Low-energy-threshold analysis of the Phase I and Phase II data sets of the Sudbury Neutrino Observatory

DOI: 10.1103/PhysRevC.81.055504 PACS number(s): 26.65.+t, 13.15.+g, 14.60.Pq, 95.85.Ry

Results are reported from a joint analysis of Phase I and Phase II data from the Sudbury Neutrino Observatory. The effective electron kinetic energy threshold used is \( E_{\text{th}} = 3.5 \text{ MeV} \), the lowest analysis threshold yet achieved with water Cherenkov detector data. In units of \( 10^6 \text{ cm}^{-2} \text{s}^{-1} \), the total flux of active-flavor neutrinos from {}^{8}\text{B} decay in the Sun measured using the neutral current (NC) reaction of neutrinos on deuterons, with no constraint on the {}^{8}\text{B} neutrino energy spectrum, is found to be \( \Phi_{\text{NC}} = 5.140^{+0.160}_{-0.158}(\text{stat})^{+0.095}_{-0.081}(\text{syst}) \). These uncertainties are more than a factor of 2 smaller than previously published results. Also presented are the spectra of recoil electrons from the charged current reaction of neutrinos on deuterons and the elastic scattering of electrons.

A fit to the Sudbury Neutrino Observatory data in which the free parameters directly describe the total {}^{8}\text{B} neutrino flux and the energy-dependent \( \nu_e \) survival probability provides a measure of the total {}^{8}\text{B} neutrino flux \( \Phi_{8B} = 5.046^{+0.195}_{-0.192}(\text{stat})^{+0.107}_{-0.103}(\text{syst}) \). Combining these new results with results of all other solar experiments and the KamLAND reactor experiment yields best-fit values of the mixing parameters of \( \theta_{12} = 34.06^{+0.16}_{-0.15} \) degrees and \( \Delta m_{21}^2 = 7.59^{+0.20}_{-0.19} \times 10^{-5} \text{eV}^2 \). The global value of \( \Phi_{8B} \) is extracted to a precision of \( \pm 2.95\% \). In a three-flavor analysis the best fit value of \( \sin^2 \theta_{13} = 2.00^{+0.09}_{-0.13} \times 10^{-2} \) is achieved. This implies an upper bound of \( \sin^2 \theta_{13} < 0.057 \) (95\% C.L.).
I. INTRODUCTION

It is by now well-established that neutrinos are massive and mixed, and that these properties lead to the oscillations observed in measurements of neutrinos produced in the Sun [1–10], in the atmosphere [11], by accelerators [12,13], and by reactors [14]. The mixing model predicts not only neutrino oscillations in vacuum but also the effects of matter on the oscillation probabilities (the “MSW” effect) [15,16]. To date, the effects of matter have only been studied in the solar sector, where the neutrinos’ passage through the core of both the Sun and the Earth can produce detectable effects. The model predicts three observable consequences for solar neutrinos: a suppression of the $\nu_e$ survival probability below the average vacuum value of $1 - \frac{1}{2} \sin^2 2\theta_{12}$ for high-energy ($^8$B) neutrinos, a transition region between matter-dominated and vacuum-dominated oscillations, and a regeneration of $\nu_e$s as the neutrinos pass through the core of the Earth (the day/night effect). In addition to improved precision in the extraction of the total flux of $^8$B neutrinos from the Sun, an advantage of the low-energy-threshold analysis (LETA) presented here is the enhanced ability to explore the MSW-predicted transition region and, in addition, more stringent testing of theories of nonstandard interactions that affect the shape and position of the predicted rise in survival probability [17–24].

We present in this article a joint analysis of the data from the first two data acquisition phases of the Sudbury Neutrino Observatory (SNO), down to an effective electron kinetic energy of $T_{\text{eff}} = 3.5$ MeV, the lowest analysis energy threshold yet achieved for the extraction of neutrino signals with the water Cherenkov technique. The previous (higher threshold) analyses of the two data sets have been documented extensively elsewhere [7,8], and so we focus here on the improvements made to calibrations and analysis techniques to reduce the threshold and increase the precision of the results.

We begin in Sec. II with an overview of the SNO detector and physics processes and provide an overview of the data analysis in Sec. III. In Sec. IV we briefly describe the SNO Phase I and Phase II data sets used here. Section V describes changes to the Monte Carlo detector model that provides the improvements made to fit our data, and Sec. VI describes the improvements made to the hit-level calibrations of PMT times and charges that allow us to eliminate some important backgrounds.

Sections VII–IX describe our methods for determining observables like position and energy and estimating their systematic uncertainties. Section X describes the cuts we apply to our data set, while Sec. XI discusses the trigger efficiency and Sec. XII presents the neutron capture efficiency and its systematic uncertainties. We provide a detailed discussion of all background constraints and distributions in Sec. XIII. Section XIV describes our “signal extraction” fits to the data sets to determine the neutrino fluxes, and Sec. XV gives our results for the fluxes and mixing parameters.

II. THE SNO DETECTOR

SNO was an imaging Cherenkov detector using heavy water ($^2$H$_2$O, hereafter D$_2$O) as both the interaction and detection medium [25]. SNO was located in Vale Inco’s Creighton Mine, at $46^\circ 28’ 30”$ N latitude, $81^\circ 12’ 04”$ W longitude. The detector was 1783 m below sea level with an overburden of 5890 m water equivalent, deep enough that the rate of cosmic-ray muons passing through the entire active volume was just three per hour.

One thousand metric tons (tonnes) of D$_2$O was contained in a 12-m-diameter transparent acrylic vessel (AV). Cherenkov light produced by neutrino interactions and radioactive backgrounds was detected by an array of 9456 Hamamatsu model R1408 20-cm photomultiplier tubes (PMTs), supported by a stainless steel geodesic sphere (the PMT support structure or PSUP). Each PMT was surrounded by a light concentrator (a “reflector”), which increased the effective photocathode coverage to nearly 55%. The channel discriminator thresholds were set to 1/4 of a photoelectron of charge. Over seven kilotonnes ($7 \times 10^9$ kg) of H$_2$O shielded the D$_2$O from external radioactive backgrounds: 1.7 kT between the AV and the PSUP and 5.7 kT between the PSUP and the surrounding rock. Extensive purification systems were used to purify both the D$_2$O and the H$_2$O. The H$_2$O outside the PSUP was viewed by 91 outward-facing 20-cm PMTs that were used to identify cosmic-ray muons. An additional 23 PMTs were arranged in a rectangular array and suspended in the outer H$_2$O region to...
view the neck of the AV. They were used primarily to reject events not associated with Cherenkov light production, such as static discharges in the neck.

The detector was equipped with a versatile calibration-source deployment system that could place radioactive and optical sources over a large range of the x-z and y-z planes (where z is the central axis of the detector) within the D2O volume. Deployed sources included a diffuse multilamewrench laser that was used to measure PMT timing and optical parameters (the “laserball”) [26], a 16N source that provided a triggered sample of 6.13-MeV γ's [27], and a 8Li source that delivered tagged βs with an end point near 14 MeV [28]. In addition, 19.8-MeV γ's were provided by a 3H(p, γ)He (“pT”) source [29] and neutrons by a 252Cf source. Some of the sources were also deployed on vertical lines in the H2O between the AV and PSUP. “Spikes” of radioactivity (24Na and 222Rn) were added at times to the light water and D2O volumes to obtain additional calibration data. Table I lists the primary calibration sources used in this analysis.

SNO detected neutrinos through three processes [30]:

\[
\begin{align*}
\nu_e + e^- &\rightarrow \nu_e + e^-, \quad \text{(ES)} \\
\nu_e + d &\rightarrow p + p + e^-, \quad \text{(CC)} \\
\nu_e + d &\rightarrow p + n + \nu_e', \quad \text{(NC)}
\end{align*}
\]

For both the elastic scattering (ES) and charged current (CC) reactions, the recoil electrons were detected directly through their production of Cherenkov light. For the neutral current (NC) reaction, the neutrons were detected via de-excitation γ's following their capture on another nucleus. In SNO Phase I (the “D2O phase”), the detected neutrons captured predominantly on the deuterons in the D2O. Capture on deuterium releases a single 6.25-MeV γ ray, and it was the Cherenkov light of secondary Compton electrons or e⁺e⁻ pairs that was detected. In Phase II (the “salt phase”), 2 tonnes of NaCl were added to the D2O, and the neutrons captured predominantly on 35Cl nuclei, which have a much larger neutron capture cross section than deuterium nuclei, resulting in a higher neutron detection efficiency. Capture on chlorine also releases more energy (8.6 MeV) and yields multiple γ's, which aids in identifying neutron events.

The primary measurements of SNO are the rates of the three neutrino signals, the energy spectra of the electrons from the CC and ES reactions, and any asymmetry in the day and night interaction rates for each reaction. Within the Phase I and II data sets, we cannot separate the neutrino signals on an event-by-event basis from each other or from backgrounds arising from radioactivity in the detector materials. Instead, we “extracted” the signals and backgrounds statistically by using the fact that they are distributed differently in four observables: effective kinetic energy (\(T_{\text{eff}}\)), which is the estimated energy assuming the event consisted of a single electron, cube of the reconstructed radial position of the event (\(R^3\)), reconstructed direction of the event relative to the direction of a neutrino arriving from the Sun (\(\cos \theta_{\odot}\)), and a measure of event “isotropy” (\(\beta_{14}\)), which quantifies the spatial distribution of PMT hits in a given event (Sec. IX). Low values of \(\beta_{14}\) indicate a highly isotropic distribution.

Figure 1 shows the one-dimensional projections of the distributions of these observables for the three neutrino signals, showing CC and ES in Phase II and NC for both data sets. The Phase II distributions are normalized to integrate to 1 except in Fig. 1(c), in which the CC and NC distributions are scaled by a factor of 10 relative to ES for the sake of clarity. The Phase I NC distributions are scaled by the ratio of events in the two phases to illustrate the increase in Phase II. In the figure, and throughout the rest of this article, we measure radial positions in units of AV radii, so \(R^3 \equiv (R_{AV}/R_{AV})^3\). Figure 2 shows the same distributions for some of the detector backgrounds, namely “internal” 214Bi and 208Tl (within the D2O volume) and “AV” 208Tl (generated within the bulk acrylic of the vessel walls). While some of the 214Bi nuclei came from decays of intrinsic 238U, the most likely source of 214Bi was from decays of 222Rn entering the detector from mine air. The 208Tl nuclei came largely from decays of intrinsic 232Th. Near the \(T_{\text{eff}} = 3.5\) MeV threshold the dominant signal was from events originating from radioactive decays in the PMTs. These events could not be generated with sufficient precision using the simulation, and so were treated separately from other event types, as described in Sec. XIII C. There were many other backgrounds; these are described in Sec. XIII.

The energy spectra provide a powerful method for separating different event types. The CC and ES spectra depend on the shape of the incident neutrino spectrum. We treated the CC and ES spectra in two different ways: in one fit we made no model assumptions about the underlying spectral shape, allowing the CC and ES spectra to vary in the fit, and in a second fit we...
assumed that the underlying incident neutrino spectrum could be modeled as a smoothly distorted $^8\text{B}$ spectrum. The shapes of NC and background spectra do not depend on neutrino energy and so were fixed in the fit, to within the systematic uncertainties derived later. Decays of $^{214}\text{Bi}$ and $^{208}\text{Tl}$ in the detector both led to $\gamma$ rays above the deuteron binding energy.
of 2.2 MeV, which created higher energy events when the photodisintegration neutron was subsequently captured on either deuterium (Phase I) or predominantly $^{35}$Cl (Phase II). A significant fraction of $^{214}$Bi decays produce a 3.27-MeV-end point $\beta$. These background events are therefore characterized by steeply falling energy spectra with a photodisintegration tail, as shown in Fig. 2(a).

CC and ES events produced single electrons and, hence, the observed light from these events was fairly anisotropic, yielding a correspondingly high value for the isotropy parameter, $\beta_{14}$. The $\beta_{14}$ distributions show small differences due to the different energy spectra of the two event types, which affects $\beta_{14}$ through the known correlation between energy and isotropy of an event. The isotropy of Phase I NC events looks similar to that of CC and ES events, because the $\gamma$ ray tended to produce light dominated by that from one Compton electron. By contrast, the isotropy distribution of Phase II NC events is peaked noticeably lower because neutron capture on $^{35}$Cl atoms nearly always resulted in multiple $\gamma$s, which could each scatter an electron and, hence, produce a more isotropic PMT hit pattern. Therefore, $\beta_{14}$ provides a sensitive method for separation of electron-like events from neutron capture events in this phase, without requiring a constraint on the shapes of the CC and ES energy spectra, thus providing an oscillation-model-independent measurement of the flux of solar neutrinos. The isotropy distributions for $^{214}$Bi events and $^{208}$Tl events inside the heavy water are noticeably different because, above the $T_{\text{eff}} = 3.5$ MeV threshold, Cherenkov light from $^{214}$Bi events was dominated by that from the ground state $\beta$ branch while that from $^{208}$Tl events was from a $\beta$ and at least one additional Compton electron. The difference allowed these events to be separated in our fit, as was done in previous SNO in situ estimates of detector radioactivity [7,8].

The $\cos \theta_C$ distribution is a powerful tool for distinguishing ES events since the scattering of $\nu_e$ from the Sun resulted in electron events whose direction is strongly peaked away from the Sun’s location. The direction of CC events displays a weaker correlation of $\sim (1 - \frac{1}{4} \cos \theta_C)$ relative to the direction of the Sun. The NC distribution is flat since the $\gamma$s generated by neutron capture carried no information about the incident neutrino direction. Background events had no correlations with the Sun’s location and, thus, also exhibit a flat distribution, as shown in Fig. 2(c).

The radial position of events within the detector yields a weak separation between the three neutrino interaction types but a much more powerful level of discrimination from external background events. CC and ES events occurred uniformly within the detector and hence have relatively flat distributions. NC events occurred uniformly, but neutrons produced near the edge of the volume were more likely to escape into the AV and H$_2$O regions, where the cross section for neutron capture was very high due to the hydrogen content. Neutron capture on hydrogen produced 2.2-MeV $\gamma$s, below the analysis threshold and thus less likely to be detected. Therefore, the radial profile of NC events falls off at the edge of the volume. This effect is more noticeable in Phase I, since the neutron capture efficiency on deuterium is lower than on $^{35}$Cl and, hence, the neutron mean-free path was longer in Phase I than in Phase II.

### III. ANALYSIS OVERVIEW

The LETA analysis differs from previous SNO analyses in the joint fit of two phases of data, the much lower energy threshold (which both result in increased statistics), and significantly improved systematic uncertainties. The neutrino signal rates were determined by creating probability density functions (PDFs) from distributions like those in Figs. 1 and 2 and performing an extended maximum likelihood fit to the data. The CC and ES spectra were determined by either allowing the flux to vary in discrete energy intervals (an “unconstrained fit”) or by directly parameterizing the $v_e$ survival probability with a model and fitting for the parameters of the model. There were three major challenges in this analysis: reduction of backgrounds, creation of accurate PDFs (including determination of systematic uncertainties on the PDF shapes), and extracting the neutrino signals, energy spectra, and survival probabilities from the low-threshold fits.

Three new techniques were applied to reduce backgrounds compared to previous SNO analyses [7,8]. First, we made substantial improvements to energy reconstruction by developing a new algorithm that included scattered and reflected light in energy estimation. The inclusion of “late light” narrowed the detector’s effective energy resolution by roughly 6%, substantially reducing the leakage of low-energy background events into the analysis data set by $\sim 60\%$. Second, we developed a suite of event-quality cuts using PMT charge and time information to reject external background events whose reconstructed positions were within the fiducial volume. Third, we removed known periods of high radon infiltration that occurred during early SNO runs and when pumps failed in the water purification system.

Creation of the PDFs was done primarily with a Monte Carlo (MC) simulation that included a complete model of physics processes and a detailed description of the detector. We made substantial improvements to the Monte Carlo model since our previous publications, and we describe these improvements in detail in Sec. V.

Our general approach to estimating systematic uncertainties on the Monte Carlo–simulated PDF shapes was based on a comparison of calibration source data to Monte Carlo simulation, as in previous SNO analyses. In cases where the difference between calibration data and simulation was inconsistent with zero, and we had evidence that the difference was not caused by a mismodeling of the calibration source, we corrected the PDF shapes to better match the data. For example, we applied corrections to both the energy (Sec. VIII) and isotropy (Sec. IX) of simulated events. Any residual difference was used as an estimate of the uncertainty on the Monte Carlo predictions. Corrections were verified with multiple calibration sources, such as the distributed “spike” sources as well as encapsulated sources, and additional uncertainties were included to account for any differences observed between the various measurements. Uncertainties were also included to take into account possible correlations of systematic effects with the observable parameters. So, for example, we allowed for an energy dependence in the fiducial volume uncertainty, and the uncertainty on the energy scale was evaluated in...
a volume-weighted fashion to take into account possible variations across the detector.

The final extraction of signal events from the data was a multidimensional, many-parameter fit. Although marginal distributions like those shown in Figs. 1 and 2 could be used as PDFs, in practice there are nontrivial correlations between the observables that can lead to biases in the fit results. We therefore used three-dimensional PDFs for most of the backgrounds and for the NC signal, factoring out the dimension in $\cos \theta_{13}$, which is flat for these events. The CC and ES events had PDFs whose dimensionality depended on the type of fit. For the unconstrained fit, we used three-dimensional PDFs in $(R^3, \beta_{14}, \cos \theta_{23})$, factoring out the $T_{\text{eff}}$ dimension because the fit was done in discrete intervals, within which the $T_{\text{eff}}$ spectrum was treated as flat. For the direct fit for the $\nu_e$ survival probability, we used fully four-dimensional PDFs for the CC and ES signals.

The parameters of the “signal extraction” fits were the amplitudes of the signals and backgrounds, as well as several parameters that characterized the dominant systematic uncertainties. A priori information on backgrounds and systematic uncertainties was included. To verify the results, we pursued two independent approaches, one using binned and the other unbinned PDFs. We describe both approaches in Sec. XIV.

We developed and tuned all cuts using simulated events and calibration source data. Signal extraction algorithms were developed on Monte Carlo “fake” data sets and tested on a 1/3-livetime sample of data. Once developed, no changes were made to the analysis for the final fit at our analysis threshold on the full data set.

In treating systematic uncertainties on the PDF shapes, we grouped the backgrounds and signals into three classes: “electron-like” events, which include true single-electron events as well as those initiated via Compton scattering from a single $\gamma$; neutron capture events on chlorine that produced a cascade of many $\gamma$s with a complex branching table; and PMT $\beta$-$\gamma$ decays, which occurred in the glass or envelope of the PMT assembly and support structure. The PMT $\beta$-$\gamma$ events were treated separately from other $\beta$-$\gamma$ events because they were heavily influenced by local optical effects near the PMT concentrators and support structure and are therefore hard to model or simulate. The analysis results presented here have substantially reduced uncertainties on the neutrino interaction rates, particularly for SNO’s signature neutral current measurement. Although there are many sources of improvement, the major causes are:

(i) the lower energy threshold increased the statistics of the CC and ES events by roughly 30% and of the NC events by $\sim$70%;
(ii) in a joint fit, the difference in neutron detection sensitivity in the two phases provided improved neutron/electron separation, beyond that due to differences in the isotropy distributions;
(iii) significant background reduction due to improved energy resolution, removal of high radioactivity periods, and new event quality cuts;
(iv) use of calibration data to correct the PDF shapes.

IV. DATA SETS

The Phase I and Phase II data sets used here have been described in detail elsewhere [7,8]. We note only a few critical details.

SNO Phase I ran from November 2, 1999 to May 31, 2001. Periods of high radon in Phase I were removed for this analysis based on the event rate. To minimize bias, we used Chauvenet’s criterion to eliminate runs in which the probability of a rate fluctuation as high or higher than observed was smaller than 1/(2$N$), where $N$ is the total number of runs in our data set ($\sim$500). With this cut, we reduced the previously published 306.4 live days to 277.4. Most of the runs removed were in the first 2 months of the phase or during a period in which a radon degassing pump was known to have failed. This $\sim$9% reduction in livetime removed roughly 50% of all $^{214}\text{Bi}$ events from the Phase I data set. SNO Phase II ran from July 2001 to August 2003, for a total of 391.4 live days.

SNO had several trigger streams, but the primary trigger for physics data required a coincidence of $N_{\text{conc}}$ or more PMT hits within a 93-ns window. From the start of Phase I until December 20, 2000, $N_{\text{conc}}$ was set to 18; it was subsequently lowered to 16 PMT hits. This hardware threshold is substantially below the analysis threshold, and no efficiency correction was required, even at 3.5 MeV (see Sec. XI).

V. MONTE CARLO SIMULATION

SNO’s Monte Carlo simulation played a greater role here than in previous publications, as we used it to provide PDFs of not only the neutrino signals but for nearly all backgrounds as well. The simulation included a detailed model of the physics of neutrino interactions and of decays of radioactive nuclei within the detector. Propagation of secondary particles was done using the EGS4 shower code [31], with the exception of neutrons, for which the MCNP [32] neutron transport code developed at Los Alamos National Laboratory was used. Propagation of optical photons in the detector media used wavelength-dependent attenuations of D$_2$O and H$_2$O that were measured in situ with laserball calibrations and acrylic attenuations measured ex situ. The simulation included a detailed model of the detector geometry, including the position and orientation of the PSUP and the PMTs, the position and thickness of the AV (including support plates and ropes), the size and position of the AV “neck,” and a full three-dimensional model of the PMTs and their associated light concentrators. SNO’s data acquisition system was also simulated, including the time and charge response of the PMTs and electronics. Details of the simulation have been presented in Refs. [7,8]; we describe here the extensive upgrades and changes that were made for this analysis.

Ultimately, SNO’s ability to produce accurate PDFs depends on the ability of the Monte Carlo simulation to reproduce the low-level characteristics of the data, such as the distributions of PMT hit times and charges. We therefore improved our timing model to more correctly simulate the “late pulsing” phenomenon seen in the Hamamatsu R1408s used by SNO. We also added a complete model of the PMT single photoelectron charge distribution that includes PMT-to-PMT...
variations in gain. Gain measurements were made monthly with the laserball source at the center of the detector, and the simulation uses different charge distributions for each PMT according to these gain measurements.

Addition of the more complete charge spectrum also allowed us to add a detailed model of each electronics channel’s discriminator. On average, the threshold voltage was near 1/4 of that for a single photoelectron, but there were large variations among channels because of variations in noise level. Over time, the channel thresholds were adjusted as PMTs became quieter or noisier; these settings were used in the simulation for each run. The discriminator model also provided for channel-by-channel efficiencies to be included, thus improving simulation of the detector’s energy resolution.

We made several important changes to the optical model as well. The first was a calibration of PMT efficiencies, which accounted for tube-to-tube variations in the response of the photomultipliers and light concentrators. These efficiencies are distinct from the electronics discriminator efficiency described above, as they depended on the PMT quantum efficiency, local magnetic field, and individual concentrator reflectivity, while the discriminator efficiency depended on PMT channel gain and threshold setting. The PMT efficiencies were measured using the laserball, as part of the detector’s full optical calibrations, which were performed once in Phase I and three times in Phase II. The efficiencies in the simulation were varied over time accordingly.

The light concentrators themselves are known to have degraded over time and the three-dimensional model of the collection efficiency of the PMT-concentrator assembly used in previous analyses had to be modified. We developed for this analysis a phenomenological model of the effects of the degradation to the concentrator efficiency. Rather than modifying the concentrator model itself, we altered the PMT response as a function of the position at which the photon struck the photocathode. In effect, this produced a variation in the response of the concentrator and PMT assembly as a function of photon cathode angle. A simultaneous fit was performed to laserball calibration data at six wavelengths, with each wavelength data set weighted by the probability that a photon of that wavelength caused a successful PMT hit. The extraction of optical calibration data was extended to a larger radius than in previous analyses, in order to extract the PMT response at wider angles. Ex situ data were also included in the fit to model the response at >40° for events in the light water region. Time dependence was accommodated by performing separate fits in time intervals defined by the available calibration data: one interval in Phase I and three in Phase II. This change improved the modeling of any position dependence of the energy response but did not affect the overall energy scale, which was calibrated using the $^{16}$O source. We also made a global change to the light concentrator reflectivity based on measurements with the $^{16}$O source. Figure 3 compares the new model of the PMT-concentrator response as a function of incidence angle to that used in earlier publications.

The laserball calibration data were used as a direct input to the energy reconstruction algorithms, providing media attenuations, PMT angular response measurements, and PMT efficiencies. For wavelengths outside the range in which data were taken, the Monte Carlo simulation was used to predict the response.

VI. HIT-LEVEL CALIBRATIONS

The accuracy with which we know the charge and time of each PMT hit directly affects event position and energy uncertainties. To calibrate the digitized charges and time, we performed pulser measurements twice weekly, measuring pedestals for the charges and the mapping of ADC counts to nanoseconds for the times. The global channel-to-channel time offsets and the calibration of the pulse rise-time corrections were done with the laserball source deployed near the center of the detector. These calibrations have been described elsewhere [7].

Four significant changes were made to the calibration of PMT charges and times. The first was the removal of hits associated with channel-to-channel crosstalk. Crosstalk hits in the SNO electronics were characterized by having low charges, slightly late times, and being adjacent to a channel with very high charge.

The second change was a correction to the deployed positions of the laserball source to ensure that the time calibrations were consistent between calibration runs. Prior to this correction, the global PMT offsets had been sensitive to the difference between the nominal and true position of the source, which varied from calibration run to calibration run. The new correction reduced the time variations of the PMT calibrations noticeably, but there was a residual 5-cm offset in the reconstructed $z$ position of events, for which a correction was applied to all data.

There were a variety of ways in which PMTs could fail, and we therefore applied stringent criteria for a PMT to be included in position and energy reconstruction. The criteria were applied to both calibration and “neutrino” data sets as well as to run simulations.

The last improvement was a calibration to correct for a rate dependence in the electronics charge pedestals. Crosstalk hits were used to monitor the pedestal drift and a time-varying
correction was applied. With this correction we could use the PMT charge measurements to remove certain types of background events, and to substantially reduce systematic uncertainties on the energy scale associated with variations in PMT gain, which affected the photon detection probability.

Figure 4 shows the distributions of PMT time-of-flight residuals and measured photoelectron charges for a $^{16}$N calibration run at the center of the detector compared to a simulation of that run. The simulation includes the upgrades discussed in Sec. V. The time residuals show excellent agreement in the dominant prompt peak centered near $\Delta t = 0$ ns, as well as good agreement for the much smaller prepulsing ($\Delta t \sim -20$ ns) and late-pulsing ($\Delta t \sim 15$ ns and $\Delta t \sim 35$ ns) features. For the charge distribution, the agreement is also excellent above 10 ADC counts or so, which corresponds to the majority of the charges used in the analysis. Thus, we are confident that the simulation models the behavior of reconstruction and cuts with sufficient accuracy.

VII. POSITION AND DIRECTION RECONSTRUCTION

The primary reconstruction algorithm used in this analysis was the same as in previous Phase I publications. We used reconstructed event position and direction to produce the PDFs shown in Figs. 1 and 2 and to reject background events originating outside the AV. Knowledge of event position and direction was also used in the estimation of event energy (see Sec. VIII). Below we outline the reconstruction method, and then discuss the uncertainties in our knowledge of event positions and directions.

A. Reconstruction algorithm

The vertex and direction reconstruction algorithm fitted event position, time, and direction simultaneously using the hit times and locations of the hit PMTs. These values were found by maximizing the log-likelihood function,

$$\log L(\vec{r}_e, \vec{v}_e, t_e) = \sum_{i=1}^{N_{hit}} \log P(t^*_{i, \text{res}}, \vec{r}_i; \vec{r}_e, \vec{v}_e, t_e),$$  

(1)

with respect to the reconstructed position ($\vec{r}_e$), direction ($\vec{v}_e$), and time ($t_e$) of the event. $P(t^*_{i, \text{res}}, \vec{r}_i; \vec{r}_e, \vec{v}_e, t_e)$ is the probability of observing a hit in PMT $i$ (located at $\vec{r}_i$) with PMT time-of-flight residual $t^*_{i, \text{res}}$ [Eq. (2)], given a single Cherenkov electron track occurring at time $t_e$ and position $\vec{r}_e$, with direction $\vec{v}_e$. The sum is over all good PMTs for which a hit was recorded. The PMT time-of-flight residuals relative to the hypothesized fit vertex position are given by:

$$t^*_{i, \text{res}} = t_i - t_e - |\vec{r}_i - \vec{r}_e| n_{\text{eff}} \frac{c}{n},$$  

(2)

where $t_i$ is the hit time of the $i$th PMT. The photons are assumed to travel at a group velocity $c/n$, with $n_{\text{eff}}$ an effective index of refraction averaged over the detector media.

The probability $P$ contains two terms to allow for the possibilities that the detected photon arrived either directly from the event vertex ($P_{\text{direct}}$) or resulted from reflections, scattering, or random PMT noise ($P_{\text{other}}$). These two probabilities were weighted based on data collected in the lazerball calibration runs.

The azimuthal symmetry of Cherenkov light about the event direction dilutes the precision of reconstruction along the event direction. Thus, photons that scattered out of the Cherenkov cone tended to systematically drive the reconstructed event vertex along the fitted event direction. After initial estimates of position and direction were obtained, a correction was applied to shift the vertex back along the direction of the event to compensate for this systematic drive. The correction varied with the distance of the event from the PSUP as measured along its fitted direction.

The reconstruction algorithm returned a quality-of-fit statistic relative to the hypothesis that the event was a correctly reconstructed single electron. This statistic was used later in the analysis to remove backgrounds and reduce tails on the reconstruction resolution. Details of the reconstruction algorithm can be found in Ref. [7].

B. Uncertainties on position and direction

Many effects that could produce systematic shifts in reconstructed positions were modeled in the simulation. Data from calibration sources deployed within the detector were compared to Monte Carlo predictions, and the differences were used to quantify the uncertainty on the simulation. The observed differences were not deemed significant enough to warrant applying a correction to the Monte Carlo–generated positions, and so the full size of the difference was taken as the magnitude of the uncertainty. The differences between data and Monte Carlo events were parameterized as four types:
(i) vertex offset: a constant offset between an event’s true and reconstructed positions;
(ii) vertex scale: a position-dependent shift of events either inward or outward;
(iii) vertex resolution: the width of the distribution of reconstructed event positions;
(iv) angular resolution: the width of the distribution of reconstructed event directions relative to the initial electron direction.

These uncertainties can have an impact on the flux and spectral measurements in two ways: by altering the prediction for the number of events reconstructing inside the fiducial volume and by affecting the shape of the PDFs used in the signal extraction.

Reconstruction uncertainties were determined primarily from $^{16}$N source data. In previous analyses [7], the volume density of Compton-scattered electrons relative to the source location was modeled with the analytic function $S(r) \sim \exp(-\frac{r}{\sigma})/r^2$. Model improvements for this analysis allowed us to extract this distribution for each $^{16}$N source run from the Monte Carlo simulation of that run and take into account the exact source geometry, effect of data selection criteria on the distribution, and any time-dependent detector effects.

The distribution of electron positions was convolved with a Gaussian, representing the detector response, and the resulting function was fit to the one-dimensional reconstructed position distribution along each axis, allowing both the mean and standard deviation of the Gaussian to vary for each orthogonal axis independently. An example of such a fit is shown in Fig. 5. This fit was done separately for the $^{16}$N data and the Monte Carlo simulation of each $^{16}$N run. The difference in the Gaussian means gives the vertex offset for that run and the square root of the difference in the variances represents the difference in vertex resolution.

1. Vertex offset

Analysis of the differences between the reconstructed and true event vertex positions at the center of the detector, or “central vertex offset,” was done using runs with the source within 25 cm of the center, where the source position is known most accurately. This avoids confusion with any position-dependent effects, which are taken into account in the scale measurement (Sec. VII B2). A data-MC offset was determined for each run, along each detector axis. The offsets from the runs were combined in weighted averages along each axis, with the uncertainty for each run offset increased to include the uncertainty in source position. Although the results showed a small mean offset along each axis, the magnitude was comparable to the source position uncertainty and therefore we did not correct the PDFs based on this difference. Instead, asymmetric double-sided uncertainties were formulated by using the uncertainty in the weighted average and increasing it by the magnitude of the weighted average itself on the side on which the offset was measured. The effects of these uncertainties were determined during signal extraction by shifting the position of each event by the positive and negative values of the uncertainty along each axis independently and recomputing the PDFs. The values of the uncertainties are given in Table II in Sec. VII B6.

2. Vertex scale

A potential position-dependent bias in the reconstructed position that can be represented as being proportional to the distance of the event from the center of the detector is defined as a vertex scale systematic.

In previous SNO analyses, uncertainty in the position of the calibration source was a major contribution to reconstruction uncertainties, especially away from the $z$ axis of the detector, where sources were deployed in a less accurate mode. A new method was derived for this analysis to reduce sensitivity to this effect. Although the absolute source position was known only to $\sim 2$ cm on the $z$ axis and $\sim 5$ cm away from this axis, changes in position once the source was deployed were known with much greater precision. By comparing the result from each $^{16}$N run to a run at the center of the detector from the same deployment scan, possible offsets between the recorded and true source position were removed, thus reducing source position uncertainties. In addition, any constant offset in vertex position, such as that measured in Sec. VII B1, was inherently removed by this method, thus deconvolving the measurement of scale from offset. This method allowed data from different scans to be combined, providing a more representative sampling across the time span of the data set and improving the statistics of the measurement.

Vertex scale was investigated by using the data-MC reconstructed position offset along each detector axis, as shown in Fig. 6, using only runs within 50 cm of that axis to minimize correlations among the three. The runs were grouped into 50-cm bins along each axis by source position, and the weighted average of the offsets for the runs within each bin was found. A linear function was fit to the bins as a function of position along that axis. Since the method was designed to remove any central vertex offset, the function was defined to be zero at the center of the detector.

The slope from the fit provides the scaling required to bring the simulation into agreement with data. We did not apply a correction but instead treated it as an asymmetric
uncertainty on the reconstructed positions of all events. The effects observed along the \(x\) and \(y\) axes were of a very similar magnitude and, therefore, were assumed to be due to a radial effect, possibly caused either by small errors in the modeling of the wavelength-dependent refractive index or residual PMT timing calibration errors. Conservatively, the larger of the \(x\) and \(y\) values was used to bound this effect. The resulting uncertainty was applied in our signal extraction fits by multiplying the \(x\), \(y\), and \(z\) position of each event in our PDFs by the value of the scale uncertainty, thus shifting events either inwards or outwards in the detector and taking the difference from the nominal fit. Since the effect observed along the \(z\) axis was larger, the difference of this from the radial effect was treated as an additional uncertainty, applied only to the \(z\) position of events. The values used for each uncertainty are listed in Table II in Sec. VII B6.

Since only runs within 50 cm of each Cartesian axis were used to determine vertex scale, diagonal axis runs could be used for verification. The method described measured the scale used to determine vertex scale, diagonal axis runs could be listed in Table II in Sec. VII B6.

A similar analysis was performed using \(^{252}\text{Cf}\) source data in Phase II. The results were consistent with those shown here, verifying that the same uncertainties could be applied to both electron-like and neutron capture events.

We investigated several other potential causes of variation in reconstruction accuracy. The \(^{16}\text{N}\)-source event rate during most calibration runs was high in comparison to our expected neutrino event rate, so the results were checked using low-rate \(^{16}\text{N}\) data. The stability over time was determined by comparing runs across the span of the two phases. As in previous analyses \([7]\), calibration-source dependence was investigated by verifying \(^{16}\text{N}\) results using the \(^{8}\text{Li}\) source. This also provides a check on the energy dependence because the \(^{8}\text{Li}\) data extended to higher energies than the \(^{16}\text{N}\) data. The results were all consistent within the uncertainties presented here.

The position resolution achieved in this analysis was \(\sim 20\) cm for data events. The difference in resolutions between data and Monte Carlo events was modeled as a Gaussian of standard deviation (or “width”) \(\sigma_{\text{extra}}\), by which the Monte Carlo distribution should be smeared to reproduce the data. \(\sigma_{\text{extra}}^2\) was given by \((\sigma_{\text{Data}}^2 - \sigma_{\text{MC}}^2)\) for each \(^{16}\text{N}\) run. This procedure is valid only for \(\sigma_{\text{MC}} < \sigma_{\text{Data}}\), which was the likely scenario since any minor detector nonuniformities tended to cause a broader resolution in the data. In some cases, the simulation and data were close enough to one another that statistical variation caused \(\sigma_{\text{Data}}\) to appear to be less than \(\sigma_{\text{MC}}\). In these cases, \(|(\sigma_{\text{Data}}^2 - \sigma_{\text{MC}}^2)|\) was taken to represent the uncertainty in the comparison. The results from the runs were combined in a weighted average, independently for each detector axis. The resulting values for \(\sigma_{\text{extra}}\) are listed in Table II in Sec. VII B6. These were applied during the signal extraction by smearing the positions of all Monte Carlo events by a Gaussian of the appropriate width. This was achieved for the binned signal extraction (Sec. XIV B) by generating a random number for each event from a Gaussian of the correct width and adding the result to the event’s position and, for the unbinned method, by a direct analytic convolution (Sec. XIV C).

The \(^{16}\text{N}\) source was used for this measurement by relying on the high degree of colinearity of Compton scattered electrons with the initial \(\gamma\) direction. The mean of the distribution of reconstructed event positions was used to estimate the source position. The reconstructed event position was used as an estimate for the scattering vertex. To reduce the effect of reconstruction errors, only events reconstructing more than 120 cm from the source were used. The angle between the initial \(\gamma\) direction (taken to be the vector from the source position to the fitted scattering vertex) and the reconstructed

\end{align*}\]

3. Vertex resolution

4. Angular resolution
An additional check was performed using neutrino data from outside the fiducial volume. All standard analysis cuts were applied, as described in Sec. X, as well as a 5.5-MeV threshold to select a clean sample of neutrino events. A Hill function was fit to the radial distribution of the events, with the half-point of the function representing the position of the AV. Statistics in the data were limited, so the fit was performed in just three energy bins. Monte Carlo simulation of the three types of neutrino interactions was combined in the signal ratios found in a previous SNO analysis [8] and the same fit was performed. The ratio of the resulting fitted AV position in the data and simulation is a measure of the radial scaling and, therefore, the energy dependence of this ratio is a check on the analysis described above. The results were in good agreement. In Phase II the energy dependence was 0.8 ± 2.1%/MeV, in comparison to −0.07 ± 0.41%/MeV measured using the $^8$Li source.

6. Summary of reconstructed position uncertainties

Table II summarizes the uncertainties in reconstructed position and direction.

It is worth noting that in previous analyses [8] the radial scaling uncertainty was evaluated at ±1%, which translates to a 3% uncertainty in fiducial volume. The improved analysis presented here has reduced the scale uncertainty to a little over 0.5% at its maximum and significantly less in most dimensions. The resolution differences observed previously were on the order of 9 cm [7], whereas the differences measured here are roughly one-third that in most dimensions. The angular

VIII. ENERGY RECONSTRUCTION

We estimated the kinetic energy of an event after its position and direction were reconstructed. The energy estimate was used both to reject background events and to produce the PDFs shown in Figs. 1 and 2. Improving the resolution of the energy estimation algorithm was critical because of the low energy threshold of the analysis—a 6% improvement in energy resolution reduces the number of background events reconstructing above threshold by \(\sim 60\%\).

A. Total light energy estimator

A new algorithm, called FTK, was designed to use all the detected PMT hits in the energy estimate, including scattered and reflected light [33]. The look-up table approach of the prompt-light fitter used in previous publications was abandoned in favor of a maximum likelihood method, in which photon detection probabilities were generated based on the reconstructed event position and direction. The best value of the effective kinetic energy, \(T_{\text{eff}}\), was found by maximizing the likelihood given the observed number of hit PMTs, \(N_{\text{hit}}\), and taking into account optical effects due to the reconstructed position and direction of the event. In principle, one could consider a more sophisticated approach in which both the number and distribution of all hit PMTs are used along with the recorded time of each hit, but such an approach is much more time intensive and was judged to be impractical for the present analysis.

We considered five sources of PMT hits in an event, defined by the following quantities:

(i) \(n_{\text{dir}}^{\text{exp}}\): the expected number of detected photons that traveled directly to a PMT, undergoing only refraction at the media boundaries;
(ii) \(n_{\text{cat}}^{\text{exp}}\): the expected number of detected photons that were Rayleigh scattered once in the D2O or H2O before detection (scattering in the acryllic is neglected);
(iii) \(n_{\text{av}}^{\text{exp}}\): the expected number of detected photons that reflected off the inner or outer surface of the acryllic vessel;
(iv) \(n_{\text{pmt}}^{\text{exp}}\): the expected number of detected photons that reflected off the PMTs or light concentrators;
(v) \(n_{\text{noise}}^{\text{exp}}\): the expected number of PMT noise hits, based on run-by-run measurements.

FTK computed the probabilities of a single photon being detected by any PMT via the four event-related processes: \(\rho_{\text{dir}}\), \(\rho_{\text{cat}}\), \(\rho_{\text{av}}\), \(\rho_{\text{pmt}}\). The direct light probability was found by tracing rays from the event vertex to each PMT and weighting each ray by the attenuation probability in each medium, transmittance at each boundary, solid angle of each PMT, and detection probability given the angle of entry into the light concentrator. Scattering and reflection probabilities were found using a combination of ray tracing and tables computed from Monte Carlo simulation of photons propagating through the detector.

If \(N_{\gamma}\) is the number of potentially detectable Cherenkov photons produced in the event given the inherent PMT detection efficiency, then the expected number of detected photons given these probabilities is:

\[
n_{\text{exp}}(N_{\gamma}) = N_{\gamma} \times (\rho_{\text{dir}} + \rho_{\text{cat}} + \rho_{\text{av}} + \rho_{\text{pmt}}). \tag{3}\n\]

To be able to compare \(n_{\text{exp}}\) to the observed \(N_{\text{hit}}\), we need to account for noise hits and convert from detected photons to PMT hits, since multiple photons in the same PMT produced only one hit. Given the rarity of multiple photons in a single PMT at solar neutrino energies, FTK made a correction only to the dominant source term, \(n_{\text{dir}}^{\text{exp}} = N_{\gamma} \rho_{\text{dir}}\). Letting \(N_{\text{MPC}}(n_{\text{exp}}^{\text{dir}})\) be the multiphoton corrected number of direct PMT hits, the total expected number of hits is:

\[
N_{\text{exp}}(N_{\gamma}) \approx N_{\text{MPC}}(n_{\text{exp}}^{\text{dir}}) + N_{\gamma} \times (\rho_{\text{cat}} + \rho_{\text{av}} + \rho_{\text{pmt}}) + n_{\text{noise}}^{\text{exp}}. \tag{4}\n\]

The probability of observing \(N_{\text{hit}}\) hits when \(N_{\text{exp}}\) are expected is given by the Poisson distribution:

\[
P(N_{\text{hit}}|N_{\text{exp}}) = \frac{(N_{\text{exp}})^{N_{\text{hit}}}e^{-N_{\text{exp}}}}{N_{\text{hit}}!}. \tag{5}\n\]

To obtain a likelihood function for \(T_{\text{eff}}\), rather than \(N_{\gamma}\), we integrate over the distribution of \(N_{\gamma}\) given an energy \(T_{\text{eff}}\):

\[
L(T_{\text{eff}}) = \int \left( \frac{(N_{\gamma})^{N_{\text{hit}}}e^{-N_{\gamma}}}{N_{\text{hit}}!} \times P(N_{\gamma}|T_{\text{eff}})dN_{\gamma} \right), \tag{6}\n\]

where \(P(N_{\gamma}|T_{\text{eff}})\) is the probability of \(N_{\gamma}\) Cherenkov photons being emitted in an event with energy \(T_{\text{eff}}\). The negative log-likelihood was then minimized in one dimension to give the estimated energy of the event.

B. Energy scale corrections and uncertainties

We measured the energy scale of the detector by deploying the tagged \(^{16}\text{N}\) \(\gamma\) source at various locations in the \(x\text{-}z\) and \(y\text{-}z\) planes within the D2O volume. Although \(^{16}\text{N}\) was a nearly monoenergetic \(\gamma\) source, it produced electrons with a range of energies through multiple Compton scattering and \(e^+e^-\) pair production. As a result, the single 6.13-MeV \(\gamma\) produced an “effective electron kinetic energy” \((T_{\text{eff}})\) distribution that peaked at approximately 5 MeV.

Using the \(^{16}\text{N}\) \(\gamma\)-ray source to determine the detector’s energy scale is complicated by its broad spectrum of electron energies. To separate the detector’s response from this intrinsic electron energy distribution, we modeled the reconstructed energy distribution with the integral

\[
P(T_{\text{eff}}) = N \int P_{\text{source}}(E_{\gamma}) \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(E_{\gamma}-E_{\text{eff}})^2}{2\sigma^2}} dE_{\gamma}, \tag{7}\n\]

where \(N\) is a normalization constant, \(\sigma(E_{\gamma}) = p_1 + p_2\sqrt{E_{\gamma}}\) is the detector resolution, and \(P_{\text{source}}\) is the apparent electron energy distribution from the \(^{16}\text{N}\) \(\gamma\) rays without including the detector optical response. \(p_3\) sets the displacement of the \(^{16}\text{N}\) peak, and therefore the offset in energy scale at that source location. The \(P_{\text{source}}\) distribution was computed from a Monte Carlo simulation of \(\gamma\) propagation through the
source container and production of Cherenkov photons from Compton-scattered $e^-$ and pair-produced $e^+e^-$. We translated the number of Cherenkov photons in each simulated event to a most probable electron (MPE) kinetic energy with the same tables that were used in the FTK energy estimation algorithm, and generated the distribution, $P_{\text{MPE}}$, of event values [33].

Given this fixed distribution for the $^{16}$N calibration source, we fit for $N$, $p_1$, $p_2$, and $p_3$ in each source run for both data and for Monte Carlo simulation of the same source position and detector state. The parameter differences between data and Monte Carlo, run-by-run, determined the energy corrections and uncertainties. Parameters $p_1$ and $p_2$ measure the detector energy resolution, and are discussed further in Sec. VIII C. Parameter $p_3$ was used here to define the spatial energy scale correction and uncertainties. The Monte Carlo was initially tuned by adjusting a global collection efficiency parameter in the simulation to minimize the difference between data and Monte Carlo energy scales for $^{16}$N runs at the center of the detector. A series of additional corrections were then applied to the estimated energy of all the data and Monte Carlo events to remedy known biases.

Approximations in FTK’s handling of multiple hits on a single tube lead to a small energy nonlinearity, and we derived a correction for this by comparing the reconstructed energy for Monte Carlo events to their true energies. Similarly, the simple PMT optical model used by FTK produced a small radial bias in event energies and, again, comparison of reconstructed energies of Monte Carlo events to their true values were used to provide a correction.

Two additional corrections were based on evaluations of data. The first was to compensate for the degradation of the PMT light concentrators, which changed the detector’s energy response over time during Phase I. The degradation affected the fraction of light that was reflected off the PMT array. We tracked the variation using $^{16}$N runs taken at the center of the detector and created a time-dependent correction to event energies that shifted their values by up to 0.4% [33].

The final correction was applied to remove a variation in energy with the detector $z$ coordinate. Figure 9(a) shows the difference between the average reconstructed energies of events from the $^{16}$N source for each calibration run, and the Monte Carlo simulation of the run, as a function of the radial position of the source. As can be seen, for events in the top (positive $z$) hemisphere of the detector, the Monte Carlo underestimated the event energies by as much as 3% and, in the bottom hemisphere, it overestimated the energies by almost the same amount. The cause of the former was the simulation’s poor optical model of the acrylic in the neck of the av. The latter was likely caused by accumulation of residue at the bottom of the acrylic vessel and variations in the degradation of the PMT light concentrators.

To correct for the $z$ dependence of the energy scale, we first split the $^{16}$N calibration runs into two groups. One group contained runs on the $x$-$z$ plane along with half of the runs on the $z$ axis and was used to construct the correction function. The second group contained runs on the $y$-$z$ plane along with the other half of the $z$-axis runs and was used later to independently evaluate the spatial component of the energy scale uncertainty.

![FIG. 9. (Color online) Difference between $^{16}$N data and Monte Carlo energy scales as a function of radius for Phase I $^{16}$N source runs in the upper hemisphere, on the equatorial plane, and in the lower hemisphere. (a) The significant variation in these three regions before the spatial energy correction. (b) The same runs after the spatial energy scale correction is applied. (The fiducial volume cut is at 550 cm.)](image-url)

We found that the variation in the energy scale best correlated with the vertical position of the event ($z$) and the direction cosine of the event relative to the $z$ axis ($u_z$). All of the $^{16}$N events in the first group were binned in the ($z$, $u_z$) dimensions and the peak of the $^{16}$N energy distribution was found for data and Monte Carlo events separately. We fit a second-order polynomial in $z$ and $u_z$ to the ratio of the data and Monte Carlo peak energies. This smooth function provided the spatial energy correction for data events. Figure 9(b) shows the spatial variation after this energy correction.

To evaluate the spatial component of the energy scale uncertainty, we assumed azimuthal symmetry in the detector and divided the second group of $^{16}$N calibration runs into regions based on radius and polar angle. Within each region, the rms of the individual run differences between the corrected data and Monte Carlo energy scales defined the uncertainty on the energy scale in that volume. All regions were then combined into a volume-weighted measure of the uncertainty on the overall energy scale in the detector due to spatial variation and nonuniform sampling of the detector volume. As a verification of the procedure, we reversed the roles of the two calibration groups (using the $y$-$z$ plane to construct the calibration function and the $x$-$z$ plane to evaluate the uncertainties) and found very similar corrections and uncertainties.
The energy scale uncertainty of the detector also includes uncertainty in modeling of energy loss in the $^{16}$N source itself, uncertainties in the online status of PMTs, variation in the channel response between high-rate calibration data and low-rate neutrino data, and uncertainties in the data acquisition channel gains and thresholds, which affect the photon detection probability. Many of these uncertainties have been substantially reduced compared to previous publications by the improvements to the Monte Carlo model described in Sec. V and the rate-dependent correction to the channel pedestals described in Sec. VI.

The components of the energy scale uncertainties are summarized in Table III. We take the source uncertainty as 100% correlated between phases and the other uncertainties as uncorrelated. To verify the validity of the $^{16}$N-derived energy corrections and uncertainties over a wider range of energies, we compared the data and Monte Carlo energy distributions for $^{252}$Cf neutron source runs and the D$_2$O-volume radon spike, for both of which events are more widely distributed in the detector than for the $^{16}$N source. In both cases, the agreement between the data and Monte Carlo was well within the uncertainties stated in Table III.

### Energy resolution

Energy resolution was a significant systematic uncertainty because of its impact on background acceptance above the 3.5-MeV energy threshold. Due to differing event topologies in the two phases, the resolution uncertainties were treated as three independent, uncorrelated systematic parameters: Phase I events (both electron-like and neutron capture events), Phase II electron-like events, and Phase II neutron capture events. In all cases, the resolution was found to be slightly broader in the data than for Monte Carlo events. The difference was parameterized as a Gaussian of width $\sigma_{\text{extra}}$, with which the Monte Carlo distribution was convolved to reproduce the data. The width of the Gaussian was given by the quadrature difference of the data and Monte Carlo resolutions: $\sigma_{\text{extra}} = \sqrt{(\sigma_{\text{data}}^2 - \sigma_{\text{MC}}^2)}$. A resolution correction was formulated using calibration source data and applied to the Monte Carlo events used in PDF generation. The uncertainties on this correction were then taken from the spread of the calibration data.

#### 1. Energy resolution uncertainties for Phase II electron-like events

The $^{16}$N source was the primary source for this measurement. We evaluated the uncertainties in two ways by measuring the resolution for the spectrum of Compton electrons differentially and integrally.

The MPE fit described in Sec. VIII B unfolds source effects from the event distribution, allowing the extraction of the intrinsic monoenergetic electron resolution as a function of energy. The fit was performed for both data and Monte Carlo simulation of $^{16}$N runs and the resulting resolutions were compared differentially in energy. The energy resolution at threshold is the dominant concern for electron-like events, due to the exponential rise of the backgrounds, and the value at 3.5 MeV was therefore used as representative of the detector resolution. $\sigma_{\text{extra}}$ at threshold was found to be $0.152 \pm 0.053$ MeV. In terms of the fractional difference

$$\sigma_{\text{frac}} = \frac{(\sigma_{\text{data}} - \sigma_{\text{MC}})}{\sigma_{\text{MC}}}, \quad (8)$$

this translates to $\sigma_{\text{frac}} = 2.4 \pm 1.6\%$ at threshold.

To measure the integrated Compton electron resolution using the monoenergetic $\gamma$ rays produced by the $^{16}$N source, the reconstructed energy distribution for Monte Carlo–simulation $\gamma$s was convolved with a smearing Gaussian and the result was fit directly to the data, allowing the mean and width of the smearing Gaussian to vary. The resulting $\sigma_{\text{extra}}$ of the smearing Gaussian was $0.0 \pm 0.046$ MeV. This measurement represents a higher average energy than the “unfolded” MPE value since the $^{16}$N provides $\gamma$s at 6.13 MeV. The value of $\sigma_{\text{frac}}$ from this $\gamma$-ray measurement is $0.00 \pm 0.08\%$.

Two $^{222}$Rn spikes were deployed during Phase II, one in the D$_2$O and one in the H$_2$O volume. These provided a low energy source of $\beta$s and $\gamma$s, below the analysis threshold and, therefore, all observed decays appeared due to the detector energy resolution, making the spikes particularly sensitive to this effect. The unbinned signal extraction code (Sec. XIV C) was used in a simplified configuration to fit the data from each spike.

The internal spike was fit with three PDFs in two dimensions: energy and isotropy. The PDFs were $^{214}$Bi electron-like events (primarily $\beta$s) in the D$_2$O volume, $^{214}$Bi photodisintegration neutrons, and a “quiet” data set drawn from neutron runs near the date of the spike. The latter provides the energy distribution of all “background” events to the spike measurement, including other radioactive decays such as PMT $\beta$-$\gamma$s as well as neutrino interactions. An analytic convolution parameter was also floated, defining the width of the convolving Gaussian applied to the Monte Carlo electron-like events. The resulting $\sigma_{\text{extra}}$ was $0.139 \pm 0.036$ MeV, which is equivalent to $\sigma_{\text{frac}} = 2.0 \pm 1.0\%$ at threshold. Floating the $^{214}$Bi electrons and neutrons independently also allowed a verification of the Monte Carlo prediction for the photodisintegration rate. The results were in good agreement, giving $0.91 \pm 0.13$ times the Monte Carlo predicted rate.

The external spike was fit with two PDFs in just the energy dimension, due to lower statistics. The electron to neutron ratio in the $^{214}$Bi PDF was fixed to the Monte Carlo prediction and the overall normalization of this PDF was taken as a free parameter, along with the quiet data normalization. The Monte Carlo events were again convolved with a Gaussian, whose width was allowed to vary in the fit. The resulting value for $\sigma_{\text{extra}}$ was $0.273^{+0.030}_{-0.035}$ MeV, which gives $\sigma_{\text{frac}} = 7.6 \pm 1.9\%$ at threshold.
threshold. The broader resolution for external events, which were generated in the \( \text{H}_2\text{O} \) region but either traveled or were misreconstructed into the \( \text{D}_2\text{O} \), is not unexpected since the detector’s energy response was modeled less well in the outer detector regions.

These four measures were combined to give the resolution correction and associated uncertainty for electron-like events in Phase II. Since the two \( ^{16}\text{N} \) measurements are not independent, they were not used together. The weighted mean of the MPE fit and the two spike points was used to give the correction, with an associated uncertainty. The difference of that value from the weighted mean of the \( ^{16}\text{N} \) point and the two spike points was then taken as an additional one-sided (negative) uncertainty, to take into account the difference in the two \( ^{16}\text{N} \) measurements. This results in a final value of \( \sigma_{\text{extra}} = 0.168_{-0.080}^{+0.041} \) MeV, which was applied as a constant smearing across the energy range. The four measurements and the resulting one sigma band on the final correction value for Phase II electron-like events are shown in Fig. 10.

The MPE fit was also applied to the \( ^{8}\text{Li} \) source but this was not included in the calculation due to the low statistics of the measurement. However, the energy dependence of both the \( ^{8}\text{Li} \) and the \( ^{16}\text{N} \) MPE fits were used to demonstrate that the use of a constant \( \sigma_{\text{extra}} \) across the energy spectrum was consistent with the data available.

2. Energy resolution uncertainties for Phase II neutron capture events

The energy resolution for neutron capture events in Phase II was measured using the \( ^{252}\text{Cf} \) source, with a verification performed using a “muon follower” data set, consisting of neutron capture events occurring within a defined time window after a muon passed through the detector.

There are fewer uncertainties associated with the neutron measurement since the \( ^{252}\text{Cf} \) source produced neutrons whose captures on \( ^{35}\text{Cl} \) and deuterium resulted in the same \( \gamma \) cascades as those from NC events. The measurement was performed by numerically convolving a spline-fit of the Monte Carlo energy distribution with a Gaussian and fitting the resulting form to the data. The mean and width of the convolving Gaussian were allowed to vary, in order to take into account possible correlations between energy scale and resolution effects. The result was \( \sigma_{\text{extra}} = 0.153 \pm 0.018 \) MeV. The observed energy scale from this measurement agreed very well with that evaluated in Sec. VIII B.

The statistics of the muon follower data set were low, and the resulting uncertainty on the measurement was therefore relatively large. Nevertheless, a similar analysis was performed, giving a \( \sigma_{\text{extra}} \) of 0.237 ± 0.144 MeV.

The weighted mean of the two points was used for the final correction to the energy resolution of neutron capture events in Phase II, with its associated uncertainty, with the value dominated by the \( ^{252}\text{Cf} \) measurement: \( \sigma_{\text{extra}} = 0.154 \pm 0.018 \) MeV. Both points are also shown on Fig. 10.

3. Energy resolution uncertainties for Phase I electron-like events

No radon spikes were deployed in Phase I, and so only the two \( ^{16}\text{N} \) measurements were available. Both the MPE fit and the Gaussian convolution to the \( \gamma \)-ray energy distribution were performed for Phase I \( ^{16}\text{N} \) runs, in the same manner as for Phase II (Sec. VIII C1). The central correction value was taken from the MPE fit directly, giving \( \sigma_{\text{extra}} = 0.155 \pm 0.036 \) MeV.

The small number of energy resolution measurements in Phase I provides fewer handles on the uncertainty than the much-better calibrated Phase II. The uncertainties in Phase I were therefore chosen to match those of Phase II. The width of the convolving Gaussian for Phase I events was therefore taken as \( \sigma_{\text{extra}} = 0.155_{-0.080}^{+0.042} \) MeV. This was also applied to neutron capture events in Phase I, since the event topologies were similar.

D. Energy linearity

The corrections derived in Sec. VIII B were done primarily using the \( ^{16}\text{N} \) source, and therefore the uncertainty in the energy scale at the \( ^{16}\text{N} \) energy is very small. An additional uncertainty was included to account for possible differential changes in the energy scale that were not correctly modeled in the Monte Carlo simulation. Such changes could be caused by residual crosstalk hits or mismodeling of the multi-photon PMT hit probabilities in the energy reconstruction algorithm. The differential changes were determined relative to the \( ^{16}\text{N} \) point and used calibration sources whose energies were substantially higher.

The pT source provided \( \gamma \)s roughly 14 MeV higher in energy than those from \( ^{16}\text{N} \), resulting in a good lever arm on any nonlinear effects. This source was only deployed in Phase I since deployment in Phase II would have resulted in an overwhelming neutron signal. The difference between data and Monte Carlo–reconstructed event energies was measured to be \(-1.36 \pm 0.01\%\) at the energy of the pT source.

The MPE fit described in Sec. VIII B was applied here to the \( ^{8}\text{Li} \) source, including an additional term in the
parameterization to model first-order differential changes in the energy scale. The fit was done to both data and Monte Carlo events, and a difference of just $-0.011 \pm 0.004\%$ was found, evaluated at the same energy as the pT source $\gamma$ rays.

Giving the pT and $^8$Li sources equal weight, the average shift in energy scale at the energy of the pT source was found to be $-0.69\%$. Using this as a measure of the degree by which the Monte Carlo energy scale could vary differentially from the data and assuming a linear interpolation between the $^{16}$N and pT energies, the linearity uncertainty was parameterized in terms of the difference of an event’s energy from the $^{16}$N source ($\sim 5.05$ MeV). This results in a scaling factor that can be applied to the energy of each Monte Carlo event used to build the PDFs in the signal extraction procedure. Conservatively, this was applied as a two-sided uncertainty:

$$T_{\text{eff}} = \left[ 1.0 \pm 0.0069 \times \left( \frac{T_{\text{eff}} - 5.05}{19.0 - 5.05} \right) \right] T_{\text{eff}},$$

where 19 MeV is the effective energy of the pT source, $T_{\text{eff}}$ is the original effective kinetic energy of an individual event, and $T'_{\text{eff}}$ is the modified energy.

Tests using both the $^8$Li and $^{252}$Cf sources suggested no evidence for any linearity shift in Phase II. We expect any source of linearity shift to be common across the two phases, however, and therefore the results from Phase I were conservatively taken to apply to both phases in a correlated fashion.

IX. EVENT ISOTROPY

As discussed in Sec. II, we used a measure of event “isotropy” as one dimension of our PDFs to help distinguish different types of events. By isotropy we mean the degree of uniformity in solid angle of the hit PMTs relative to the fitted event location.

Single electron events, like those created in neutrino CC and ES reactions, had a Cherenkov cone that, at solar neutrino energies, was somewhat diffuse due to electron multiple scattering in the water. Nevertheless, even with the multiple scattering, these events were characterized by a fairly tight cluster of PMT hits in a cone aligned with the forward direction of the electron.

Neutron capture events on deuterium in Phase I led to a single 6.25 MeV $\gamma$ ray. Although these events could produce multiple Compton electrons and, hence, a number of Cherenkov cones that distributed hits more widely than single electrons, Phase I neutron capture events in the data set were dominated by single Compton scatters and, thus, isotropy was not useful in distinguishing them from CC or ES events.

In contrast, in Phase II neutrons captured primarily on $^{35}$Cl, which typically led to a $\gamma$ cascade that differs significantly from single electrons. Neutron capture on $^{35}$Cl typically produced several $\gamma$ rays, with energies totaling 8.6 MeV, which distributed PMT hits more uniformly in solid angle. The isotropy distribution for these events is thus a convolution of the isotropy distribution of single $\gamma$-ray events with the directional distribution of the $\gamma$ rays emitted in the possible $\gamma$-decay cascades.

The isotropy of background events can also significantly differ from that of single electron and neutron events. Decays of $^{208}$Tl, for example, produce both a $\beta$ and a 2.614-MeV $\gamma$ ray and, thus, resulted in a different distribution of hit PMTs than either single electrons or single $\gamma$s. The measure of isotropy was therefore critical to the analysis, helping us to separate CC and ES events from NC events and both of these from low-energy background events.

We examined several measures of isotropy, including a full correlation function, the average angle between all possible pairwise combinations of hit PMTs, and constructions of several variables using Fisher discriminants. We found that, for the most part, they all had comparable separation power between the single electron (CC and ES) and the neutron (NC) signals. As in our previous Phase II publications [8], we opted to use a linear combination of parameters, $\beta_{14} \equiv \beta_1 + 4\beta_4$, where:

$$\beta_i = \frac{2}{N(N-1)} \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} P_l(\cos \theta_{ij}).$$

In this expression, $P_l$ is the Legendre polynomial of order $l$, $\theta_{ij}$ is the angle between triggered PMTs $i$ and $j$ relative to the reconstructed event vertex, and $N$ is the total number of triggered PMTs in the event. Very isotropic events have low (even negative) values of $\beta_{14}$.

A. Uncertainties on the isotropy measure

We parameterized the difference between the predicted $\beta_{14}$ PDF and the true PDF by a fractional shift in the mean, $\bar{\beta}_{14}$, and a broadening of the width, $\sigma_{\beta_{14}}$. We also allowed for an energy dependence in the shifts.

Figure 11 shows $\beta_{14}$ distributions of Phase II data from $^{252}$Cf and $^{16}$N sources and from corresponding MC simulations. The $^{16}$N source emitted a single 6.13-MeV $\gamma$ ray, which usually underwent Compton scattering and produced one or more electron tracks, while neutrons from the $^{252}$Cf source were typically captured in Phase II by the chlorine additive, leading to a cascade of several $\gamma$ rays. It is clear from the figure that the $^{16}$N data and Monte Carlo agree very well, while the
Monte Carlo simulation of the \(^{252}\text{Cf}\) source shows a very small shift toward higher \(\beta_{14}\) values (less isotropic events than in the data). This shift is discussed in Sec. IX A3.

Errors in the simulated distributions of \(\beta_{14}\) can have several sources: incorrect modeling of the detector optics or photomultiplier tubes, unmodeled event vertex reconstruction errors, errors in the model of the production of Cherenkov light (including the interactions of \(\gamma\) rays and electrons in the detector), and, for neutrons captured on \(^{34}\text{Cl}\), uncertainties in our knowledge of the \(\gamma\) cascade sequences and correlations between the directions of the multiple \(\gamma\) rays.

Except for the last item, these errors affect all event types. For Phase I, in which neutrons were captured on deuterons, we allowed for correlations among the uncertainties on all signals and most backgrounds. For Phase II, we treated the uncertainties on the mean and width of the \(\beta_{14}\) distribution for NC events and photodisintegration neutrons separately from the other event types. Uncertainties on the \(\beta_{14}\) distributions of \(\beta s\) and \(\gamma s\) from radioactive background events were treated the same as for CC and ES events. The one exception to this was PMT \(\beta-\gamma\) events, whose location at the PMT array led to effects on the \(\beta_{14}\) distribution that are not present in the other signals. The \(\beta_{14}\) distribution and associated uncertainties for PMT \(\beta-\gamma\) are discussed in Sec. XIII C.

As usual in this analysis, we derived uncertainties on the mean, width, and energy dependence of the \(\beta_{14}\) distribution by comparing calibration source data to Monte Carlo simulations of the calibration source runs. When we found a difference that was corroborated by more than one source, or was caused by known errors in the simulation, we adjusted the simulated distribution by shifting the mean of the distribution and/or convolving the distribution with a smearing function to better match the calibration data. In such cases, additional uncertainties associated with the correction were included.

1. \(\beta_{14}\) uncertainties for Phase II electron-like events

The primary measure of isotropy uncertainties for Phase II electron-like events comes from comparisons of \(^{16}\text{N}\) calibration source data to Monte Carlo simulation. We fit Gaussians to both the data and simulated events for each run and calculated the fractional difference between the fitted parameters. Figure 12 shows the fractional difference in the means as a function of \(R^3\). Each point shown is the fractional difference for a single run, with the error bar evaluated as the combination of the uncertainty on the fit parameters for data and Monte Carlo events. The detector region in which the source was deployed has been identified for each run.

Also shown in Fig. 12 are the averages of these differences, in several radial bins. The uncertainty on each average is the standard deviation of the points in that bin, weighted by the volume represented by the bin (smaller volumes have larger uncertainties). The overall weighted average within the entire 550-cm radius fiducial volume is consistent with zero, with an uncertainty of \(\pm 0.21\%\). The calibration data were collected at a high rate relative to normal neutrino data runs and so we added to this an uncertainty to account for the difference in \(\beta_{14}\) between high-rate and low-rate data (\(\pm 0.1\%\)) by comparing low-rate and high-rate \(^{16}\text{N}\) source runs, as well as a small uncertainty of \(\pm 0.002\%\) associated with a possible unmodeled time dependence obtained by comparing data and Monte Carlo differences over time. The quadrature combination of these uncertainties on the mean of the \(\beta_{14}\) distribution totals \(\pm 0.24\%\). A similar analysis was performed for the width of the \(\beta_{14}\) distribution, yielding a total fractional uncertainty of \(\pm 0.54\%\).

2. \(\beta_{14}\) uncertainties for Phase I electron-like events

We applied an identical analysis to the Phase I \(^{16}\text{N}\) data but, as shown in Fig. 13, we found a difference of \(-0.81 \pm 0.20\%\) between the means of the \(\beta_{14}\) distributions for source data and source simulations. Comparison of \(^{16}\text{N}\) data between Phase I and Phase II showed them to be consistent, and the data–Monte Carlo difference seen in Fig. 13 to be due to a shift in the simulated events. Further investigation showed that the difference was caused by the value of the Rayleigh scattering length used in the Phase I simulation. Explicit measurements of the Rayleigh scattering had been made and used in the simulation for Phase II but no such measurements existed for Phase I. Use of the Phase II Rayleigh scattering length in Phase I simulations was found to produce the desired magnitude of shift, and we therefore corrected the \(\beta_{14}\) values of all simulated Phase I events by a factor of \((1 - 0.0081) = 0.9919\).

We included three uncertainties associated with this correction. The first was 0.20% on the correction itself, evaluated from the volume-weighted average of the data and Monte Carlo differences for Phase I, as shown in Fig. 13. To take into account the fact that we used the consistency in the \(^{16}\text{N}\) data between the two phases to support the correction of \(-0.81\%\), we added in quadrature the uncertainty on the difference between the means of the Phase I and Phase II \(^{16}\text{N}\) \(\beta_{14}\) distributions, which was 0.34%. Finally, because we used the consistency of the Phase II data with the Monte Carlo simulation as evidence that the Phase I \(\beta_{14}\) distribution was correct, aside from the Rayleigh-scattering correction,
we included the volume-weighted Phase II uncertainty on the offset of the mean (0.21% from Fig. 12 in Sec. IX A1).

The evaluations of the uncertainties associated with rate dependence and time dependence in Phase I were 0.08% and 0.03%, respectively, and the overall uncertainty on the mean of the $\beta_{14}$ distribution in Phase I thus totaled 0.42%. We evaluated the uncertainty on the width of the $\beta_{14}$ distribution for Phase I in the same way as for Phase II, finding a fractional uncertainty which also totaled 0.42%.

### 3. $\beta_{14}$ uncertainties for Phase II neutron capture events

Neutron capture events in Phase II were distinct from other neutrino-induced events and backgrounds in that the $\gamma$ cascade was more isotropic than a single electron or $\gamma$ ray. The primary measurement of the uncertainty on the mean of the $\beta_{14}$ distribution comes from deployments of the $^{252}$Cf source, which produced several neutrons per fission decay. The $\beta_{14}$ distribution of the resulting neutron capture events was noticeably non-Gaussian, and we therefore derived uncertainties on the mean and width by fitting the $\beta_{14}$ distributions from simulated $^{252}$Cf runs directly to the distributions of data. The fit allowed for scaling as well as convolution with a Gaussian smearing function. Figure 14 shows the fit of a simulated $^{252}$Cf run to data, in which the fitted scaling was $-1.2\%$ and the smearing was an additional $1.8\%$ of the width of the Monte Carlo distribution.

We derived scaling factors from fits like that in Fig. 14 for all $^{252}$Cf runs and then volumed weighted them in the same way as for the $^{16}$N data. The average of the volume-weighted differences showed an overall offset between the means of the $\beta_{14}$ distributions for data and Monte Carlo of $\sim -1.4\%$. This result was not consistent with that from the $^{16}$N data for Phase II (which, as discussed above, had no significant offset), which indicated that the shift was not due to a detector effect. To check whether the shift was caused by mismodeling of the $^{252}$Cf source in the simulation, we performed the same analysis on several types of neutron capture events: neutrons produced by passage of a muon through the detector (“muon followers”), neutrons from a tagged Am-Be source, and neutrons produced by deuteron photodisintegration during the deployment of a radon spike in the detector. Figure 15 shows results from these sources. An energy-dependent fit to all sources except $^{252}$Cf showed an offset of $-1.12 \pm 0.31\%$, consistent with the data from the $^{252}$Cf source. This indicated that the offset was likely not a source effect but was instead associated with the simulation of the $\gamma$ cascade from neutron captures on chlorine, possibly with some contribution from the energy-dependent correction of the Monte Carlo value for $\beta_{14}$ presented in Sec. IX A5. All sources taken together gave an overall offset of $-1.44\%$, and we therefore corrected the $\beta_{14}$ PDF by multiplying each simulated event’s $\beta_{14}$ value by $(1 + \delta_{\beta_{14}}) = (1 - 0.0144) = 0.9856$.

The uncertainties on this correction came first from the uncertainty on the overall average, which was $0.17\%$. To this we added in quadrature the same rate- and time-dependent uncertainties as were calculated for the Phase II $^{16}$N sources. We also added an uncertainty associated with the multiplicity...
of neutrons from the $^{252}$Cf source of 0.09% (neutrons produced by either photodisintegration of deuterons or the NC reaction are singles, whereas the $^{252}$Cf source produces multiple neutrons per decay) and 0.03% uncertainty to account for the relatively sparse sampling of the detector, giving a total of 0.22%. Conservatively, we included a further uncertainty based on the difference between $^{252}$Cf and the other neutron-source data, a one-sided uncertainty of 0.31%. The total uncertainty on the mean of the $\beta_{14}$ distribution for Phase II neutron captures was therefore $0.22\%$. As well as a measure of any required shift, the fit described above also allowed for the widths of the data and Monte Carlo distributions to differ. A resolution parameter was varied in the fit, as the standard deviation of the Gaussian by which the Monte Carlo distribution was analytically convolved. The results for each $^{252}$Cf run were volume weighted using the procedure described above to result in an average overall smearing value. The same fit was performed on a sample of Monte Carlo–generated data, and the bias determined from these fits was subtracted from the overall average. The result was a fractional smearing correction to be applied to the PDFs of 0.43%, with an uncertainty (including all sources described above: time, rate, multiplicity, and sampling) of 0.31%.

4. $\beta_{14}$ uncertainties for Phase I neutron capture events

Neutrons created in Phase I captured on deuterons, releasing a single 6.25-MeV $\gamma$ ray. The uncertainties on the mean and width of the $\beta_{14}$ distribution were therefore well estimated by the measurements made with the $^{16}$N 6.13 MeV $\gamma$-ray source, already discussed in Sec. IX A2. We therefore used the same uncertainties for both event types, applied in a correlated fashion.

5. Energy dependence of $\beta_{14}$ uncertainties

A final systematic uncertainty on the $\beta_{14}$ distributions is their energy dependence. In Fig. 16 we show the energy dependence of the fractional difference between Monte Carlo predictions of the mean of the $\beta_{14}$ distribution and data from several different sources: the Phase II radon spike, low- and high-energy $^{16}$N source events, the $^{252}$Cf source (with the data corrected by the 1.44% shift discussed above), and $^8$Li-source $\beta$ events in three energy bins. There clearly is an energy dependence in the data, which we fit with a function of the form:

$$ f = \delta_{\beta_{14}} + m_{\beta_{14}}(T_{\text{eff}} - 5.6 \text{ MeV}), $$

where $T_{\text{eff}}$ is kinetic energy and 5.6 MeV is the kinetic energy at the high-energy $^{16}$N point (the point used to determine the offset in the mean of the Phase II electron $\beta_{14}$ distribution). With this parameterization, the offset ($\delta_{\beta_{14}}$) and the slope ($m_{\beta_{14}}$) are uncorrelated. Given that all the sources exhibited the same trend, we applied the same slope to all event types but used the different offsets and uncertainties for $\delta_{\beta_{14}}$ described in the previous sections. We performed a similar analysis for Phase I, although fewer calibration data were available, and found that the same slope fit the $^{16}$N and $^8$Li data in this phase. We found no energy dependence in the broadening of the width of the $\beta_{14}$ distributions. These uncertainties were therefore treated as independent of energy. The corrections and uncertainties to the $\beta_{14}$ distributions are listed in Tables IV and V.

### X. CUTS AND EFFICIENCIES

The data set contains two main types of background events: physics backgrounds, due to radioactive decays, and instrumental backgrounds, caused by the detector itself. Two sets of cuts were developed to remove these events, described in Secs. X A and X B. Each set of cuts had an associated level of signal loss, which was taken into account in the measurement of neutrino flux and spectra as described in Sec. X E 3.

#### A. Low-level (Instrumental) cuts

There were many sources of instrumentally generated events in the SNO detector, which produced hits originating either in the PMTs or in the electronics channels. Static
discharges in the nitrogen in the neck of the acrylic vessel and "flasher" PMTs, in which discharges occurred within a photomultiplier tube itself, produced light in the detector. Electronic pickup generated by noise on the deck above the detector or by high-voltage breakdown could produce hits in electronics channels. We removed these instrumental backgrounds with a suite of loose "low-level" cuts that rejected events before event reconstruction. The cuts were based on event characteristics such as the distribution of PMT hit times, the presence of unusually low or high PMT charges, or unusual time correlations between events (such as bursts of events with large numbers of hits). More details on these low-level cuts can be found in Refs. [7,8]. We used the same cuts and cut criteria here, with the exception that the simple burst cut used in Ref. [7] was not used in this analysis because it was redundant with other burst cuts.

The acceptance of these cuts was re-evaluated for this analysis, particularly in the low-threshold region (below \( T_{\text{eff}} = 5.0 \text{ MeV} \)) where the cuts had not previously been examined in detail. We discuss the results of these cut acceptance measurements in Sec. XE3.

B. High-level cuts

Background radioactivity events were produced primarily by the decays of \(^{214}\text{Bi}\) and \(^{208}\text{Tl}\). Lower-energy (\( T_{\text{eff}} < 3 \text{ MeV} \)) decays of these nuclei in the heavy water could appear above our \( T_{\text{eff}} = 3.5 \text{ MeV} \) threshold because of the broad energy resolution intrinsic to a Cherenkov detector. Decays within the walls of the acrylic vessel, the light water surrounding the vessel, and the photomultiplier tube array could pass the energy cut and have misreconstructed vertex positions which falsely placed them within the fiducial volume. The PMT array was, by far, the radioactively hottest component of the SNO detector and, consequently, the largest source of background events. We designed a suite of 13 loose cuts that used "high-level" information (reconstructed event position, direction, and energy) to remove events whose likely origin was either outside the fiducial volume or whose true energy was below our threshold. All of the cuts were adjusted based exclusively on simulated events and calibration data. Several of the cuts had a high degree of redundancy in order to maximize background rejection. The acceptance of the cuts was therefore evaluated collectively, as described in Sec. XE1.

Five of the high-level cuts removed backgrounds using Kolmogorov-Smirnov (KS) tests of the hypothesis that the event had a single Cherenkov-electron track. Two of these tests compared azimuthal and two-dimensional (polar vs. azimuthal) angular distributions to those expected for Cherenkov light produced by an electron, and two others did the same for hits restricted to a narrow prompt time window. The fifth of these KS tests was a comparison of the distribution of fitted PMT time residuals [see Eq. (2)] with the expected distribution for direct Cherenkov light.

Three more of the cuts applied event "isotropy" to remove misreconstructed events. Events whose true origins were well outside the fiducial volume but which reconstructed inside tend to appear very anisotropic. For one of these cuts we used the mean angle between pairs of PMTs, \((\theta_{ij})\), and for another the isotropy parameter \(\rho_{14}\), which is described in Sec. IX.

Both of these have been used in previous SNO analyses [7,8]. The third of these cuts was based on the charge-weighted mean pair angle, \(\theta_{ij}\), in which each pair angle is weighted by the product of the detected charges of the two PMTs in the pair.

Further cuts used information from the energy reconstruction algorithm discussed in Sec. VIII A. Two cuts removed events whose reported energy uncertainty was well outside the range expected from the known energy resolution. These are referred to in Secs. XE3–XE5 as the "energy-uncertainty" cuts. The third was a comparison of the energy estimated with FTK (which used all hits) with that from a prompt-light-only energy estimator. Events whose origins were outside the acrylic vessel and which pointed outward often had a larger fraction of prompt hits because the direct light was not attenuated by the acrylic vessel. Such an event would have a higher energy as measured by a prompt-light energy estimator than by the total-light energy reconstruction of FTK. We normalized the ratio of these two energy estimates by the ratio of prompt to total hits in the event. The cut itself was two-dimensional: events were removed if the normalized ratio of energy estimates was unusually large and the charge-weighted \(\theta_{ij}\) was unusually low (the latter indicating an outward-pointing event with a tight cluster of hits).

The last two high-level cuts were also used in determining the PDFs for radioactive backgrounds from the PMTs. The first of these, the in-time ratio (ITR) cut, removed events based on the ratio of the prompt hits to the total hits. The prompt time window for the ITR cut extended from 2.5 ns before the reconstructed event time to 5.0 ns after, and the full-event window was roughly 250 ns long. The mean of the ITR distribution for SNO events is at 0.74. Events that were reconstructed at positions far from their true origin tend to have small ITR values, because the PMT hits were spread across the entire time window. In previous analyses [7–9] we used the ITR cut with a fixed threshold, rejecting events with an in-time ratio smaller than 0.55. For the lower-energy events included in this analysis, the lower number of hits caused the distribution of ITR to broaden and introduced a large, energy-dependent bias in the acceptance of the cut. We therefore changed the cut threshold to scale with the number of hits \((N_{\text{hit}})\) in an event. The fixed value of 0.55 used in earlier publications corresponded to cutting events that fell more than 2.7\(\sigma\) below the mean of the distribution, and we retained this criterion, so the new version of the ITR cut rejected events that were more than 2.7\(\sigma\) below the mean of 0.74, where now \(\sigma = 0.43/\sqrt{N_{\text{hit}}}\).

The last cut was aimed directly at removing events produced by radioactive decays in the PMTs themselves. Such events produced light either in the PMT glass or in the light water, just in front of the PMTs. Although only a tiny fraction of such events were misreconstructed inside the fiducial volume, the PMT array was relatively hot, with a total decay rate from uranium and thorium chain daughters of a few kilohertz. Because of their origin within or near the PMTs, these events were characterized by a large charge in one PMT (or distributed over a few nearby PMTs) with hit times that
had removed any event within 250 ms of a previous event that muons that, in turn, disintegrated deuterons. We therefore rate of cosmic rays at SNO's depth. Atmospheric neutrinos additional overall detector dead time because of the very low activity. The muon follower cut resulted in a very small number of hits observed in the early time window to the expected number, given the total number of hits in the event. If the Poisson probability of having the observed number in the early time window was below 0.002, the event was cut.

C. Burst removal

Atmospheric neutrinos, spontaneous fission, and cosmic-ray muons could all produce bursts of events that were clearly not due to solar neutrinos. Most of these bursts had a detectable primary event (like a high-energy atmospheric-neutrino event) followed by several neutron events. In addition, many instrumentally generated events came in bursts, such as those associated with high-voltage breakdown in a PMT.

We therefore applied several cuts to the data set to remove most of these time-correlated events. Four of these were part of the suite of instrumental cuts described in Sec. XA. The first removed events that were within 5 µs of a previous event and, therefore, eliminated events associated with PMT afterpulsing or Michel electrons from decays of stopped muons. The second removed all events within 20 s of an event that had been tagged as a muon. Most of these “muon followers” were neutrons created by passage of a cosmic-ray muon through the heavy water, which captured either on deuterons or, in Phase II, on 35Cl, but the cut also removed longer-lived cosmogenic activity. The muon follower cut resulted in a very small additional overall detector dead time because of the very low rate of cosmic rays at SNO’s depth. Atmospheric neutrinos could also produce neutrons, either directly or by creating muons that, in turn, disintegrated deuterons. We therefore removed any event within 250 ms of a previous event that had \( N_{hit} > 60 \) (Phase I) or \( N_{hit} > 150 \) (Phase II). The fourth cut was aimed primarily at residual instrumental bursts and removed events that were part of a set of six or more with \( N_{hit} > 40 \) that occurred within an interval of 6 s.

Because of the relatively loose criteria used, after these cuts were applied there were still time-correlated events in the SNO data set that were very unlikely to be solar neutrinos but were primarily low-multiplicity neutrons created by atmospheric neutrino interactions. We therefore applied a final “coincidence cut” that removed events if two or more occurred within a few neutron capture times of each other. For Phase I this window was 100 ms; a shorter window of 15 ms was used for Phase II because of the shorter neutron capture time on chlorine compared to deuterium. The cut was “retriggerable,” in that the window was extended for its full length past the last event found. If a new event was thus “caught,” the window was again extended. We calculated that this cut removed less than one pair of events from each data set due to accidental coincidences.

D. Cut summary

The numbers of events in the data sets after successive application of each set of cuts are shown in Table VI. The burst cuts described in Sec. XC are included in instrumental cuts, except for the final coincidence cut, which appears in the last line of the table.

E. Cut acceptance

As in previous analyses [7], the fraction of signal events expected to pass the full set of analysis cuts (the “cut acceptance”) was determined by separating the cuts into three groups: instrumental, reconstruction, and high level. Correlations between these groups had been shown to be minimal [8], and it was verified that this was still true after the addition of new high-level cuts for this analysis.

The \(^{16}\text{N}\) and \(^{8}\text{Li}\) calibration sources were used for the primary measurements of cut acceptance and the \(^{252}\text{Cf}\) source was used for neutron capture events in Phase II. Neutron events in Phase I are well modeled by \(^{16}\text{N}\) events since capture on deuterium resulted in a single \( \gamma \) at 6.25 MeV and \(^{16}\text{N}\) was a source of 6.13 MeV \( \gamma \)s.

I. Instrumental cut acceptance

The instrumental cuts were not simulated in the Monte Carlo code and, therefore, we could not make a relative estimate of their acceptance by comparing simulation to data. Instead, an absolute measure of their acceptance was made using calibration data and applied as a correction (with uncertainties) to the PDFs.

Being a near-perfect source of CC-like electron events, the \(^{8}\text{Li}\) source was used to evaluate the signal loss for electron-like events, and \(^{252}\text{Cf}\) was used for Phase II neutron capture events. The \(^{16}\text{N}\) source was used as a check and any difference in the values obtained was conservatively taken as a two-sided systematic uncertainty. Figure 17 shows the...
The measurements from $^{16}\text{N}$ and $^{8}\text{Li}$ were in very good agreement and were both consistent with the acceptance ratio having no dependence on energy. The normalization correction for the PDFs was therefore evaluated using the $^{16}\text{N}$ source data by taking the weighted mean of the values in each energy bin. The data was reproduced by the simulation to within the statistical uncertainties. Analysis of runs taken during the two phases showed no significant deviation with time. A position-dependent uncertainty was evaluated by taking the ratio of the acceptance of $^{16}\text{N}$ data and Monte Carlo events as a function of source deployment position. The difference of the weighted average of the points from 1.0 was taken as the value of the uncertainty. The $^{8}\text{Li}$ source was used to investigate energy dependence. As expected, the signal loss decreased at higher energies, where more information was available to reconstruct an event. The simulation was shown to reproduce this effect very accurately and the uncertainty was therefore treated in the same manner as the position-dependent uncertainty.

Combining the systematic uncertainties in quadrature, we obtained the final uncertainties associated with reconstruction acceptance:

(i) Phase I: $\pm 0.034\% \text{ (stat)} \pm 0.060\% \text{ (syst)}$
(ii) Phase II $e^{-}$: $\pm 0.037\% \text{ (stat)} \pm 0.090\% \text{ (syst)}$
(iii) Phase II $n$: $\pm 0.000\% \text{ (stat)} \pm 0.009\% \text{ (syst)}$

3. High-level cut acceptance

To take into account the acceptance of the high-level cuts, the ratio of the cut acceptance for data and Monte Carlo events was calculated and applied to the PDFs as a normalization correction. This ratio was evaluated as a function of energy, position, and time.

The energy-uncertainty cuts described in Sec. XB were observed to have much stronger variations in signal loss as a function of position and energy than the other high-level cuts and were therefore treated separately. It was verified that the correlations between the two resulting subsets of high-level cuts were minimal, so treating them independently was a valid approach. The following sections describe the analysis for each subset of cuts, where “reduced high-level cuts” refers to the subset that does not include the energy-uncertainty cuts.

4. Reduced high-level cut acceptance

The data/Monte Carlo acceptance ratio and its uncertainty were calculated for each calibration source run. The runs were divided into radial bins, and the error-weighted mean and standard deviation were calculated in each bin. Finally, the volume-weighted average of the bin values was calculated.

The energy dependence of the acceptance ratio was investigated using $^{16}\text{N}$ and $^{8}\text{Li}$ data for electron-like events and $^{252}\text{Cf}$ for Phase II neutron capture events. The $^{16}\text{N}$ data were restricted to the energies below 9 MeV to avoid complications associated with event pileup caused by the high rate of the calibration source.

The measurements from $^{16}\text{N}$ and $^{8}\text{Li}$ were therefore evaluated using the $^{16}\text{N}$ source data by taking the weighted mean of the values in each energy bin.
The median deviation of the $^8$Li points from the best fit was taken as a systematic uncertainty on the energy dependence.

The acceptance ratio for Phase II neutron capture events was evaluated using $^{252}$Cf data. To avoid pileup of fission $\gamma$s, the events were required to have energies in the interval 4.5–9.5 MeV. An energy-dependent uncertainty was included to account for any variation of individual energy bins from the overall average. The stability of the acceptance as a function of time was studied using $^{16}$N runs taken in the center of the detector. No trend was observed, but the time variability was incorporated as an additional systematic uncertainty.

The $^{16}$N source was also used to evaluate a systematic uncertainty associated with a possible position dependence of the acceptance ratio. Runs were binned by position in the detector, the volume-weighted average of the bins was found, and the mean deviation of the ratio in each bin from this value was calculated. A comparison of $^{16}$N and $^{252}$Cf source data showed that they exhibited statistically equivalent position dependences, so the more widely deployed $^{16}$N source was used to quantify this effect for both electron-like and neutron capture events.

The acceptance corrections and associated uncertainties derived from the difference between the high-level cut acceptances for data and Monte Carlo events are summarized in Table VII.

### Table VII. Correction and associated uncertainties for the high-level cut acceptance ratio. The Phase II neutron energy-dependent uncertainty was treated differentially with energy; the quoted range covers the value across the energy spectrum.

The $^{16}$N and $^{252}$Cf data showed statistically equivalent position-dependent behavior in the acceptance of the energy-uncertainty cuts, and we therefore evaluated position-dependent uncertainties using the more widely deployed $^{16}$N source. $^{16}$N source data were divided into 50-cm slices along the $z$ axis, and the acceptance ratios calculated in the slices were combined in a volume-weighted average. The uncertainty on this average was derived from the deviation of the points from unity.

The energy-uncertainty cuts were even more sensitive to the effects of pileup than were the other high-level cuts. Therefore, to evaluate an energy-dependent uncertainty on the acceptance ratio for electron-like events, events from the $^{16}$N source were restricted to energies below 7 MeV, and the lower rate $^8$Li source was used for measurements at higher energies. $^{252}$Cf data were used for Phase II neutron capture events, with the deviations from unity measured in the 8.5- to 9-MeV bin also applied to higher-energy events. This resulted in energy-dependent uncertainties for both electron-like and neutron capture events. The uncertainties in acceptance were applied as uncertainties in normalization of the PDFs. The values are summarized in Table VIII.

### Table VIII. Uncertainties on the energy-uncertainty cut acceptance ratio. Energy-dependent uncertainties were treated differentially with energy and are not shown. The uncertainty in position is asymmetric.

### 6. Overall cut acceptance

The final correction to the PDF normalization comes from combination of the high-level cut correction (Table VII) and the instrumental cut correction (Sec. XE1). The various contributions to uncertainty on signal loss were treated as uncorrelated and combined in quadrature to give the final uncertainty on the cut acceptance correction. Table IX lists the final corrections and uncertainties.

Figure 18 shows a comparison of the cut acceptance for data and Monte Carlo events from a single $^{252}$Cf run in Phase II. The full set of analysis cuts was applied to both data and simulation, and the Monte Carlo–predicted acceptance was corrected by the value from Table IX. As the figure shows, the Monte Carlo
simulation reproduces the shape of the data distribution very closely.

**XI. TRIGGER EFFICIENCY**

As discussed in Sec. IV, the primary trigger for SNO was a coincidence of PMT hits within a 93-ns time window, set to \( N_{\text{coinc}} = 18 \) hits for the early part of Phase I and to \( N_{\text{coinc}} = 16 \) hits for the remainder of Phase I and all of Phase II. We define the “efficiency” of the trigger as the probability that an event with \( N_{\text{coinc}} \) hits actually triggered the detector. Small shifts in the analog (DC-coupled) baseline, noise, and disabled trigger electronics channels could all lead to a nonunity efficiency. We measured the efficiency using the isotropic laser source, by triggering on the laser pulse and comparing an offline evaluation of the trigger (by counting hits in a sliding 93-ns window) to the output of the hardware trigger. We found that for the \( N_{\text{coinc}} = 18 \) hit threshold, events with 23 or more hits in coincidence triggered the detector with an efficiency greater than 99.9% and, for the \( N_{\text{coinc}} = 16 \) hit threshold, the efficiency reached 99.9% at 21 hits. Figure 19 shows the efficiency measured as a function of \( N_{\text{coinc}} \), for Phase I at the higher \( N_{\text{coinc}} = 18 \) threshold, and for Phase II at the lower \( N_{\text{coinc}} = 16 \) hit threshold.

For events at our \( T = 3.5 \) MeV analysis threshold, the mean number of hits in an event over the full 400-ns event window was \( \sim 30 \) for Phase I and \( \sim 27 \) for Phase II, with rms’s of 1.8 hits and 1.7 hits, respectively. The numbers of hits in the 400-ns event window and in the 93-ns trigger coincidence window differed primarily in the contribution from random PMT noise which, for both phases, contributed on average roughly one additional hit in the 400-ns event window. Thus, for both phases, the trigger efficiency was above 99.9% for all but a negligible fraction of events with a high enough \( N_{\text{coinc}} \) to pass the analysis cuts.

Because our PDFs and overall normalization were derived from simulation, we compared the trigger-efficiency estimate from the data to the simulation’s prediction. We also compared the idealized simulated trigger to a simulation that included variations in the trigger baseline as measured by an online monitor. We found that the Monte Carlo simulation’s prediction of trigger efficiency was in excellent agreement with our measurement for both SNO phases and that the measured variations contributed a negligible additional uncertainty to our overall acceptance.

**XII. UNCERTAINTIES ON THE NEUTRON CAPTURE EFFICIENCIES**

In Phase I, neutrons produced through the NC reaction and background processes were captured on deuterons within the heavy water, releasing a single 6.25-MeV \( \gamma \) ray. In Phase II, the neutrons were captured primarily on \(^{35}\text{Cl}\), releasing a \( \gamma \) cascade of total energy 8.6 MeV. The absolute cross sections for these capture reactions, along with detector acceptance, determined the rate of detected neutron events. The uncertainty on the neutron capture efficiency for Phase II overwhelmingly dominates that for Phase I in the final flux determinations because of the larger capture cross section.

In this analysis, we used the Monte Carlo simulation to define the central values of the neutron capture efficiencies. Included in our simulation were the measured isotopic purity of the heavy water, as well as its density and temperature and, for Phase II, the measured density of salt added to the D₂O.

To assess the systematic uncertainties on the neutron capture efficiencies, we used data taken with the \(^{252}\text{Cf}\) source deployed at many positions throughout the detector and compared the observed counting rates to simulations of the source runs. The differences between data and simulated events provide an estimate of the simulation’s accuracy. The Phase I and Phase II data sets noticeably differ in their neutron detection efficiency because of the much larger capture cross section in Phase II and the higher-energy \( \gamma \) cascade from neutron capture on chlorine. We therefore assessed the uncertainties in the two phases slightly differently, as discussed below. We also compared the results of this “direct counting” approach with a “time series analysis,” in which the relative times of events were used to extract the capture efficiency. The
radius efficiencies in the D$_2$O volume, given the two functions shown of capture efficiency, we first calculated the mean capture efficiency in Phase I it is
efficiency function: were each fitted to a phenomenologically motivated neutron deployment mechanism. The efficiencies shown in Fig. 20 to eliminate the large positioning uncertainties of the source
\[ \epsilon(s) = A \{ \tanh[B(s - C)] - 1 \}, \]
where \( \epsilon(s) \) gives the neutron capture efficiency at source radius \( s \).
To determine the uncertainty on the simulation’s prediction of capture efficiency, we first calculated the mean capture efficiency in the D$_2$O volume, given the two functions shown in Fig. 20, as follows:
\[ \epsilon = \frac{\int_0^{600} \int_0^{600} s^2 \epsilon(s) ds}{\int_0^{600} s^2 ds}. \]
We took the difference of 0.8% between data and simulation as a baseline uncertainty. (The mean detection efficiency measured this way was 35.6%.)

The normalization of the curves shown in Fig. 20 depends on the strength of the $^{252}$Cf source, which we know to 0.7% based on ex situ measurements. An overall shift in reconstructed event positions, discussed in Sec. VI, also changed the measured efficiency in data relative to the simulation results. By varying the value of this shift within its range of uncertainty we found it resulted in an additional 0.3% uncertainty in capture efficiency. The uncertainty in the fit parameters of the neutron detection efficiency function was included conservatively by taking the entire statistical uncertainty on the data efficiency measurements of Fig. 20, which yields another 0.9%. Last, we included a 0.1% uncertainty to account for the fraction of $^{250}$Cf in the $^{252}$Cf source (only $^{252}$Cf is simulated by the Monte Carlo code). The overall uncertainty on the neutron capture efficiency, calculated by adding these in quadrature, was 1.4%.

We checked these results by performing an independent time-series analysis, in which we fit directly for the efficiency at each source deployment point based on the rates of neutron capture and $\gamma$ fission events (the source strength is not an input parameter). The fit included parameters associated with the overall fission rate, backgrounds from accidental coincidences, and the mean capture time for neutrons. We obtained the efficiency as a function of source radial position, to which we fit the same efficiency function from Eq. (12), and extracted the volume-weighted capture efficiency directly (rather than by comparison to Monte Carlo). The mean efficiency calculated this way was $35.3 \pm 0.6\%$, in excellent agreement with the value of 35.6% from the direct counting method and well within the uncertainties on both measurements.

A. Phase II neutron capture efficiency uncertainties

For the Phase II analysis, neutron events from the $^{252}$Cf source were selected using the same burst algorithm that was used in previous SNO publications [8]. Neutrons were identified by looking for prompt fission $\gamma$ events from the $^{252}$Cf decay and tagging subsequent events that occurred within 40 ms. Figure 20 plots the neutron detection efficiency for each source run as a function of radial position of the source in the detector for both data and Monte Carlo simulated events. The source position for a run was determined by finding the mean reconstructed position of the prompt fission $\gamma$ events to eliminate the large positioning uncertainties of the source deployment mechanism. The efficiencies shown in Fig. 20 were each fitted to a phenomenologically motivated neutron detection efficiency function:
\[ \epsilon(s) = A \{ \tanh[B(s - C)] - 1 \}, \]
where \( \epsilon(s) \) gives the neutron capture efficiency at source radius \( s \).
To determine the uncertainty on the simulation’s prediction of capture efficiency, we first calculated the mean capture efficiency in the D$_2$O volume, given the two functions shown in Fig. 20, as follows:
\[ \epsilon = \frac{\int_0^{600} \int_0^{600} s^2 \epsilon(s) ds}{\int_0^{600} s^2 ds}. \]
We took the difference of 0.8% between data and simulation as a baseline uncertainty. (The mean detection efficiency measured this way was 35.6%.)

The normalization of the curves shown in Fig. 20 depends on the strength of the $^{252}$Cf source, which we know to 0.7% based on ex situ measurements. An overall shift in reconstructed event positions, discussed in Sec. VI, also changed the measured efficiency in data relative to the simulation results. By varying the value of this shift within its range of uncertainty we found it resulted in an additional 0.3% uncertainty in capture efficiency. The uncertainty in the fit parameters of the neutron detection efficiency function was included conservatively by taking the entire statistical uncertainty on the data efficiency measurements of Fig. 20, which yields another 0.9%. Last, we included a 0.1% uncertainty to account for the fraction of $^{250}$Cf in the $^{252}$Cf source (only $^{252}$Cf is simulated by the Monte Carlo code). The overall uncertainty on the neutron capture efficiency, calculated by adding these in quadrature, was 1.4%.

We checked these results by performing an independent time-series analysis, in which we fit directly for the efficiency at each source deployment point based on the rates of neutron capture and $\gamma$ fission events (the source strength is not an input parameter). The fit included parameters associated with the overall fission rate, backgrounds from accidental coincidences, and the mean capture time for neutrons. We obtained the efficiency as a function of source radial position, to which we fit the same efficiency function from Eq. (12), and extracted the volume-weighted capture efficiency directly (rather than by comparison to Monte Carlo). The mean efficiency calculated this way was $35.3 \pm 0.6\%$, in excellent agreement with the value of 35.6% from the direct counting method and well within the uncertainties on both measurements.

B. Phase I neutron capture efficiency uncertainties

The measurement of neutron capture efficiency uncertainty for Phase I is more difficult than for Phase II, primarily because the lower capture cross section in Phase I made identification of neutron events from the $^{252}$Cf source difficult. The number of detected neutrons per fission was small (less than one on average), and the long capture time (roughly 50 ms) made coincidences more likely to be accidental pileup of prompt fission $\gamma$s than neutrons following the $\gamma$s. Instead of using the burst algorithm, we separated neutron events from fission $\gamma$s based on their differing energies and mean free paths in D$_2$O. Events were required to be more than 150 cm from the source position and to have energies above the mean energy expected for a neutron capture event for both data and Monte Carlo events. The detected rate of events after these cuts was used for the data and Monte Carlo simulation comparison.

An additional parameter was added to the neutron detection efficiency function for these data, as follows:
\[ \epsilon(s) = A \{ \tanh[B(s - C)] - D \}, \]
and the resulting fits to data and Monte Carlo are shown in Fig. 21. The difference of the volume-weighted integrals of the two curves is just 0.9%, but the small value is clearly due to cancellation differences at different radii. The shape difference is driven by small differences between the data and Monte Carlo fits at large radii, which are likely due to unassessed systematic errors on the data points themselves. We included additional uncertainties to account for these. In particular, we included a 0.6% uncertainty associated with the statistical uncertainties of the data and Monte Carlo neutron

FIG. 20. (Color online) Data and Monte Carlo neutron detection efficiencies in Phase II fitted to the phenomenologically motivated neutron detection efficiency function.
detection efficiency function parameters, and an additional 0.6% uncertainty associated with knowledge of the source position. We also included a further uncertainty of 0.9% to account for data and Monte Carlo differences in the energy cut applied to select neutrons.

We applied the same source-strength uncertainties as for the Phase II analysis, namely the 0.7% absolute source strength calibration and 0.1% from the (unmodeled) contamination of $^{250}\text{Cf}$ in the $^{252}\text{Cf}$ source. The total uncertainty on the neutron capture efficiency for Phase I comes to 2%.

To check our estimates, we also performed a time-series analysis of the $^{252}\text{Cf}$ data. Unlike Phase II, for Phase I we cannot extract the absolute efficiency to compare with that derived from the direct counting method because of the 150-cm reconstruction cut. Instead, we performed the time-series analysis on both Monte Carlo and source data runs and compared them. We found the fractional difference between the source-derived and Monte Carlo–derived efficiencies to be just 0.3%, well within the 2% uncertainty obtained from the direct counting method. One output of the time-series analysis is the neutron capture time: the time between neutron emission from the $^{252}\text{Cf}$ source and capture on a deuteron. Figure 22 shows the neutron capture time as a function of source radial position for both data and Monte Carlo. As the $^{252}\text{Cf}$ source approaches the acrylic vessel and light water region, the capture time decreases significantly. The overall agreement between the measured capture times in data and Monte Carlo is very good throughout most of the volume.

### XIII. Backgrounds

Lowering the energy threshold opened the analysis window to additional background contamination, predominantly from radioactive decays of $^{214}\text{Bi}$ and $^{208}\text{Tl}$ in the $^{238}\text{U}$ and $^{232}\text{Th}$ chains, respectively. In Phase II, neutron capture on $^{23}\text{Na}$ produced a low level of $^{24}\text{Na}$ in the detector which, in its decay to $^{24}\text{Mg}$, produced a low-energy $\beta$ and two $\gamma$s. One of these $\gamma$s has an energy of 2.75 MeV, which could photodisintegrate a deuteron. The result was some additional electron-like and neutron capture background events. In addition, radon progeny that accumulated on the surface of the AV during construction could have created neutrons through $(\alpha,n)$ reactions on isotopes of carbon and oxygen within the acrylic.

In the past, most of these backgrounds were estimated using separate self-contained analyses and then subtracted from the measured neutrino fluxes. In this analysis, the Monte Carlo simulation was used to create PDFs for each of 17 sources of background events (except for PMT $\beta$-$\gamma$ events, for which an analytic PDF was used in each phase, as described in Sec. XIII C), and the numbers of events of each type were parameters in the signal extraction fits. Table X lists the sources of physics-related backgrounds that were included in the fits.

All of the Monte Carlo–generated PDFs were verified using calibration sources. 

### A. Background PDFs

Most of the PDFs used in the signal extraction were created from Monte Carlo simulations of the specific event could have created neutrons through $(\alpha,n)$ reactions on isotopes of carbon and oxygen within the acrylic.

In the past, most of these backgrounds were estimated using separate self-contained analyses and then subtracted from the measured neutrino fluxes. In this analysis, the Monte Carlo simulation was used to create PDFs for each of 17 sources of background events (except for PMT $\beta$-$\gamma$ events, for which an analytic PDF was used in each phase, as described in Sec. XIII C), and the numbers of events of each type were parameters in the signal extraction fits. Table X lists the sources of physics-related backgrounds that were included in the fits.

All of the Monte Carlo–generated PDFs were verified using calibration sources. Ex situ measurements [34,35] of background levels in the $\text{D}_2\text{O}$ and $\text{H}_2\text{O}$ provided a priori information for several of them, which were used as constraints in the signal extraction fits. In addition, corrections were applied after the signal extraction fits to account for a number of background event types that contributed much smaller levels of contamination. The following sections describe these procedures.

#### Table X. The sources of physics-related background events in the LETA analysis.

types. However, because of the limited number of simulated PMT $\beta$-$\gamma$ events available in the radial range of interest, an analytic parameterization of the PDF was used, as described in Sec. XIII C. This was verified by comparison to the simulation and uncertainties associated with the value of each parameter were propagated in the signal extraction fits.

The remainder of the background PDFs were verified by comparison of calibration data to simulated events. The D$_2$O and H$_2$O backgrounds were verified using the D$_2$O- and H$_2$O-region radon spikes in Phase II and calibration sources deployed in these regions. Bulk AV backgrounds were verified using the $^{238}$U and $^{232}$Th sources, and surface ($\alpha,n$) neutrons using the $^{252}$Cf source deployed near the AV.

In all cases, the data and Monte Carlo event distributions agreed to within the systematic uncertainties already defined for the PDFs. Figure 23 shows the energy dimension of a fit to the internal radon spike data.

FIG. 23. (Color online) One dimensional projection of the fit to the internal radon spike data.

The cross section for photodisintegration affects the relative normalization of the neutron and electron parts of the background PDFs. The simulation used a theoretical value for the cross section and the associated 2% uncertainty was propagated in the signal extraction fits.

The simulation of $^{24}$Na events used to generate a PDF was done under the assumption of a uniform distribution of events within the detector, since a primary source of $^{24}$Na was the capture of neutrons produced by deployed calibration sources on $^{23}$Na. $^{24}$Na was also introduced via the neck, and via the water systems, which connected near the top and bottom of the AV. Therefore, the signal extraction fits were redone with different spatial distributions, in which the events originated either at the neck of the AV or at the bottom, with a conservatively chosen 10% linear gradient along the $z$ axis.

The difference from the baseline (uniform distribution) fit was taken as a systematic uncertainty.

B. Low-energy background constraints

Several radioassays were performed during data taking to measure the concentrations of radon and radium in the D$_2$O and H$_2$O regions, as described in previous publications [7,34,35]. Although equilibrium was broken in the decay chains, the results are expressed in terms of equivalent amounts of $^{238}$U and $^{232}$Th assuming equilibrium for ease of comparison with...

other measurements. The results were used to place constraints on the expected number of background events in the analysis window. During Phase II, there was a leak in the assay system used to measure the $^{238}$U chain contamination that was not discovered until after data taking had ended, so there is no accurate constraint on the $^{238}$U level in the D$_2$O during that phase. Other limits based on secondary assay techniques were found to be too loose to have any impact on the signal extraction results and so were disregarded. The results of the assays are given in Tables XI and XII.

These concentrations were converted into an expected number of events and were applied as constraints in the signal extraction fits, as described in Sec. XIV E. In situ analyses [36] were used to predict the number of background events from $^{24}$Na decays in Phase II. The predicted value of $392 \pm 117.6$ events was applied as a constraint in the signal extraction fits.

C. PMT $\beta$-$\gamma$ PDF

We use the term “PMT events” to refer to all radioactive decays in the spherical shell encompassing the PMTs and the PSUP. These events were primarily $^{208}$Tl decays originating from $^{232}$Th contamination in the PMT/PSUP components.

PMT events occurred at a high rate, but only a tiny fraction of them reconstructed inside the signal box and within the fiducial volume: in Phase I, the acceptance was only $1.7 \times 10^{-8}$ and in Phase II it was $5.9 \times 10^{-8}$. Therefore, an enormous amount of computer time would be needed to generate enough events to create a PDF. Creation of a multidimensional PDF based entirely on simulation was therefore deemed to be impractical.

A high rate thorium source was deployed near the PSUP in both phases to help model these events. However, interpretation of this data was complicated by the fact that a point source with a sufficiently high rate tends to produce significant “pileup” of multiple events that trigger in the same time window. This pileup changes the topology of the events to the extent that they are not characteristic of PMT $\beta$-$\gamma$s, so they cannot be used directly as a model.

Therefore, an analytic parameterization of the PDF, given in Eq. (15), was used. For this, the cos$\theta_{cz}$ dimension was assumed to be flat; the remaining three-dimensional PDF was of the form:

$$P_{\text{PMT}}(T_{\text{eff}}, \bar{\beta}_{14}, R^3) = e^{AT_{\text{eff}}} \times (e^{BR^3} + C)\mathcal{N}(\bar{\beta}_{14}|\bar{\beta}_{14} = D + ER^3, \sigma = F),$$

where $\mathcal{N}(x|\bar{x}, \sigma)$ is a Gaussian distribution in $x$ with mean $\bar{x}$ and standard deviation $\sigma$. The $\bar{\beta}_{14}$ dimension was determined from a Gaussian fit to Monte Carlo events, in which $\bar{\beta}_{14}$ was allowed a linear dependence on $R^3$.

The source location of the PMT events, their large number, and the fact that they must reconstruct nearly 3 m from their origin to appear inside the fiducial volume means that they have features that distinguish them from other sources of backgrounds. Therefore, we were able to extract a prediction for the total number of PMT events, as well as for the shape of the energy and radial dimensions of the PDF, from the data itself, by performing a bifurcated analysis.

In a bifurcated analysis, two independent cuts are selected that discriminate signal from background. The behavior of these cuts when applied both separately and in combination is used to assess the number of signal and background events in the analysis window. We assume that the data set consists of $\nu$ signal events and $\beta$ background events, so that the total number of events is $S = \beta + \nu$. The background contamination in the final signal sample is just the fraction of $\beta$ that passes both cuts. If the acceptances for background and signal events by cut $i$ are $y_i$ and $x_i$, respectively, the contamination is $y_1y_2\beta$ and the number of signal events is $x_1x_2\nu$.

Given the number, $a$, of events that pass both cuts, the number, $b$, that fail cut 1 but pass cut 2, and the number, $c$, that pass cut 1 but fail cut 2, we then relate these with a system of equations:

$$a + c = x_1\nu + y_1\beta,$$

$$a + b = x_2\nu + y_2\beta,$$

$$a = x_1x_2\nu + y_1y_2\beta,$$

$$\beta + \nu = S,$$

(16) (17) (18) (19)

which we solve analytically, using Monte Carlo predictions for the cut acceptances to determine the contamination, $K = y_1y_2\beta$, in the signal sample. A feature of this method is that it produces a contamination estimate without including events from the signal box (those that pass both cuts) in the analysis.

In this analysis, the “background” comprised the PMT events and the “signal” all other events, including both neutrino interactions and non-PMT radioactive decays. The cuts chosen were the in-time ratio (ITR) cut, because it selected events that were reconstructed far from their true origin, and the early charge (EQ) cut, because it selected events in which a large amount of light produced hits early in time in a small number of tubes. These tend to be characteristics of PMT events (see Sec. X.B).
For a bifurcated analysis to work, the probabilities of passing the cuts must be statistically independent. To demonstrate this, we loosened the cuts and found that the increase in the number of background events agreed well with what would be expected if they were independent.

One result of the bifurcated analysis is a prediction for the number of PMT events in the analysis window, which was used as a constraint in the binned likelihood signal extraction fits, as described in Sec. XIV E.

The acceptance of signal events \((x_1, x_2) \neq 1.0\) and therefore some non-PMT events were also removed by the cuts. Such events falsely increase the count of background events in the three “background boxes.” We limited the impact of this effect by restricting the analysis to the 3.5- to 4.5-MeV region, which was overwhelmingly dominated by PMT events. We also included a correction for the number of non-PMT events in each of the background boxes by using estimates from the Monte Carlo simulation for the acceptance of all other signals and backgrounds and verifying these predictions with radon spike data. (\(^{214}\)Bi, a radon daughter, is the dominant background other than the PMT events in this region.)

To estimate the number of non-PMT events in each of the three background boxes, we multiplied the Monte Carlo predicted acceptances of non-PMT events by the expected total number of these events in the data set. The procedure was therefore iterative: a PMT PDF was created using initial estimates for the total number of non-PMT events in the data set and their acceptances; the bifurcated analysis was used to predict the number of PMT events in the signal box; the data were refit with this new PMT constraint; the total number of non-PMT events in the data set, based on the new fit, was then used to update the non-PMT event correction in the background boxes in the bifurcated analysis, and so on. In practice, the bifurcated analysis itself was simply included within the signal extraction fit, so the prediction for the number of PMT events could be recalculated as the fit progressed, and the penalty factor in the likelihood calculation from the resulting constraint could be varied accordingly. To determine systematic uncertainties on this overall procedure, we tested the analysis on sets of fake data and compared the prediction of the bifurcated analysis to the known true number of PMT \(\beta-\gamma\) events in the signal box.

We verified the bifurcated analysis results by comparing the prediction of the total number of PMT \(\beta-\gamma\) events in the signal box to an estimate made with an independent analysis performed outside the fiducial volume. This independent analysis looked for events that occurred at high radius and were inward pointing, which are characteristics of PMT \(\beta-\gamma\) events, and extrapolated that count into the fiducial volume. The measurements agreed with the bifurcated analysis to well within the uncertainties on the two methods.

To predict the shape of the PMT PDF, the bifurcated analysis was performed in discrete bins in \(T_{\text{eff}}\) and \(R^3\). Unlike the prediction for the total number of PMT events in the data set, this calculation was not included in the signal extraction, so a fixed estimate of the contamination of non-PMT events in the three background boxes was applied. This estimate was derived from a signal extraction fit performed on a small subset of the data. To take uncertainties into account, bifurcated analyses were performed on Monte Carlo–generated “fake” data sets with the dominant systematic and statistical uncertainties applied in turn to determine the effect of each on the extracted shape for the PMT PDF. The differences of the results from the unshifted version were added in quadrature to obtain an additional uncertainty on the shape.

A number of functional forms were fit to the \(T_{\text{eff}}\) and \(R^3\) distributions to determine the best parameterizations for the shapes. An exponential was found to be a good fit to the energy profile and an exponential plus a constant offset to the radial distribution [see Eq. (15)]. The fit results for Phase II are shown in Fig. 25.

The parameters from the fits shown in Fig. 25 were varied in the signal extraction by applying a Gaussian penalty factor to the likelihood function, as described in Sec. XIV E. The mean of the Gaussian was the central fit value from Fig. 25 and the standard deviation was taken as the total uncertainty in this value, including both the fit uncertainty from Fig. 25 and the additional systematic uncertainties described above. Results for both phases are shown in Table XIII. The fits to the bifurcated analysis prediction for the \(R^3\) distribution showed a significant correlation between the exponent and the offset, with correlation coefficients of 0.846 and 0.883 in Phases I and II, respectively. This correlation was included in the Gaussian penalty factor in the signal extraction fits.
D. Limits on instrumental backgrounds

Because instrumental background events were not modeled by the simulation, their contamination in the analysis window was determined directly from the data. A bifurcated analysis was used, similar to that described in Sec. XIII C. In this instance, two sets of cuts were used to define the analysis: the instrumental cuts and the high-level cuts, described in Sec. X. The numbers of events in the data set failing each and both sets of cuts were used to estimate the contamination by instrumental backgrounds.

As was done in Sec. XIII C, a prediction of the number of good (physics) events that failed the instrumental cuts was used to correct the number of events in each of the background boxes. We obtained this prediction using the cut acceptances given in Sec. XE1 and an estimate of the numbers of signal and radioactive background events in the data set. The analysis was performed at two energy thresholds in order to study the energy dependence of the contamination. Results are given in Table XIV.

Since these events were not modeled in the simulation, it is difficult to directly predict their effect on the signal extraction fit results. However, because virtually all of them fall into the lowest energy bin, they are unlikely to appear like neutron events. Since the $T_{\text{eff}}$ distributions of CC and ES signals were unconstrained in the signal extraction fit, they could mimic these event types. Therefore, a conservative approach was taken, in which the estimated contamination from the 3.5-MeV analysis was applied as an additional uncertainty in the lowest energy bin for both the CC and ES signals.

E. Atmospheric backgrounds

The NUANCE neutrino Monte Carlo simulation package [37] was used to determine the contribution of atmospheric neutrino events to the data set. The estimated number of atmospheric neutrino events was not large enough to merit introducing an additional event type into the already complex signal extraction procedure. Instead, 15 artificial data sets were created that closely represented the best estimate for the real data set, including all neutrino signals and radioactive backgrounds in their expected proportions. The NUANCE simulation was used to predict the distribution of atmospheric neutrino events in each of the four observable parameters used to distinguish events in the signal extraction fit (see Sec. XIV), and a number of such events were included in each artificial data set, drawn from the estimate for the number in the true data. Signal extraction was performed on these sets to determine which signal the events would mimic in the extraction. This resulted in a small correction to the NC flux of $4.66 \pm 0.76$ and $17.27 \pm 2.83$ events to be subtracted in Phases I and II, respectively, and small additional uncertainties for the CC and ES rates, mostly at the subpercentage level.

Atmospheric events were often characterized by a high-energy primary followed by several neutrons. Therefore, there was significant overlap with events identified by the "coincidence cut," which removed events that occurred within a fixed time period of each other. This overlap was exploited to verify the predicted number of atmospheric events. Without application of the coincidence cut, a total of $28.2 \pm 5.4$ and $83.9 \pm 15.9$ atmospheric neutrino events were predicted in Phases I and II, respectively. The coincidence cut reduced these numbers to $21.3 \pm 4.0$ and $29.8 \pm 5.7$ events, which were the numbers used in the creation of the initial artificial data sets. A second group of sets was created, using the precoincidence cut estimates for the number of events, to determine the change in the NC flux due to the additional events. The signal extraction was then performed on a subset of the real data, both with and without the application of the coincidence cut, and the observed difference in the NC flux was entirely consistent with the predictions, thus verifying the method used to derive the NC flux correction.

F. Isotropic acrylic vessel background

Early in the SNO analyses, a type of instrumental background was discovered that reconstructed near the AV and was characterized by very isotropic events ($\beta_{14} < 0.15$). At higher energies ($N_{\text{hit}} > 60$), these events form a distinct peak in a histogram of $\beta_{14}$, and they are easily removed from the data by a combination of the fiducial volume and isotropy cuts. However, at lower energies, position reconstruction errors increase and the isotropy distributions of the isotropic acrylic vessel background (IABV) and other events broaden and join, so removal of the IAVB events by these cuts is no longer assured.

Accurate simulation of these events is difficult because the physical mechanism that produces the IAVB events has not been identified and crucial IAVB event characteristics cannot be predicted. These include the light spectrum, photon timing distribution, location, and effective event energy. To circumvent this problem, simulated events were generated that covered a wide range of possibilities. Three event locations were modeled: on the exterior and interior AV surfaces and uniformly distributed within the AV acrylic. Events were generated at three different photon wavelengths that cover the range of SNO detector sensitivity: 335, 400, and 500 nm. The photons were generated isotropically, with the number of

photons in an event chosen from a uniform distribution with a
maximum above the energy range used in the neutrino analysis.
The photon time distribution was a negative exponential,
with the time constant for an event chosen from a truncated
Gaussian with mean and standard deviation of 5 ns.

Using PDFs derived from the simulated event samples,
maximum likelihood signal extraction code was used to
estimate the number of IAVB events in the data in the vicinity
of the AV, between 570 and 630 cm from the detector center, in
accompaniment with the CC, ES, and NC neutrino event types
and 208Tl and 214Bi backgrounds in the D2O, AV, H2O, and
PMTs. This was done separately for each of the nine simulated
photon wavelength/event location combinations. Because the
energy distribution of the IAVB events was unknown, the IAVB
extractions were done as a function of \( N_{\text{hit}} \) in 11 bins. The ratio
of the number of IAVB events that passed all the neutrino cuts
to those that fit near the AV in each \( N_{\text{hit}} \) bin was calculated
for each simulated IAVB case as a function of event energy.
These ratios were used, together with the estimated numbers of
such events near the AV, to estimate the IAVB contamination
in the neutrino sample as a function of energy for each of the
simulated IAVB cases.

The polar-angle distributions of hit PMTs in the simulated
IAVB events were studied in a coordinate system centered
on the middle of the AV, with its \( z \) axis along the radial
vector through the fitted event location. There are marked
differences in these distributions among the different simulated
cases due to optical effects of the AV. Comparisons of these
distributions were made between simulated events and high-
\( N_{\text{hit}} \), high-isotropy events in the data that reconstruct near the
AV (presumed to be IAVB events). A fit was made to find
the weighted combination of the simulated cases that best
fit the high-\( N_{\text{hit}} \) data. The resulting weights were assumed
to be valid at all energies and were used together with the
contamination ratios discussed above: first, to estimate the total
IAVB background expected in the neutrino analysis data set as
a function of energy (totaling 27 and 32 events above 3.5 MeV
in Phases I and II, respectively) and, second, to generate a set
of simulated IAVB events representative of those expected to
contaminate the neutrino data.

A test similar to that described in Sec. XIII E was
performed. Fifteen artificial data sets were created that also
contained simulated IAVB events based on estimates of the
weighted contributions of the simulated cases and their energy
distributions. It was found that the majority of the IAVB events
fit out as other background event types, so the result of adding
the simulated IAVB background was only small additional
uncertainties for each of the neutrino flux parameters, with
no required corrections. The increase in uncertainty for the
NC flux was evaluated at 0.26%. The increases of the CC
uncertainties were also mostly at the subpercentage level,
and the increase in uncertainties on the ES rates were so small as
to be negligible (<0.01%).

### G. Additional neutron backgrounds

A full study of other possible sources of neutrion back-
ground events, such as from events such as \((\alpha,n)\) reactions and
terrestrial and reactor antineutrino interactions, was presented
in previous publications [7,8]. The full set of simulated NC
events was used to adjust these numbers for the lowered energy
threshold and for the live times and detection efficiencies in
the two phases to give a final correction to the NC flux of
3.2 ± 0.8 and 12.0 ± 3.1 neutron capture events in Phases I
and II, respectively.

### XIV. SIGNAL EXTRACTION METHODS

An extended maximum likelihood method was used to
separate event types based on four observable parameters:
the effective electron kinetic energy, \( T_{\text{eff}} \); the angle of the
event direction with respect to the vector from the Sun, \( \cos \theta_{\odot} \); the
normalized cube of the radial position in the detector, \( R^3 \); and the isotropy of the PMT hits, \( \beta_{14} \). Two independent
techniques were used, as described in Secs. XIV B and XIV C.
One method used binned PDFs and the other an unbinned,
“kernel estimation” approach.

We performed two distinct types of fit. The first extracted
the detected electron energy spectra for CC and ES events
in individual \( T_{\text{eff}} \) bins, without any model constraints on the
shape of the underlying neutrino spectrum. We refer to this as an “unconstrained” fit. The second fit exploited the unique
capabilities of the SNO detector to directly extract the energy-
dependent \( \nu_e \) survival probability (Sec. XIV D). The survival
probability was parameterized as a polynomial function and
applied as a distortion to the \( ^8\text{B} \) neutrino energy spectrum
(taken from Ref. [38]). The shapes of the CC and ES \( T_{\text{eff}} \)
spectra were recomputed from the distorted \( ^8\text{B} \) spectrum as the
fit progressed, allowing the polynomial parameters to vary
in the fit. The overall fluxes were also constrained in this fit
through the requirement of unitarity. The features in common
for the two signal extraction approaches are described below.

The types of events included in the fit were the three neu-
trino interaction types (CC, ES, and NC) and 17 background
event types across the two phases of data, as defined in Table X.
The likelihood was maximized with respect to the number of
events of each signal type and several systematic parameters
affecting the shapes of the PDFs, as described in Secs. XIV B
and XIV C.

To extract energy spectra for the CC and ES neutrino signals
in the unconstrained fits, CC and ES PDFs were created in
discrete \( T_{\text{eff}} \) intervals and the fitted numbers of events in
these intervals were allowed to vary independently. The energy
spectra for events from the NC interaction and from radioactive
backgrounds have no dependence on the neutrino oscillation
model, and so the shapes of these spectra were fixed within
their systematic uncertainties.

The flux of solar neutrinos was assumed to be constant, so
a single set of neutrino-related fit parameters was applied to
both phases. Therefore, the neutrino signal parameters varied
in the fit were an NC rate and a number of CC and ES
rates in discrete energy intervals, as defined in Secs. XIV B
and XIV C. Although SNO was primarily sensitive to the \( ^8\text{B} \)
chain of solar neutrinos, we included a fixed contribution of
solar hep neutrinos, which was not varied in the fit. Based on
results from a previous SNO analysis [8], we used 0.35, 0.47,
and 1.0 times the standard solar model (SSM) prediction for CC, ES, and NC hep neutrinos, respectively. Taken together, these correspond to 16.4 events in Phase I and 33.3 events in Phase II.

To take into account correlations between parameters, multidimensional PDFs were used for all signals. In the unconstrained fits, CC and ES were already divided into discrete energy bins, and three-dimensional PDFs were created in each bin for the other observables: $P(\beta_{14}, R^3, \cos \theta_\odot)$. In the survival probability fits, fully four-dimensional PDFs were used for CC and ES events. For the NC and background PDFs the $\cos \theta_\odot$ distribution is expected to be flat, since there should be no dependence of event direction on the Sun’s position, but correlations exist between the other observables. For these event types, the PDFs were factorized as $P(T_{\text{eff}}, \beta_{14}, R^3) \times P(\cos \theta_\odot)$.

Uncertainties in the distributions of the observables were treated as parameterized distortions of the Monte Carlo PDF shapes. The dominant systematic uncertainties were allowed to vary in the fit in both signal extraction methods. Less significant systematics were treated as in previous SNO analyses [7], using a “shift-and-refit” approach: the data were refit twice for each systematic uncertainty, with the model PDFs perturbed by the estimated positive and negative 1σ values for the uncertainty in a given parameter. The differences between the nominal flux values and those obtained with the shifted PDFs were taken to represent the 68% C.L. uncertainties, and the individual systematic uncertainties were then combined in quadrature to obtain total uncertainties for the fluxes.

### A. Systematic uncertainties: phase correlations

Uncertainties related to theoretical quantities that are unaffected by detector conditions (such as the photodisintegration cross section uncertainty) were applied to both phases equally. Uncertainties in quantities dependent on detector conditions (such as energy resolution) were treated independently in each phase. Uncertainties in quantities that partly depend on the operational phase (such as neutron capture efficiency, which depends both on a common knowledge of the $^{252}$Cf source strength and on the current detector conditions) were treated as partially correlated. For the latter, the overall uncertainty associated with each phase thus involved a common contribution in addition to a phase-specific uncertainty. Since neutron capture events were more similar to electron-like events in Phase I than in Phase II, several of the neutron-related uncertainties applied to Phase II only. The correlations are summarized in Table XV.

### B. Binned-histogram unconstrained fit

In this approach, the PDFs were created as three-dimensional histograms binned in each observable dimension, as summarized in Table XVI. For CC and ES, three-dimensional PDFs were created in each $T_{\text{eff}}$ interval to fully account for correlations between all four observable dimensions. Fifty rate parameters were fitted: the CC and ES rates in each of 16 spectral bins, the NC normalization, and 17 background PDF normalizations. Dominant systematic uncertainties were allowed to vary within their uncertainties, or “floated,” by performing one-dimensional scans of the likelihood in the value of each systematic parameter. This involved performing the fit multiple times at defined intervals in each systematic parameter and extracting the value of the likelihood, which included a Gaussian factor whose width was defined by the independently estimated uncertainty on that parameter, as described in Sec. XIV E. This combined a priori knowledge from the calibration data and Monte Carlo studies used to parameterize systematic uncertainties with information inherent in the data itself. If a new likelihood maximum was found at an offset from the existing best estimate of a particular systematic parameter, then the offset point was defined as the new best estimate. An iterative procedure was used to take into account possible correlations between parameters. The final uncertainties on each parameter were defined by where the log likelihood was 0.5 less than at the best-fit point, and the differences in each fitted flux parameter between these points and the best-fit point were taken as the associated systematic uncertainties for that parameter. For more details of this approach, see Ref. [39].
The parameters floating used, along with their relevant correlations, as described in Sec. XIV A, were as follows:

(i) energy scale (both correlated and uncorrelated in each phase)
(ii) energy resolution (uncorrelated in each phase)
(iii) $\beta_{14}$ scale for electron-like events (correlated between phases)
(iv) PMT $\beta\gamma$ $R^3$ exponent (uncorrelated in each phase, see Sec. XIII C)
(v) PMT $\beta\gamma$ $R^3$ offset (uncorrelated in each phase, see Sec. XIII C)
(vi) PMT $\beta\gamma$ $T_{\text{eff}}$ exponent (uncorrelated in each phase, see Sec. XIII C)

The remaining systematic uncertainties were applied using the shift-and-refit approach.

### C. Unbinned unconstrained fit using kernel estimation

In this approach, the PDFs were created by kernel estimation. Like standard histogramming techniques, kernel estimation starts with a sample of event values, $t_i$, drawn from an unknown distribution, $P(x)$. Based on this finite sample, the parent distribution is approximated by $\hat{P}(x)$, which is a sum of kernel functions, $K_i(x)$, each centered at an event value from the sample

$$\hat{P}(x) = \frac{1}{n} \sum_{i=1}^{n} K_i(x - t_i). \quad (20)$$

The most common choice of form of kernel functions is the normalized Gaussian distribution,

$$K(x/h) = \frac{1}{h\sqrt{2\pi}} e^{-(x/h^2)/2}. \quad (21)$$

where $h$ is called the bandwidth of the kernel. One can pick a different bandwidth, $h_i$, for the kernel centered over each event.

Kernel-estimated density functions have many useful properties. If the kernel functions are continuous, then the density function will also be continuous. In one dimension, kernel estimation can also be shown to converge to the true distribution slightly more quickly than a histogram with bin size the same as the kernel bandwidth. Generalizing the kernel estimation method to multiple dimensions is done by selecting a kernel with the same dimensionality as the PDF. We used a multidimensional Gaussian kernel that was simply the product of one-dimensional Gaussians. We followed the prescription given in Ref. [40] for the selection of bandwidths for each event in each dimension.

By varying the values associated with the events in the PDF sample individually, kernel estimation can very naturally be extended to incorporate systematic variation of PDF shapes. For example, energy scale is incorporated by a transformation of the simulated event values, $t_i \rightarrow (1 + \alpha) \times t_i$, where $\alpha$ is a continuously variable parameter. Such transformations preserve the continuity and analyticity of the PDF. We can then add these systematic distortion parameters to the likelihood function and also optimize with respect to them using a gradient descent method. This allows correlations between systematics and neutrino signal parameters, as well as between systematics themselves, to be naturally handled by the optimization algorithm. In addition, the information in the neutrino data set itself helps to improve knowledge of detector systematics.

Three kinds of systematic distortions can be represented within this formalism. Transformations like energy scale and position offset have already been mentioned. A Gaussian resolution systematic can be floated by transforming the bandwidth, $h$, through analytic convolution. Finally, reweighting systematics, such as the neutron capture efficiency, are represented by varying the weight of events in the sum.

The main challenge in using kernel estimation with large data sets is the computational overhead associated with repeatedly re-evaluating the PDFs as the parameters associated with detector response vary. We made several algorithmic improvements to make kernel estimation more efficient and did much of the calculation on off-the-shelf 3D graphics processors. For more detail on the implementation of the fit on the graphics processors, see [41].

The kernel-estimated PDFs had the same dimensionality over the same ranges of the observables as the binned fit, except with an upper energy limit of 20 MeV instead of 11.5 MeV. CC rates were extracted in 0.5-MeV intervals up to 12 MeV, with a large 12- to 20-MeV interval at the end of the spectrum. To reduce the number of free parameters in the fit, ES rates were extracted in a 3.5- to 4.0-MeV interval, in 1-MeV intervals from 4 MeV to 12 MeV, and in a final 12- to 20-MeV interval. The CC and ES PDFs were fixed to be flat in the $T_{\text{eff}}$ dimension within each $T_{\text{eff}}$ interval. During fitting, the following parameters, corresponding to the dominant systematic uncertainties, were allowed to vary continuously:

(i) energy scale (both correlated and uncorrelated in each phase)
(ii) energy resolution (uncorrelated in each phase)
(iii) $\beta_{14}$ electron and neutron scales
(iv) PMT $\beta\gamma$ $R^3$ exponent (uncorrelated in each phase)
(v) PMT $\beta\gamma$ $R^3$ offset (uncorrelated in each phase)
(vi) PMT $\beta\gamma$ $T_{\text{eff}}$ exponent (uncorrelated in each phase)

Altogether there were 18 CC parameters, 10 ES parameters, 1 NC parameter, 17 background normalization parameters, and 16 detector systematic parameters. The remaining systematic uncertainties were applied using the shift-and-refit approach.
D. Energy-dependent $\nu_e$ survival probability fit using kernel estimation

The unique combination of CC, ES, and NC reactions detected by SNO allowed us to fit directly for the energy-dependent $\nu_e$ survival probability without any reference to flux models or other experiments. Such a fit has several advantages over fitting for the neutrino-mixing parameters using the NC rate and the “unconstrained” CC and ES spectra described in the previous sections.

The unconstrained fits described in Secs. XIV B and XIV C produce neutrino signal rates for CC and ES in intervals of reconstructed energy, $T_{\text{eff}}$, with the free parameters in the fit directly related to event counts in each $T_{\text{eff}}$ interval. Although this simplifies implementation of the signal extraction fit, physically relevant quantities, such as total $^8$B neutrino flux and neutrino energy spectra, are entangled with the energy response of the SNO detector. Comparing the unconstrained fit to a particular model therefore requires convolving a distorted $^8$B neutrino spectrum with the differential cross sections for the CC and ES interactions and then further convolving the resulting electron energy spectra with the energy response of the SNO detector to obtain predictions for the $T_{\text{eff}}$ spectra.

Moreover, the unconstrained fits of Secs. XIV B and XIV C have more degrees of freedom than are necessary to describe the class of MSW distortions that are observable in the SNO detector. For example, the rms width of $T_{\text{eff}}$ for a 10-MeV neutrino interacting via the CC process is nearly 1.5 MeV. Therefore, adjacent $T_{\text{eff}}$ bins in the unconstrained fit are correlated, but this information is not available to the minimization routine to constrain the space of possible spectra. By fitting for an energy-dependent survival probability, we enforce continuity of the energy spectrum and thereby reduce covariances with backgrounds, most notably $^{214}$Bi events. Events from the CC reaction can no longer easily mimic the steep exponential shape of the background energy distribution. In addition, systematic uncertainties that are correlated between the CC and NC events will naturally cancel in this approach within the fit itself.

We therefore performed a signal extraction fit in which the free parameters directly described the total $^8$B neutrino flux and the energy-dependent $\nu_e$ survival probabilities. We made the following assumptions:

(i) The observed CC and ES $T_{\text{eff}}$ spectra come from a fixed distribution of neutrino energies, $E_\nu$, with the standard differential cross sections;
(ii) The $\nu_e$ survival probability can be described by a smooth, slowly varying function of $E_\nu$ over the range of neutrino energies to which the SNO detector is sensitive;
(iii) The CC, ES, and NC rates are directly related through unitarity of the neutrino mixing matrix;
(iv) $\nu_e$ regeneration in the Earth at night can be modeled as a linear perturbation to the daytime $\nu_e$ survival probability.

Given these assumptions, we performed a fit in which the neutrino signal was described by six parameters:

(i) $\Phi_{^8B}$: the total $^8$B neutrino flux;
(ii) $c_0$, $c_1$, $c_2$: coefficients in a quadratic expansion of the daytime $\nu_e$ survival probability around $E_\nu = 10$ MeV;
(iii) $a_0$, $a_1$: coefficients in a linear expansion of the day/night asymmetry around $E_\nu = 10$ MeV.

The day/night asymmetry, $A$, daytime $\nu_e$ survival probability, $P_{ee}^\text{day}$, and nighttime $\nu_e$ survival probability, $P_{ee}^\text{night}$, that correspond to these parameters are:

\[
A(E_\nu) = a_0 + a_1(E_\nu - 10 \text{ MeV}),
\]
\[
P_{ee}^\text{day}(E_\nu) = c_0 + c_1(E_\nu - 10 \text{ MeV}) + c_2(E_\nu - 10 \text{ MeV})^2,
\]
\[
P_{ee}^\text{night}(E_\nu) = P_{ee}^\text{day} \times \frac{1 + A(E_\nu)/2}{1 - A(E_\nu)/2}.
\]

The survival probabilities were parameterized in this way to reduce correlations between $c_0$ and the higher order terms by expanding all functions around the detected $^8$B spectrum peak near 10 MeV. The simulated neutrino energy spectrum after application of the analysis cuts, shown in Fig. 26, rapidly drops in intensity away from 10 MeV. The broad $T_{\text{eff}}$ resolution of the detector in combination with the limited range of detectable neutrino energies limits our sensitivity to sharp distortions. For this reason, we chose to fit for a smooth, polynomial expansion of the survival probability. By using a generic form, we allow arbitrary models of neutrino propagation and interaction to be tested, including standard MSW effects, as long as they meet the assumptions described above. Monte Carlo studies demonstrated that this analytical form was sufficient to model the class of MSW distortions to which the SNO detector was sensitive. We propagated the uncertainty in the shape of the undistorted $^8$B energy spectrum as an additional shift-and-refit systematic uncertainty to ensure the extracted survival probability incorporated this model dependence.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig26}
\caption{(Color online) Simulation of the undistorted energy spectrum of $^8$B neutrinos that trigger the detector, before the application of the $T_{\text{eff}}$ threshold, and after a $T_{\text{eff}} > 3.5$ MeV cut is applied, normalized to the SSM prediction. The sharp cut in $T_{\text{eff}}$ results in a smooth roll-off in detection efficiency for energies less than the peak energy. Also shown is the spectrum of incident neutrinos predicted by Ref. [38], arbitrarily normalized, to illustrate the effect of detector sensitivity.}
\end{figure}
To implement this fit, we performed a “four-phase” signal extraction, dividing the data and the PDFs into Phase I-day, Phase I-night, Phase II-day, and Phase II-night groups. Background decay rates from solid media, such as the acrylic vessel and the PMTs, were constrained to be identical day and night. Decay rates in the D$_2$O and H$_2$O regions were free to vary between day and night to allow for day/night variations in the water circulation and filtration schedules. We floated the same detector systematics as in the unconstrained fit described in Sec. XIV C. The fit has 6 neutrino parameters, 26 background normalization parameters, and 16 detector systematic parameters, for a total of 48 free parameters.

We constructed the PDFs in the same way as described in Sec. XIV C, with the exception of the CC and ES signals. Instead of creating a 3D PDF ($\beta_{14}$, $R^3$, cos $\theta_0$) for intervals in $T_{\text{eff}}$ in the undistorted spectrum, we created 4D PDFs ($T_{\text{eff}}$, $\beta_{14}$, $R^3$, cos $\theta_0$) for separate $E_\nu$ intervals in the undistorted spectrum. There were 9 CC and 9 ES PDFs in each of the 4 day/night phases, with $E_\nu$ boundaries at 4, 6, 7, 8, 9, 10, 11, 12, 13, and 15 MeV.

During optimization, the signal rates associated with the 76 CC, ES, and NC PDFs were not allowed to vary freely but were determined by the 6 neutrino parameters. We defined an “ES survival probability”:

$$R_{\text{ES}}(E_\nu) = P_{\text{ee}} + \epsilon [1 - P_{\text{ee}}(E_\nu)]$$  \hspace{1cm} (25)

$$P_{\text{ES}}^{\text{night}}(E_\nu) = P_{\text{ee}} + \epsilon [1 - P_{\text{ee}}(E_\nu)]$$  \hspace{1cm} (26)

where $\epsilon = 0.156$ is the approximate ratio between the $\nu_\mu$ and $\nu_\tau$ ES cross sections. The ES cross-section ratio is not constant as a function of neutrino energy, so we took the variation with energy as an additional systematic uncertainty. The signal rates were defined in terms of $\Phi_{\text{1B}}, P_{\text{ee}},$ and $P_{\text{ES}}$ to be

$$R_{\text{NC}} = \Phi_{\text{1B}},$$

$$R_{\text{CC},i}^{\text{day}} = \frac{\Phi_{\text{1B}}}{E_i - E_{i-1}} \int_{E_{i-1}}^{E_i} dE_\nu P_{\text{ee}}(E_\nu),$$

$$R_{\text{ES},i}^{\text{night}} = \frac{\Phi_{\text{1B}}}{E_i - E_{i-1}} \int_{E_{i-1}}^{E_i} dE_\nu P_{\text{ee}}(E_\nu),$$

$$R_{\text{CC},i}^{\text{night}} = \frac{\Phi_{\text{1B}}}{E_i - E_{i-1}} \int_{E_{i-1}}^{E_i} dE_\nu P_{\text{ee}}(E_\nu),$$

$$R_{\text{ES},i}^{\text{day}} = \frac{\Phi_{\text{1B}}}{E_i - E_{i-1}} \int_{E_{i-1}}^{E_i} dE_\nu P_{\text{ee}}(E_\nu),$$

where $E_0$ is 4 MeV and $E_i$ is the upper energy boundary of the $i$th $E_\nu$ interval.

The survival probability fit included the same shift-and-refit systematics as the unconstrained fit, along with all of the day/night systematics used in previous analyses [7,8]. These systematics accounted for diurnal variations in reconstructed quantities, such as energy scale and vertex resolution, as well as long-term variation in detector response that could alias into a day/night asymmetry. In addition, the nonuniformity of the $\cos \theta_0$ distributions of CC and ES events can also alias into a day/night asymmetry, so we incorporated additional day/night systematic uncertainties on all observables in the CC and ES PDFs.

E. Application of constraints

A priori information from calibrations and background measurements was included in the fits to constrain some of the fit parameters, in particular several of the radioactive backgrounds (discussed in Sec. XIII B) and any systematic parameters floated in the fit. The extended likelihood function had the form:

$$L(\tilde{\alpha}, \tilde{\beta}) = L_{\text{data}}(\tilde{\alpha} | \tilde{\beta})L_{\text{calib}}(\tilde{\beta}),$$  \hspace{1cm} (32)

where $\tilde{\alpha}$ represents the set of signal parameters being fit for, $\tilde{\beta}$ represents the nuisance parameters for the systematic uncertainties that were floated in the fits, $L_{\text{data}}(\tilde{\alpha} | \tilde{\beta})$ is the extended likelihood function for the neutrino data given the values of those parameters, and $L_{\text{calib}}(\tilde{\beta})$ is a constraint term representing prior information on the systematic parameters, obtained from calibration data and ex situ measurements. The contribution to $L_{\text{calib}}(\tilde{\beta})$ for each systematic parameter had the form:

$$L_{\text{calib}}(\tilde{\beta}) = e^{-\frac{(x_\beta - \mu_\beta)^2}{2\sigma_\beta^2}},$$  \hspace{1cm} (33)

where $x_\beta$ is the value of parameter $i$ and $\mu_\beta$ and $\sigma_\beta$ are the estimated value and uncertainty determined from external measurements (with asymmetric upper and lower values for $\sigma_\beta$ where required). This results in a reduction of the likelihood as the parameter value moves away from the a priori estimate.

F. Bias testing

To verify that the signal extraction methods were unbiased, we used half the Monte Carlo events to create “fake data” sets and the remaining events to create PDFs used in fits to the fake data sets. A fit was performed for each set and the results were averaged to evaluate bias and pull in the fit results. We created 100 sets containing only neutrino events, 45 sets also containing internal background events, and 15 sets containing the full complement of neutrino events and internal and external backgrounds. The numbers of fake data sets were limited by the available computing resources.

The two signal extraction methods gave results that were in excellent agreement for every set. The biases for the neutrino fluxes were consistent with zero, and the Gaussian pull distributions were consistent with a mean of zero and standard deviation of 1.

Additional tests were performed in which one or more systematic shifts were applied to the event observables in the fake data sets, and the corresponding systematic parameters were floated in the fit, using a priori inputs as in the final signal extraction fits, to verify that the two independent methods for propagating systematic uncertainties were also unbiased. In all cases, the true values for the neutrino fluxes were recovered with biases consistent with zero.

G. Corrections to PDFs

A number of corrections were required to account for residual differences between data and PDFs derived by simulation. An offset of the laserball position along the
z axis during calibration of PMT timing introduced an offset to reconstructed positions along this axis in the data. A correction was therefore applied to all data events, as described in Sec. VI. In addition, a number of corrections were applied to the reconstructed energy and isotropy of events (see Secs. VIII B and IX, respectively). The Monte Carlo simulation was used to link the neutrino rates between the two phases, thus taking into account variations in detector efficiency and live time. Several corrections were applied to the Monte Carlo flux predictions, as described below.

The predicted number of events for signal type \( i \) per unit of incident flux, including all correction factors, is:

\[
N_i = N_i^{\text{MC}} \delta_{\text{sim}}^{\text{acc}} \delta_{\text{i}}^{\text{iso}} N_i^{\text{D}} N_i^{\text{r}} R_i \tau,
\]

where

(i) \( N_i^{\text{MC}} \) is the number of events predicted by the Monte Carlo simulation for signal \( i \) per unit incident flux. This is recalculated as needed to account for any systematic shifts applied to the PDFs.

(ii) \( \delta_{\text{sim}} \) corrects for events aborted in the simulation due to photon tracking errors. This correction increases with the number of photons in an event.

(iii) \( \delta_{\text{acc}}^{\text{iso}} \) corrects for differences in the acceptances of the instrumental and high-level cuts for data and Monte Carlo events (Sec. XI E).

(iv) \( N_i^{\text{D}} \) is a correction to account for CC interactions on chlorine and sodium nuclei in the D\(_2\)O volume that are not modeled in the simulation. This correction is relevant only to the CC signal in Phase II.

(v) \( N_i^{\text{r}} \) is a correction to the number of target deuterons and hence is relevant to CC and NC only.

(vi) \( N_i^{\text{r}} \) is a correction to the number of target electrons and hence is relevant to ES only.

(vii) \( R_i \) accounts for radiative corrections to the neutrino-deuteron interaction cross section for NC. Radiative corrections relevant to the CC and ES interactions were included in the simulation.

(viii) \( \tau \) corrects for dead time introduced into the data set by the instrumental cuts.

These corrections are summarized in Table XVII.

### XV. RESULTS

The detailed improvements made to this analysis, as described in previous sections, allow a more precise extraction of the neutrino flux parameters and, as a result, of the MSW oscillation parameters. Results from the unconstrained fit are given in Sec. XV A and from the energy-dependent fit to the \( \nu_e \) survival probability in Sec. XV B. This new method for directly extracting the form of the \( \nu_e \) survival probability from the signal extraction fit produces results that are straightforward to interpret. A direct comparison can be made of the shape of the extracted survival probability to model predictions, such as the LMA-predicted low-energy rise.

Section XV C describes the measurements of the neutrino oscillation parameters. As has been observed in a number of recent publications [42-44], the different dependence of the \( \nu_e \) survival probability on the mixing parameters \( \theta_{12} \) and \( \theta_{13} \) between solar and reactor neutrino experiments means that a comparison of solar data to reactor antineutrino data from the KamLAND experiment allows a limit to be placed on the value of \( \sin^2 \theta_{13} \). The new precision achieved with the LETA analysis in the measurement of \( \tan^2 \theta_{12} \) results in a better handle on the value of \( \sin^2 \theta_{13} \) in such a three-flavor oscillation analysis. Results of this analysis are presented in Sec. XV C, including a constraint on the value of \( \sin^2 \theta_{13} \).

#### A. Unconstrained fit

Our measurement of the total flux of active \( \nu_B \) solar neutrinos, using the NC reaction (\( \Phi_{\nu_B} \)) is found to be:

(i) binned-histogram method

\[
\Phi_{\nu_B}^{\text{bin}} = 5.140^{+0.160}_{-0.158} \text{(stat)}^{+0.132}_{-0.117} \text{(syst)} \times 10^6 \text{ cm}^{-2} \text{ s}^{-1}
\]

(ii) kernel estimation method

\[
\Phi_{\nu_B}^{\text{kernel}} = 5.171^{+0.159}_{-0.158} \text{(stat)}^{+0.132}_{-0.114} \text{(syst)} \times 10^6 \text{ cm}^{-2} \text{ s}^{-1}
\]

This represents \( +4.0\% \) total uncertainty on the flux, which is more than a factor of two smaller than the best of previous SNO results. The statistical uncertainty has been reduced by

![Graph showing flux (10^6 cm^-2 s^-1) vs. previous LETA results, LETA systematic uncertainties, and LETA results + total uncertainties.](055504-36)
nearly $\sqrt{2}$, to 3.1%. However, the largest improvement is in the magnitude of the systematic uncertainty, which has been reduced from 7.3% and 6.3% in previous analyses of Phase II [8] and Phase III [9] data, respectively, to 2.4% (taking the average of the upper and lower values).

Figure 27 shows a comparison of these results to those from previous analyses of SNO data. Note that the $^8$B spectral shape used in the previous Phase I and Phase II analyses [45] differs from that used here [38]. The bands represent the size of the systematic uncertainties on each measurement, thus illustrating the improvements achieved with this analysis.

Throughout this analysis, the quoted “statistical” uncertainties represent the uncertainty due to statistics of all signals and backgrounds in the fit, with correlations between event types taken into account. Therefore, they include uncertainties in the separation of signal events from backgrounds in the fits. For example, the statistical uncertainties on the quoted number of NC events and covariances with other event types. This is different from previous SNO analyses, in which the background events were not included in the signal extraction fits and any uncertainty in the level of background events was propagated as an additional systematic uncertainty.

The two independent signal extraction fit techniques are in excellent agreement, both in the central NC flux value and in the magnitude of the uncertainties. The result from the binned-histogram method is quoted as the final unconstrained fit result for ease of comparison to previous analyses, which used a similar method for PDF creation.

This result is in good agreement with the prediction from the BS05(OP) SSM of $5.69 \times 10^6$ cm$^{-2}$ s$^{-1}$ [46], to within the theoretical uncertainty of $\pm$16%. It is also in good agreement with the BS05(AGS,OP) model prediction of $4.51 \times 10^6$ cm$^{-2}$ s$^{-1}$ $\pm$16% [46], which was constructed assuming a lower heavy-element abundance in the Sun’s surface.

The extracted CC and ES electron spectra from both signal extraction fits, in terms of the fraction of one unoscillated SSM, using the BS05(OP) model flux of $5.69 \times 10^6$ cm$^{-2}$ s$^{-1}$ [46], are shown in Fig. 28. An unsuppressed, undistorted spectrum would correspond to a flat line at 1.0. A greater suppression is observed for CC events than ES, since the ES spectrum includes some contribution from $\nu_\mu$ and $\nu_\tau$, whereas CC is sensitive only to $\nu_e$. Both spectra are consistent with the hypothesis of no distortion. The results from the two independent signal extraction fits are again in excellent agreement for both the central fit values and the uncertainties.

Figure 29 shows the CC electron spectrum extracted from the binned-histogram signal extraction fit with the errors separated into the contributions from statistical and systematic uncertainties. As for the NC flux result, the uncertainties are dominated by those due to statistics (which includes the ability to distinguish signal from background). This demonstrates the effect of the significant improvements made both in the determination of the individual systematic uncertainties, as presented in previous sections, and in the improved treatment of the dominant systematic uncertainties, whereby the self-consistency of the data itself was used to further constrain the allowed ranges of these parameters. It is worth

The extracted CC and ES electron spectra from both signal extraction fits, with total uncertainties. The final 12- to 20-MeV bin in the kernel estimation fit is plotted at the mean of the spectrum in that range. Both spectra are consistent with the hypothesis of no distortion (a flat line).

FIG. 28. (Color online) Extracted (a) CC and (b) ES electron spectra as a fraction of one unoscillated SSM [BS05(OP)], from both signal extraction fits, with total uncertainties. The final 12- to 20-MeV bin in the kernel estimation fit is plotted at the mean of the spectrum in that range. Both spectra are consistent with the hypothesis of no distortion (a flat line).

FIG. 29. (Color online) Extracted CC electron spectrum as a fraction of one unoscillated SSM (BS05(OP)) from the binned-histogram signal extraction fit, with the uncertainties separated into statistical (blue bars) and systematic (red band) contributions. The predictions for an undistorted spectrum and for the LMA point $\Delta m^2_{21} = 7.59 \times 10^{-5}$eV$^2$ and $\tan^2 \theta_{12} = 0.468$ (taken from a previous global solar + KamLAND fit [9] and floating the $^8$B flux scale) are overlaid for comparison.
FIG. 30. (Color online) One-dimensional projections of the fit in each observable parameter in Phase I from the binned-histogram signal extraction. The panels show the fit projected onto (a) energy ($T_{\text{eff}}$), (b) radius cubed ($R^3$), (c) direction ($\cos \theta_\odot$), and (d) isotropy ($\beta_{14}$).

noting that correlations between bins, which are not shown, tend to reduce the significance of any observed shape. Fitting to an undistorted spectrum (the flat line on Fig. 29) gives a $\chi^2$ value of 21.52 for 15 degrees of freedom, which is consistent with the hypothesis of no distortion. The prediction for the $T_{\text{eff}}$ spectrum for CC events taken from the best fit LMA point from a previous global analysis of solar data [9] is also overlaid on Fig. 29. The $\chi^2$ value of the fit of the extracted spectrum to this prediction is 22.56 for 15 degrees of freedom, demonstrating that the data are also consistent with the LMA prediction.

The one-dimensional projections of the fits in each observable parameter from the binned-histogram signal extraction are shown for each phase in Figs. 30 and 31. Of
particular note is the clear ES peak observed in the $\cos \theta_{\odot}$ fits for both phases [Figs. 30(c) and 31(c)], demonstrating the extraction of ES events over the integrated energy spectrum, even with the low 3.5-MeV threshold. The error bars represent statistical uncertainties; systematic uncertainties are not shown. Figure 32 shows the one-dimensional projection in $T_{\text{eff}}$ from Phase II [as in Fig. 31(a)] but with the fitted contributions from individual signal types separated into six categories: CC, ES, and NC neutrino events, internal backgrounds (within the D$_2$O volume), external backgrounds (in the AV, H$_2$O, and PMTs), and hep neutrino events.

The $\chi^2$ for the one-dimensional projections of the fit are given in Table XVIII. These were evaluated using statistical uncertainties only and are, therefore, a conservative test of goodness-of-fit in the one-dimensional projections. In all dimensions, the final result is a good fit to the data.

Table XXII in the Appendix shows the extracted number of events for the neutrino fit parameters from the binned-histogram signal extraction fit, with total statistical plus systematic uncertainties.

Table XIX shows the total number of background events extracted by each signal extraction in each phase, and a breakdown of the number of background neutron events occurring within each region of the detector. The two methods are in good agreement based on expectations from studies of Monte Carlo–generated “fake” data sets. For comparison, the total number of events in each data set is also given (taken from Table VI). Due to the exponential shape of the energy spectra of most sources of background in this fit, the majority of the background events fit out in the lowest two bins in $T_{\text{eff}}$, illustrating one of the major challenges of the low-energy analysis.

Tables XXIII–XXIV in the Appendix show the effects of the individual systematic uncertainties on the extracted NC rate, the CC rate in two energy intervals (4.0–4.5 MeV and 9.5–10.0 MeV), and the ES rate in the 3.5- to 4.0-MeV interval, all taken from the binned-histogram fit. The dominant source of uncertainty on the total neutrino flux measured with the NC reaction is the neutron capture uncertainty. Further significant contributions come from the Phase II energy resolution, the $\beta_{14}$ scale for neutron capture events, the energy-dependent fiducial volume, and the cut-acceptance uncertainties.

Figure 33 shows the effects of several groups of systematic uncertainties on the extracted CC electron spectrum, taken from the binned-histogram fit. Four groups cover systematic effects that apply to the observables ($T_{\text{eff}}$, $\cos \theta_{\odot}$, $R^3$, and $\beta_{14}$), in which the individual contributions are summed in quadrature (for example, the $T_{\text{eff}}$ group includes the effect of energy scale, resolution, and linearity); “normalization” uncertainties include neutron capture, cut acceptance, energy-dependent fiducial volume, and photodisintegration uncertainties; the final group consists of uncertainties in the shape of the PMT $\beta-\gamma$ PDF. The dominant sources of the systematic uncertainties on the shape of the CC electron spectrum are energy resolution and the shape of the PMT $\beta-\gamma$ PDF, particularly as a function of $T_{\text{eff}}$. The $\beta_{14}$ scale for electron-like events is also a significant contributor. It is worth noting that the contribution from the fiducial volume uncertainty, which was significant in previous analyses [8], is now relatively small.

The two signal extraction methods are in excellent agreement for all the neutrino flux parameters, as well as the sources

**Table XIX.** Number of background events extracted from the signal extraction fits for each method. LETA I refers to the binned-histogram signal extraction, and LETA II refers to the kernel estimation method. The total number of events in each data set is also given, taken from Table VI.

**Table XVIII.** $\chi^2$ values for the fit of the extracted signals from the binned-histogram signal extraction to the data set for one-dimensional projections in each of the four observables, in each phase. These were evaluated using statistical uncertainties only. The number of data points used for the $\chi^2$ calculations are given afterwards in parentheses. Because these are one-dimensional projections of a fit in four observables, the probability of obtaining these $\chi^2$ values cannot be simply evaluated; these are simply quoted as a qualitative demonstration of goodness-of-fit.

of background events. This is a stringent test of the result, since the two methods differed in several fundamental ways:

(i) Formation of the PDFs
The methods used to create the PDFs were entirely independent: one using binned histograms and the other using smooth, analytic, kernel-estimated PDFs.

(ii) Treatment of systematic uncertainties
The dominant systematics in the fits were “floated” using different approaches: in the kernel method they were floated directly, whereas an iterative likelihood scan was used in the binned-histogram approach.

(iii) PMT $\beta$-$\gamma$ constraint
In the binned-histogram method, a constraint on the total number of PMT events was implemented using a bifurcated analysis of the data (Sec. XIII C), whereas no constraint was applied in the kernel method.

That these independent approaches give such similar results demonstrates the robust nature of the analysis and the final results.

B. Survival probability fit

Under the assumption of unitarity (for example, no oscillations between active and sterile neutrinos), the NC, CC, and ES rates can be directly related. Based on this premise, a signal extraction fit was performed in which the free parameters directly described the total $^8$B neutrino flux and the $\nu_e$ survival probability. This fit therefore produces a measure of the total flux of $^8$B neutrinos that naturally includes information from all three interaction types. Applying this approach, the uncertainty that these independent analyses give such similar results demonstrates the robust nature of the analysis and the final results.

![FIG. 33. (Color) Effect of systematic uncertainties on the extracted CC electron spectrum. The inset shows the same plot on a larger scale.](image)

The survival probabilities and day/night asymmetry for the LMA point $\Delta m^2_{12} = 7.59 \times 10^{-5} \text{eV}^2$ and $\tan^2 \theta_{12} = 0.468$, taken from a previous global solar + KamLAND fit [9], are shown for comparison.](image)
in Fig. 34 is 3.9 for 4 degrees of freedom, showing that the data are also consistent with LMA.

This method for parameterizing the day/night asymmetry differs from previous SNO analyses, which quoted an asymmetry for each interaction type:

$$A = \frac{(\phi_N - \phi_D)}{(\phi_N + \phi_D)}$$  \hspace{1cm} (35)

where $\phi_D$ and $\phi_N$ are the interaction rates measured for the day and night data sets, respectively. A combined analysis of the results from Phase I and Phase II, assuming an undistorted neutrino spectrum, gave a result of $A = 0.037 \pm 0.040$ [8]. For comparison, the current analysis made no assumption about the shape of the underlying neutrino spectrum, except that it is a smooth, slowly varying function of $E_{\nu}$ over the range of neutrino energies to which the SNO detector is sensitive. The value of $a_0$ extracted under this assumption was $a_0 = 0.032 \pm 0.040$. Uncertainty on the day/night asymmetry measurement has always been dominated by statistics, so the improvements made to systematic uncertainties in this analysis have a small effect. The effect of the additional statistics gained by going lower in energy appears to be balanced by the additional degrees of freedom allowed in the shape of the neutrino energy spectrum.

The one-dimensional projections of the fits in the observable parameters for Phase I-day and Phase II-night are shown in Figs. 35 and 36.

C. Mixing parameters

A three-flavor, active solar neutrino oscillation model has four parameters: $\theta_{12}$ and $\theta_{13}$, which quantify the strength of the mixing between flavor and mass eigenstates, and $|\Delta m^2_{21}|$ and $|\Delta m^2_{31}|$, the differences between the squares of the masses of the neutrino propagation eigenstates. The approximation $\Delta m^2_{31} \sim \Delta m^2_{21}$ can be made because $|\Delta m^2_{31}| \gg |\Delta m^2_{21}|$, while the remaining mixing angle, $\delta$, and the CP-violating phase, $\beta$, are irrelevant for the oscillation analysis of solar neutrino data.

For the sake of comparison with other oscillation analyses, this work employed $\tan^2 \theta_{12}$ to quantify the leading effects of the mixing angles for solar neutrino oscillations. Smaller effects due to $\theta_{13}$ are quantified with $\sin^2 \theta_{13}$. The value of $\Delta m^2_{21}$ was fixed to $+2.3 \times 10^{-3}$ eV$^2$ [47], an assumption that was necessary for the numerical determination of the three-flavor survival probabilities, but whose precise value had very little impact on our calculation.

The parameters describing the $P_{\alpha}(E_{\nu})$ function for solar neutrinos are, in order of importance, $\theta_{12}$, $|\Delta m^2_{21}|$, $\theta_{13}$, and $|\Delta m^2_{31}|$. For experiments sensitive to neutrinos from terrestrial sources, near the detector, the survival probabilities were accurately calculated using a formula without the effect of matter. The inclusion of matter effects in the survival probability calculation for solar neutrino experiments involves the numerical integration of a system of coupled differential equations:

$$i \frac{d}{dx} \psi_{\alpha}(x) = H_f \psi_{\alpha}(x),$$  \hspace{1cm} (36)

where $H_f$ is the Hamiltonian in flavor space, including matter effects in both the Sun and the Earth, $x$ is the position along the propagation direction, and $\psi_{\alpha}(x)$ is a vector containing the real and imaginary coefficients of the wave function, where $\alpha = (e, \mu, \tau)$. The system was solved for each new value of $x$ as the wave function was propagated from the Sun to a given detector on the Earth. The probabilities were then calculated from the magnitudes of the wave function coefficients. The integration was performed with the adaptive Runge-Kutta algorithm. Radial profiles of the electron density and neutrino production in the Sun were taken from the BS05(OP) model [46]. The matter density inside the Earth was taken from the preliminary reference Earth model [48], which is the most widely accepted data since the density profile is inferred from seismological considerations. For more details on the survival probability calculation, see Ref. [49].

Constraints on neutrino mixing parameters can be derived by comparing neutrino oscillation model predictions with experimental data, as has been done in previous SNO analyses [7–9]. The approach for the interpretation of the solar and reactor neutrino data used the covariance $\chi^2$ method. From a series of observables with an associated set of measured parameters from a number of experiments, the corresponding theoretical expectations were calculated for a given neutrino oscillation parameter hypothesis. In order to calculate the model prediction for the neutrino yield at a given detector, each of the neutrino fluxes that the detector was sensitive to was weighted with the neutrino survival probabilities, convolved with the cross sections for the neutrino-target interactions as well as with the detector response function and then considered above the experiment’s energy threshold. The $\chi^2$ function quantifies the difference between the experimental data and theoretical model expectation for the observable under study.

In the results presented here, the free parameters were the neutrino-mixing parameters and the total flux of the $^8$B and hep neutrinos. The survival probabilities and, hence, the fluxes and spectra of solar neutrinos and reactor antineutrinos were fully constrained by the mixing parameters. The $\chi^2$ function in each case was minimized over a fine grid of points with respect to $\tan^2 \theta_{12}, \sin^2 \theta_{13},$ and $|\Delta m^2_{21}|$. The $\Delta \chi^2 = \chi^2 - \chi^2_{\text{min}}$ differences were the indicators of the confidence levels (C.L.) in the one- and two-dimensional projections. The 68%, 95%, and 99.78% C.L. regions in two-dimensional parameter projections were drawn following the standard definitions: $\Delta \chi^2 = 2.279, 5.99,$ and 11.83, respectively. For one-dimensional projections the errors on the parameter were the standard $1 \sigma$ C.L. at $\Delta \chi^2 = 1$. For all projections shown in this section, the $\chi^2$ was minimized with respect to the undisplayed parameters at each point in the MSW space.

The information from the LETA survival probability measurement was included by evaluating the polynomial survival probability and day/night asymmetry [as defined in Eqs. (22) and (23) of Sec. XIV D] that best represented the model prediction at each point in the MSW plane. To do this, it was necessary to take into account the sensitivity of the SNO detector (including effects such as the energy dependence of the cross sections, reaction thresholds, and analysis cuts) so the parameterization of the model prediction at each point in the MSW plane sampled the neutrino energy spectrum in the same manner and over the same range as the data. We calculated the number of detected events that passed all the cuts as a function of neutrino energy using the Monte Carlo
FIG. 35. (Color online) One-dimensional projections of the fit in Phase I-day, from the polynomial survival probability fit. The panels show the fit projected onto (a) energy ($T_{\text{eff}}$), (b) radius cubed ($R^3$), (c) direction ($\cos \theta_\odot$), and (d) isotropy ($\beta_{14}$). The binning of data is purely for display purposes; the fits were performed unbinned.

simulation, and what was thus equivalent to a “detected neutrino energy spectrum” (given in Table XXVIII in the Appendix) was distorted by the model-predicted survival probability at each point in the MSW plane. This was fit to a similarly obtained spectrum, now distorted by the polynomial parameterization, allowing the five polynomial parameters to vary in the fit. At each point in the plane, we then calculated the $\chi^2$ value of the fit of the model-predicted polynomial parameters ($c_0$, $c_1$, $c_2$, $a_0$, and $a_1$) to the result from the signal extraction, taking into account all uncertainties and correlations as output by the signal extraction fit. The SNO rates from Phase III [9] were treated as a separate data set.

Figure 37 shows the allowed regions of the ($\tan^2 \theta_{12}$, $\Delta m^2_{21}$) parameter space when the LETA data were analyzed in combination with the rates from Phase III [9]. The $2\nu$ contours
were projected from the parameter space at a constant value of $\sin^2 \theta_{13} = 0.0$, making them equivalent to an effective two-flavor analysis. While the best fit point falls in the so-called LOW region, with $\Delta m^2_{21} = 1.15^{+0.38}_{-0.16} \times 10^{-7} \text{(eV}^2)$ and $\tan^2 \theta_{12} = 0.437^{+0.058}_{-0.058}$, the significance levels of the LOW and the higher mass large mixing angle (LMA) regions are very similar. The predicted shape for the survival probability is very flat in both regions, and the day/night asymmetry is expected to be small, so the SNO-only analysis has little handle on distinguishing the two regions. A notable difference between LOW and LMA is in the predicted sign of the slope of the energy dependence of the day/night asymmetry, with LOW predicting a negative slope, as was extracted in the polynomial fit reported in Sec. XV B.

As described above, the observables from the SNO LETA fit used in the hypothesis testing were the polynomial parameters of the survival probability. In a full global analysis, event yields were used for the other solar neutrino experiments, including the SNO Phase III results. For each set of parameters, the oscillation model was used to predict the rates in the Chlorine [1], Gallium [2], and Borexino [10] experiments, the Super-Kamiokande Phase I zenith spectra [50] and Phase II day/night spectra [6], and the KamLAND rates and spectrum [14], as well as the SNO rates [9] and spectra. The expected rates and spectra were divided by the respective predictions, calculated without oscillations, to remove the effects of the model scaling factors. The unitless rates were then used in the global $\chi^2$ calculation. Although the $\Phi_{11}$ scale was determined in the LETA signal extraction, we reintroduced it as a free parameter in the $\chi^2$ minimization at each point in the parameter space to constrain it with all solar data. The uncertainty of the scale was retrieved from its marginal distribution, as was done for the oscillation parameters.

The SNO LETA covariance matrix was taken from the signal extraction output given in Table XXVII, as before. For other experiments, the total covariance matrix was assembled from the individual statistical and systematic components, as described in Ref. [8]. Correlations between SNO’s LETA and other solar experimental results were allowed via the floated $\Phi_{11}$ scale parameter.

The KamLAND rates and spectrum were predicted using three-flavor vacuum oscillations. Publicly available information about the KamLAND detector and nearby reactors were included in our calculation, which reproduced the unoscillated spectrum of Fig. 1 of Ref. [14] with good accuracy. To include the effects of three-flavor oscillations, we then compared the $\chi^2$ obtained with nonzero values of $\theta_{13}$ with those obtained with $\theta_{13} = 0$, for each set of $(\tan^2 \theta_{12}, \Delta m^2_{21})$ values. In this way, we built a $\Delta \chi^2$ function to parameterize the change of the $\chi^2$ map in Fig. 2 of Ref. [14] due to a nonzero value of $\theta_{13}$. This allowed us to include the KamLAND experiment in our three-flavor neutrino oscillation analysis and to precisely reproduce KamLAND’s two-flavor neutrino contours. When including the KamLAND antineutrino spectrum we assumed CPT invariance, and we used the KamLAND data only to constrain the oscillation parameters (as opposed to the $^8\text{B}$ flux scale), whereas all other solar neutrino rates were used to collectively determine the absolute scale of the $^8\text{B}$ neutrino flux as well as the oscillation parameters.

Figure 38 shows the allowed regions of the $(\tan^2 \theta_{12}, \Delta m^2_{21})$ parameter space when the global solar data and the KamLAND data were analyzed, both separately and together, in a two-flavor analysis. It is interesting to note that the global solar analysis does not significantly alter the constraints in the LMA region relative to the SNO-only analysis.

Figure 39 shows the results of a three-flavor oscillation analysis. Figure 39(a) shows an overlay of the global solar and the KamLAND allowed regions in $(\tan^2 \theta_{12}, \Delta m^2_{21})$ parameter space, under a two-flavor hypothesis. Figure 39(b) shows the same overlay for the three-flavor hypothesis. Allowing the value of $\sin^2 \theta_{13}$ to be nonzero clearly brings the two regions into much better agreement. The three-flavor contours show the effect of allowing both $\Phi_{11}$ and $\sin^2 \theta_{13}$ to float at each point in space. Allowing these extra degrees of freedom worsens the uncertainties on the two dominant oscillation parameters, $\tan^2 \theta_{12}$ and $\Delta m^2_{21}$. The regions obtained with all solar data are consistent with the SNO-only data and show an extension of the space toward larger values of $\tan^2 \theta_{12}$ when $\sin^2 \theta_{13}$ is allowed to vary. In contrast, the three-flavor KamLAND contours show an extension toward smaller values of $\tan^2 \theta_{12}$.

Figure 40 shows the confidence regions in the $(\tan^2 \theta_{12}, \sin^2 \theta_{13})$ space. The directionality of the contours explains the excellent agreement of $\tan^2 \theta_{12}$ between the solar and KamLAND experiments when $\sin^2 \theta_{13}$ is allowed to vary in the fit.

Tables XX and XXI summarize the oscillation parameter results from the various two- and three-flavor oscillation analyses, respectively. When all solar experiments are combined with data from the KamLAND reactor antineutrino experiment in a two-flavor fit, the best fit point is found to be at $\theta_{12} = 34.06^{+1.16}_{-0.84}$ degrees and $\Delta m^2_{21} = 7.59^{+0.20}_{-0.21} \times 10^{-5} \text{ eV}^2$. The uncertainty on the mixing angle has been noticeably reduced in comparison to SNO’s previous analyses, resulting in the world’s best measurement of $\theta_{12}$ to date. The global
value of $\Phi_{1B}$ from this fit is extracted to a precision of $+2.38\%$. The combination with KamLAND in a three-flavor fit has allowed us to constrain $\sin^2 \theta_{13}$, giving a value of $\sin^2 \theta_{13} = 2.00_{-1.63}^{+2.09} \times 10^{-2}$. This implies an upper bound of $\sin^2 \theta_{13} < 0.057$ (95% C.L.).

XVI. SUMMARY AND CONCLUSIONS

We have described here a joint low-energy-threshold analysis of SNO’s Phase I and Phase II data sets down to an effective kinetic energy threshold of $T_{\text{eff}} = 3.5$ MeV. The low threshold increased the statistics of the CC and ES events by roughly 30%, and of NC events by ~70%. A new energy estimator improved the energy resolution by 6%, thus reducing the number of background events reconstructing above threshold by ~60%. Separation of electron-like and neutron capture events was improved by the joint fit of data from Phases I and II, due to the difference in neutron detection sensitivity in the two phases. In addition, use of calibration data to correct the Monte Carlo–generated PDF shapes, and reduction of systematic uncertainties, have contributed to increased precision on both the total $^8\text{B}$ solar neutrino flux and the derived neutrino mixing parameters. Fitting our data without constraints on the shape of the underlying neutrino energy spectrum or the unitarity of the mixing matrix gives a total $^8\text{B}$ neutrino flux of $\phi_{\text{NC}} = 5.14_{-0.20}^{+0.21} \times 10^6$ cm$^{-2}$ s$^{-1}$, measured by the NC reaction only, where $\oplus$ refers to the quadrature sum. This is in good agreement with the predictions of recent standard solar models. The uncertainties on this result are more than a factor of 2 better than in our previous publications. The CC and ES reconstructed electron

**FIG. 39.** (Color) Solar and KamLAND oscillation parameter analysis for (a) a two-flavor oscillation hypothesis and (b) a three-flavor hypothesis. The solar data include SNO’s LETA survival probability day/night curves, SNO Phase III integral rates, Cl, SAGE, Gallex/GNO, Borexino, SK-I zenith, and SK-II day/night spectra. The $\chi^2$ is minimized with respect to all undisplayed parameters, including $\sin^2 \theta_{13}$ and $\Phi_{1B}$. 
spectra for this fit are consistent with the hypothesis of no spectral distortion, and with the best fit LMA point.

We have also used the unique capabilities of the SNO detector to perform the first direct fit to data for the energy-dependent \( v_e \) survival probability, without any reference to flux models or other experiments. The fit for the survival probability assumes unitarity of the neutrino mixing matrix and that the underlying neutrino spectrum follows a smoothly distorted \( ^8B \) shape. We have parameterized the survival probability as a second-order polynomial, allowing for a linear energy-dependent asymmetry between day and night spectra. The fit gives us a total \( ^8B \) neutrino flux of \( \Phi_{^8B} = 5.05^{+0.19}_{-0.20} \text{ (stat \( \oplus \) syst)} \times 10^6 \text{ cm}^{-2} \text{ s}^{-1} \). No evidence for either a significant spectral distortion or a day/night asymmetry was found.

TABLE XX. Best-fit neutrino oscillation parameters and extracted \(^8B\) flux from a two-flavor oscillation analysis. The “SNO” results are from the combined LETA + Phase III oscillation analysis. Uncertainties listed are \( \pm 1\sigma \) after the \( \chi^2 \) was minimized with respect to all other parameters.

With the results of the survival probability fit, we have created contours that show the allowed regions of the mixing parameters, finding that for SNO data alone the best fit point is in the LOW region of parameter space but consistent with the LMA region at the 68.3% confidence level. Combining all solar experiments and the KamLAND reactor antineutrino experiment in a two-flavor fit, we find the best fit point is at \( \theta_{12} = 34.06^{+1.16}_{-0.84} \) degrees and \( \Delta m_{21}^2 = 7.59^{+0.20}_{-0.21} \times 10^{-5} \text{ eV}^2 \). The uncertainty on the mixing angle has been noticeably reduced from SNO’s previous analyses, resulting in the world’s best measurement of \( \theta_{12} \). The global value of \( \Phi_{^8B} \) from this fit was extracted to a precision of \( \pm 2.3\% \). In a three-flavor fit, we find \( \sin^2 \theta_{13} = 2.00^{+2.09}_{-1.63} \times 10^{-2} \). This implies an upper bound of \( \sin^2 \theta_{13} < 0.057 \) at the 95% confidence level.

APPENDIX: SNO RESULTS: DATA TABLES

Table XXII shows the extracted numbers of neutrino events from the binned-histogram signal extraction fit in each phase. The total statistical plus systematic uncertainties are given.

Tables XXIII–XXV show the effects of the individual systematic uncertainties on the extracted NC rate, the CC rate in two energy intervals (4.0–4.5 MeV and 9.5–10.0 MeV)
and the ES rate in the 3.5–4.0 MeV interval, taken from the binned-histogram unconstrained signal extraction fit.

The direct signal extraction fit to the $\nu_e$ survival probability parameterized the neutrino fluxes as:

(i) $\Phi_{\nu_1}\nu$: the total $^{8}\text{B}$ neutrino flux;

(ii) $c_0, c_1, c_2$: coefficients in a quadratic expansion of the daytime $\nu_e$ survival probability around $E_{\nu} = 10$ MeV;

(iii) $a_0, a_1$: coefficients in a linear expansion of the day/night asymmetry around $E_{\nu} = 10$ MeV.

Where the day/night asymmetry, $A$, daytime $\nu_e$ survival probability, $P_{\nu_e}^{\text{day}}$, and nighttime $\nu_e$ survival probability, $P_{\nu_e}^{\text{night}}$, that correspond to these parameters are:

$$A(E_{\nu}) = a_0 + a_1(E_{\nu} - 10 \text{ MeV}),$$

$$P_{\nu_e}^{\text{day}}(E_{\nu}) = c_0 + c_1(E_{\nu} - 10 \text{ MeV}) + c_2(E_{\nu} - 10 \text{ MeV})^2,$$

$$P_{\nu_e}^{\text{night}}(E_{\nu}) = P_{\nu_e}^{\text{day}} \times \frac{1 + A(E_{\nu})/2}{1 - A(E_{\nu})/2}.$$

The best-fit polynomial parameter values and uncertainties are shown in Table XXVI, and the correlation matrix is shown in Table XXVII.

Table XXVIII lists the Monte Carlo–generated neutrino energy spectrum for events that passed all the standard analysis cuts (the “detected neutrino energy spectrum”). Events are separated into those occurring during the daytime and during the nighttime.
TABLE XXIV. Effect of systematic uncertainties in $\cos \theta_0$ and $R^3$ on the NC rate, the CC rate in the intervals 4.0–4.5 MeV ("CC1") and 9.5–10.0 MeV ("CC12"), and the ES rate in the interval 3.5–4.0 MeV ("ES0"). The (+) and (−) labels refer to the result of applying the positive and negative side of each double-sided uncertainty.

TABLE XXVIII. Monte Carlo–generated undistorted $^8$B neutrino energy spectrum for events that passed all the applied analysis cuts divided into those occurring during the daytime and during the nighttime. The spectra have been normalized to the peak nighttime response, and the relative scales of the day and night spectra reflect the livetime and detector acceptance differences between day and night. The quoted energies are the central values of 0.4-MeV intervals. The spectrum is zero outside the displayed range.
