abl-1, five other mutations were isolated in the above screens. Complementation and mapping studies demonstrated that these five mutations defined a second complementation group and are alleles of the gene cem1-1 [83]. See Text S1 for a more detailed description of the complementation tests and mapping and the cloning of the abl-1 gene.

Quantitation of engulfment defects. Unengulfed apoptotic corpses were visualized in the heads of young larvae as refractile discs directly using Nomarski differential interference contrast (DIC) microscopy [39,84]. Apoptotic cell corpses were identified as containing candidate suppressors that had not passed the four-cell stage were viewed as described above. Briefly, the locations of the nuclei of the 16 cells that undergo programmed cell death in the anterior pharynx, animals in the third larval stage (L3) were anaesthetized and viewed with DIC microscopy as described in Wormbook (http://www.wormbook.org/chapters/). Images were analyzed with ImageJ 1.40 (rsbweb.nih.gov/ij/) using the plugins Manual Tracking (rsbweb.nih.gov/ij/plugins/track/track.html) and Ome Loci (http://www.loci.wisc.edu/ome/). p-Values for comparisons between strains were calculated using the Wilcoxon rank-sum test.

Quantitative analysis of the abl-1 promoter. A PCR product containing the abl-1 promoter (622 bp of DNA encoding the sequence between the 5’ end of the abl-1 gene and the adjacent gene start [B0336.3]) followed by the gfp gene coding sequence was constructed as described in Wormbook (http://www.wormbook.org/chapters/). The gfp gene coding sequence was cloned into pDEST-MB1 and pDEST-MB7 kindly provided by M. Boxem) using the Gateway method (Invitrogen), pDEST-MB1 and pDEST-MB7 are the plasmids pPR49.78 and pPR49.83, respectively, with Gateway cassettes inserted, allowing for Gateway cloning. The Pabl-1(gfp) plasmids have been described previously [12]. Pabl-1, Pabl-1 and Pabl-1 were injected into cad(e10)(df1993); abl-1(n1963) animals at a concentration of 20 ng/ul with a plasmid containing myo-2::rfp as a coinjection marker at 5 ng/ul and with 35 ng/ul of 1 Kb Plus DNA Ladder (Invitrogen) for a total concentration of 80 ng/ml per injection. The pharyngeal of transgenic animals were GFP-Positive.Embryos were grown at 20 °C, heat shock was given at 20 °C for 2 h. Four transgenic animals were scored in each experiment. GFP-positive animals that had not developed by the four-cell stage were viewed as described above. P-values for pairwise comparisons were calculated using the Student’s t-test.

Quantification of cell-death defects. For quantitation of cell-death defects in the anterior pharynx, animals in the third larval stage (L3) were anaesthetized and viewed with DIC microscopy as described above. Briefly, the locations of the nuclei of the 16 cells that undergo programmed cell death in the anterior pharynx are known [36]. In wild-type animals the level of cell death is approximately 2% by the L3 stage, if all of those nuclei have disappeared; any remaining nuclei in the animals tested were scored as extra cells. P-values for pairwise comparisons in the pharynges were calculated using Student’s t-test. For quantitation of cell-death defects in the ventral nerve cord, a dissecting microscope equipped with an ultraviolet light source (Kramer Scientific) was used. To analyze cell-death defects by the L3 stages, if all of those nuclei have disappeared; any remaining nuclei in the animals tested were scored as extra cells. P-values for pairwise comparisons between strains with wild-type abl-1 and mutant abl-1, we tested the null hypothesis that the median number of extra VC neuron-like cells in the wild-type strain was less than or equal to one more than the median number of VC neuron-like cells in the mutant strain. VC neuron-like cells were scored using the wild.type function of R (www.r-project.org).

Time-lapse microscopy. Gravid C. elegans were dissected, and embryos at the two-cell stage were placed at 20 °C for 180 min. Single embryos were then placed on an agar pad, sealed with petroleum jelly, and viewed at 22 °C using a Zeiss Axioskop 2 compound microscope equipped with Nomarski DIC accessories, a Hamamatsu ORCA-ER digital camera, and OpenLab image acquisition software (Improvision). Pictures were taken every 3 min for 200 min, starting 180 min after the first cell division. The time of appearance of each coordinate for each embryo was recorded. Forty serial z sections at 0.5 um/section were recorded. Recording began at 180 min after first cleavage, because the first apoptotic cell corpses appear at approximately 200 min after the first cell division [56]. Images were analyzed with ImageJ (http://rsb.info.nih.gov/ij/) using the plugins Manual Tracking (rsbweb.nih.gov/ij/plugins/track/track.html) and Ome Loci (http://www.loci.wisc.edu/ome/). p-Values for comparisons between strains were calculated using the Wilcoxon rank-sum test.

Expression analysis of the abl-1 promoter. A PCR product containing the abl-1 promoter (622 bp of DNA encoding the sequence between the 5’ end of the abl-1 gene and the adjacent gene start [B0336.5]) followed by the gfp gene coding sequence was constructed as described in Wormbook (http://www.wormbook.org/chapters/). The gfp gene coding sequence was cloned into pGFP[S656C] as a coinjection marker at 5 mg/ml, provided by M. Boxem) using the Gateway method (Invitrogen). Images were photographed using fluorescence microscopy and DIC microscopy.

RNA interference by feeding. Animals were fed bacteria that contained either the RNAi empty feeding vector L4440 [63] or an RNAi feeding vector with part of the abl-1 gene, B0336.6, cloned into the vector. Bacteria were transformed with the abl-1 plasmid from the plasmid. The DNA sequence of the clone was determined to verify its accuracy. Feeding RNAi was performed as described [63]. Briefly, bacteria were grown in liquid culture overnight and then plated on NGM plates containing 1 mM isopropyl-D-β-thiogalactoside (IPTG). Four independent non-unc transgenic lines were scored. DTC migration was scored as defective when the gonad was morphologically normal (extra turn, two arms, or bizarre twists) or when the gonad was short or long. Gonadal length was defined as abnormal when the gonad tip was distal to the ipsilateral spermatheca (short) or distal to the contralateral spermatheca (long). The vast majority of abnormalities in morphology than in length, p-Values for pairwise comparisons were calculated by Fisher’s exact test.

abl-1 rescue. Pabl-1 and Pabl-1(K340R) were constructed as follows. The entire coding sequence (bp 1–3,675) of abl-1 was synthesized by PCR from an abl-1 cDNA template (yk1483092, kindly provided by S. Kohara). The PCR product was cloned into the vector pCR8/GW/TOPO using the TA cloning kit (Invitrogen). The Pabl-1(K340R) was generated using the Quickchange Site-Directed Mutagenesis kit (Stratagene) from the pCR8/GW/TOPO plasmid containing the abl-1 PCR product described above using the following primers: forward: 5’-CGGACATGGCATGCAATATTGGGTTGAGCTTCGATGACTGCATGGC-3’; reverse: 5’-GGCGATGGCATCTTCT-CAACGCCTGCGACTCTGAATTTGTGCAGATCATGCCCC-3’. These primers created the K340R mutation. DNA sequences of PCR products were determined for accuracy and orientation. abl-1 products were then cloned into pDEST-MB1 and pDEST-MB7 kindly provided by M. Boxem) using the Gateway method (Invitrogen). Pabl-1 and Pabl-1 were analyzed for a more detailed description of the complementation tests and mapping and the cloning of the abl-1 gene.
The abl-1 products spanned bp 334–1,833 (ABL-1[112–611]) and 1,818–3,675 ABL-1[1096–1224] of yk148202, and the abl-1 product (ABL-1) spanned bp 47–1,456 of yk120412. PCR products were cloned into the vector pCR8/GW/TOPO using the TA cloning kit (Invitrogen). The cDNA product also spanned bp 47–1,456 of yk120412 but was missing bp 1,098–1,297. This construct was used as the starting point for UniqueChange Site-Directed Mutagenesis kit (Stratagen) with the CR8/GW/TOPO plasmid containing the full length abl-1 gene as a template and the following PCR primers: forward 5'-CCGACATGACCTCGACATGTCGGCATACTGTGATCTCTGTAAGATGCTGC-3'; reverse 5'-CCGACATGACCTCGACATGTCGGCATACTGTGATCTCTGTAAGATGCTGC-3'. DNA sequences of PCR products were determined for accuracy and orientation. abl-1 products were then cloned into pDEST14 using the Gateway method for expression in vitro. For ab-1 and abl-1 expression, GST fusions were made using the Gateway method for expression in E. coli. ABL-1 fragments were transcribed, translated, and labeled with 35S in vitro using the TNT T7 Quick coupled transcription/translation system (Promega) according to the manufacture’s protocol. GST and GST-ABI were expressed in BL21(DE3)-Ripl cells (BL21[DE3] Codon Plus [Strategen]). Beads lysates were prepared by lysis in a French Press in the presence of protease inhibitors (Roche Applied Science). Protein binding to glutathione beads was done as follows: Glutathione beads (GE Healthcare) were washed three times in NETN (0.5% NP-40, 20 mM Tris-Cl [pH 8], 100 mM NaCl, 1 mM EDTA) and then a 1:1 mixture of beads/NETN slurry was added to soluble GST, GST-ABI, or GST-ABI protein-bound beads containing equivalent amounts of GST, GST-ABI, or GST-ABI was added to 250 μl of a 100 mM HEPES [pH 7.6], 150 mM NaCl, 5 mM MgCl2, 0.1 mM EDTA, 0.02% Tween-20). Bead pellets were resuspended in 2X loading dye, boiled and separated on SDS-PAGE. Gels were stained with Coomassie Blue, dried, and exposed overnight on x-ray film. For quantitation of radioactivity, gels were exposed overnight on a phosphorimager screen and analyzed using a Typhoon 9400 Variable Mode Imager (Amersham Biosciences). Bands were quantified using ImageQuant 5.2 software (GE Healthcare).

**Supporting Information**

Figure S1. GFP::GEX-3 Localization Is Unchanged in Embryos Lacking ABL-1

unc-24(e138) ges-3(zu196) and unc-24(e138) ges-3(zu196); abl-1(ok171) embryos containing a rescuing gfp::gex-3 transgene were observed using a confocal microscope. (A, C, E, and G) are DIC micrographs and (B, D, F, and H) are epifluorescence micrographs. Dashed lines encircle corresponding regions in the fluorescence images.
