Beam Thrust Cross Section for Drell-Yan Production at Next-to-Next-to-Leading-Logarithmic Order

Iain W. Stewart, Frank J. Tackmann, and Wouter J. Waalewijn
Center for Theoretical Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA
(Received 21 May 2010; published 20 January 2011)

At the LHC and Tevatron strong initial-state radiation (ISR) plays an important role. It can significantly affect the partonic luminosity available to the hard interaction or contaminate a signal with additional jets and soft radiation. An ideal process to study ISR is isolated Drell-Yan production, \(pp \to X\ell^+\ell^-\) without central jets, where the jet veto is provided by the hadronic event shape beam thrust \(\tau_B\). Most hadron collider event shapes are designed to study central jets. In contrast, requiring \(\tau_B \ll 1\) provides an inclusive veto of central jets and measures the spectrum of ISR. For \(\tau_B \ll 1\) we carry out a resummation of \(\alpha_s^2\ln^n\tau_B\) corrections at next-to-next-to-leading-logarithmic order. This is the first resummation at this order for a hadron-hadron collider event shape. Measurements of \(\tau_B\) at the Tevatron and LHC can provide crucial tests of our understanding of ISR and of \(\tau_B\)’s utility as a central jet veto.

Introduction.—Event shapes play a vital role in the success of QCD measurements at \(e^+e^-\) colliders. This includes the measurements of \(\alpha_s(m_Z)\), the QCD \(\beta\) function and color factors [1], and the tuning and testing of Monte Carlo event generators (see, e.g., Ref. [2]). Event shapes for the more complicated environment at hadron colliders have been designed and studied in Refs. [3–6].

There is much anticipation that they can play a significant role at the Tevatron and LHC by improving our understanding of basic aspects of QCD in high-energy collisions such as the underlying event and initial- and final-state radiation, as well as nonperturbative effects. Here we focus on initial-state radiation (ISR). Strong ISR can significantly alter the partonic luminosity available for the hard interaction. Additional jets from ISR can also contaminate the jet signature for a specific signal. An ideal process to study ISR is isolated Drell-Yan production, \(pp \to X\ell^+\ell^-\) with a veto on central jets. By vetoing hard central jets, the measurement becomes directly sensitive to how energetic and soft ISR contributes to the hadronic final state \(X\).

Recently, an inclusive hadron collider event shape \(\tau_B\) was introduced, called “beam thrust” [6]. For \(\tau_B \ll 1\), the hadronic final state consists of two back-to-back jets centered around the beam axis. The ISR causing these jets occurs at measurable rapidities. In this limit \(\tau_B\) provides similar information as thrust in \(e^+e^-\to\) jets with the thrust axis fixed to the proton beam axis. For \(\tau_B < 1\), the final state has energetic jets at central rapidities. Thus, requiring small \(\tau_B\) provides an inclusive veto on central jets while allowing ISR in the forward direction, as depicted in Fig. 1. From Eqs. (1) and (2) we

\[
\tau_B = \frac{1}{Q^2} \sum_k |\vec{p}_{kT}| e^{-|\eta_k-Y|},
\]

where \(Q^2\) and \(Y\) are the dilepton invariant mass and rapidity, respectively. The sum runs over all (pseudo)particles in the final state except the two signal leptons, where \(|\vec{p}_{kT}|\) and \(\eta_k\) are the measured transverse momenta and rapidities with respect to the beam axis, and all particles are considered massless. The absolute value in the exponent in Eq. (1) effectively divides all particles into two hemispheres \(\eta_k > Y\) and \(\eta_k < Y\), where the former gives \(|\vec{p}_{kT}|e^{-\eta_k} = E_k - p_{kT}^+\) and the latter \(|\vec{p}_{kT}|e^{\eta_k} = E_k + p_{kT}^+\).

\[
\tau_B = \frac{1}{Q^2} \left[ e^Y \sum_{\eta_k > Y} (E_k - p_{kT}^+) + e^{-Y} \sum_{\eta_k < Y} (E_k + p_{kT}^+) \right].
\]

The dependence on \(Y\) explicitly takes into account the boost of the partonic center-of-mass frame, i.e., the fact that the collinear ISR in the direction of the boost is narrower, as depicted in Fig. 1. From Eqs. (1) and (2) we

FIG. 1 (color online). Isolated Drell-Yan production with a veto on central jets.
see that soft particles with energies $E_k \ll Q$ as well as energetic particles in the forward directions with $E_k - |p_t| \ll Q$ contribute only small amounts to $\tau_B$. In particular, unmeasured particles beyond the rapidity reach of the detector are exponentially suppressed, $|p_t|e^{-|y|} \ll 2E_k e^{-2|y|}$, and give negligible contributions to $\tau_B$. On the other hand, energetic particles in the central region with $E_k \pm p_t \sim E_k \sim Q$ give an $O(1)$ contribution to $\tau_B$. Hence, a cut $\tau_B \leq \tau_B^\text{cut} \ll 1$ vetoes central energetic jets without requiring a jet algorithm.

Beam thrust is also theoretically clean. It is infrared safe, and an all-orders factorization theorem exists for the cross section at small $\tau_B$ [6]. This allows for a higher-order summation of large logarithms, $a_s^m \ln^m \tau_B$, and the calculation of perturbative and estimation of nonperturbative contributions from soft radiation. The state of the art for resummation in hadron collider event shapes is the next-to-leading-logarithm (NLL) plus next-to-leading order (NLO) analysis in Ref. [4]. In this Letter, we present results to-leading logarithm (NLL) plus next-to-leading order resummation in hadron collider event shapes is the next-leading-logarithmic (NNLL) order. This represents the first complete calculation to this order for a hadron collider event shape. Letting $y_B = i0$ be the Fourier conjugate variable to $\tau_B$, the Fourier-transformed cross section exponentiates and has the form

$$
\ln \frac{d\sigma}{dv_B} \sim L(\alpha_s L)^k + (\alpha_s L)^k + \alpha_s(\alpha_s L)^k + \cdots, \quad (3)
$$

where $L = \ln y_B$ and we sum over $k \geq 1$. Here, the three sets of terms are the leading logarithmic (LL), NLL, and NNLL corrections.

**Beam Thrust Factorization Theorem.**—The Drell-Yan beam thrust cross section for small $\tau_B$ obeys the factorization theorem [6]

$$
d\sigma = \frac{8\pi^2}{9E_{cm}Q} \sum_{ij} H_{ij}(Q^2, \mu_H) U_H(Q^2, \mu_H, \mu) 
\times \int dt_a dt_a' B_i(t_a - t_a', x_a, \mu_B) U_B(t_a', \mu_B, \mu) 
\times \int dt_b dt_b' B_j(t_b - t_b', x_b, \mu_B) U_B(t_b', \mu_B, \mu) 
\times \int dk Q S_B(\tau_B Q - t_a + t_b - k, \mu_S) 
\times U_S(k, \mu_S, \mu), \quad (4)
$$

where $x_a = (Q/E_{cm}) e^y$ and $x_b = (Q/E_{cm}) e^{-y}$, $E_{cm}$ is the total center-of-mass energy, and the sum runs over quark flavors $ij = \{u\bar{u}, \bar{u}u, d\bar{d}, \ldots\}$. The hard function $H_{ij}(Q^2, \mu_H)$ contains virtual radiation at the hard scale $Q$ and also includes the leptonic process.

The beam functions $B_i(t_a, x_a, \mu_B)$ and $B_j(t_b, x_b, \mu_B)$ in Eq. (4) depend on the momentum fractions $x_{a,b}$ and virtualities $t_{a,b}$ of the partons $i$ and $j$ annihilated in the hard interaction. They can be calculated in an operator-product expansion [7,8]

$$
B_i(t_a, x_a, \mu_B) = \sum_k \int_{x_a}^1 d\xi_a I_k(\frac{x_a}{\xi_a}, \mu_B) f_k(\xi_a, \mu_B) \quad (5)
$$

and analogously for $B_j$. Here, the sum runs over parton species $k = \{g, u, \bar{u}, d, \bar{d}, \ldots\}$ and $f_k(\xi_a, \mu_B)$ denotes the standard parton distribution function (PDF) for parton $k$ with momentum fraction $\xi_a$. The Wilson coefficients $I_k(t_a, z_a, \mu_B)$ describe the collinear virtual and real ISR emitted by this parton at the beam scale $\mu_B^2 \approx \tau_B Q^2$. The real ISR causes the formation of a jet prior to the hard collision which is observed as radiation centered around the beam axis. The PDFs in Eq. (5) are evaluated at the beam scale $\mu_B$, because the measurement of $\tau_B$ introduces sensitivity to the virtualities $t \approx \tau_B Q^2$ of the colliding hard partons, giving large logarithms $\ln(\mu_B^2/t)$.

For small $\tau_B$, we have

$$
\tau_B = t_a \frac{Q^2}{Q^2} + t_b \frac{Q^2}{Q^2} + k \frac{Q}{Q^2} + O(\tau_B^2), \quad (6)
$$

where the last term is the contribution from soft radiation at the scale $\mu_S \approx \tau_B Q$ and is described by the soft function $S_B(k, \mu_S)$ in Eq. (4). The collinear and soft contributions are not separately measurable, which leads to the convolution of $S_B, B_i$, and $B_j$ in Eq. (4). $S_B(k, \mu_S)$ includes the effects of hadronization and soft radiation in the underlying event. For $\Lambda_{QCD} \ll \mu_S$, it is perturbatively calculable with power corrections of $O(\Lambda_{QCD}/\mu_S)$.

The large logarithms $a_s^m \ln^m \tau_B$, with $m \leq 2n$, are summed in Eq. (4) as follows. The hard, beam, and soft functions are each evaluated at their natural scale $|\mu_H| = Q$, $\mu_B = \sqrt{\tau_B} Q$, and $\mu_S = \tau_B Q$, respectively, where they contain no large logarithms and can be computed in fixed-order perturbation theory. They are then evolved to an arbitrary common scale $\mu$ by the evolution kernels $U_H, U_{H,i}^j$, and $U_S$, and this sums logarithms of the three scale ratios $\mu/\mu_H, \mu/\mu_B$, and $\mu/\mu_S$, respectively. The combination of the different evolution kernels in Eq. (4) is $\mu$-independent and sums the logarithms of $\tau_B$.

The hard function for Drell-Yan production is a timelike form factor and for $\mu_H \approx Q$ contains large $\pi^2$ terms from $\ln^2(-iQ/\mu_H)$. We sum these $\pi^2$ terms by taking $\mu_H = -iQ$ [9]. We estimate perturbative uncertainties by varying $\mu_H, \mu_B$, and $\mu_S$ about the above values. The complete summation at NNLL requires the NLO expressions for $H_{ij}, I_{qq}, I_{qg}, S_B$, as well as the NNLL expressions for $U_H, U_{H,i}^j$, and $U_S$. See Ref. [8] for a discussion and references of the required anomalous dimensions and fixed-order computations.

**Results at NNLL.**—In our numerical results we use the MSTW2008 NLO PDFs [10] with their $\alpha_s(m_Z) = 0.1208$. We also integrate over $Y$ in Eq. (4). In Fig. 2, we show the Drell-Yan cross section $d\sigma/dQ^2$ with no cut at NLO and with cuts $\tau_B \leq \{0.1, 0.02\}$ at NNLL, for the LHC with...
The cut \( \tau_B \leq 0.1 \) reduces the cross section only by a factor of around 1.3 above the \( Z \) peak (or 5–1.5 for \( \tau_B \leq 0.02 \)), showing that most of the cross section comes from small \( \tau_B \). The cross section differential in \( \tau_B \) at fixed \( Q = m_Z \) is shown in Fig. 3, where we can see explicitly that the cross section is dominated by small \( \tau_B \). To see the effect of the higher-order resummation we plot the LL, NLL, and NNLL results. The importance of resummation is illustrated by comparing them to the singular part of the fixed NLO result (dashed line), which is obtained from our NNLL result by setting \( \mu_H = \mu_B = \mu_S = Q \). (The full NLO result contains additional nonsingular terms that are not numerically relevant at small \( \tau_B \).)

Results are not plotted below \( Q/\tau_B \leq 1 \) GeV, where the soft function becomes nonperturbative and we expect large corrections of \( O(\Lambda_{QCD}/\mu_S) \) to our purely perturbative results. Correspondingly, the perturbative uncertainties get large here. In Fig. 4, we show the cross section integrated up to \( \tau_B = \tau_B^{\text{cut}} \) as a function of \( Q/\tau_B^{\text{cut}} \) for \( Q = m_Z \) and \( Q = 300 \) GeV. We see again that the logarithms are important at small \( \tau_B^{\text{cut}} \) and need to be resummed.

In Figs. 3 and 4, the perturbative scale uncertainties are given by bands from varying \( \mu_H, \mu_B, \) and \( \mu_S \). The independent variation of these three scales would overestimate the uncertainty, since it does not take into account the parametric relation \( \mu_B^2 \approx \mu_S \mu_H \) and the hierarchy \( \mu_S \ll \mu_B \ll \mu_H \). On the other hand, their simultaneous variation [case (a) in Eq. (7)] can produce unnaturally small scale uncertainties. Hence, the perturbative uncertainties in all figures are the envelope of the separate scale variations:

\[
\begin{align*}
(a) \quad \mu_H &= -r i Q, \quad \mu_B = r \sqrt{\tau_B} Q, \quad \mu_S = r \tau_B Q, \\
(b) \quad \mu_H &= -i Q, \quad \mu_B = r^{-\ln(\tau_B)/4} \sqrt{\tau_B} Q, \quad \mu_S = \tau_B Q, \\
(c) \quad \mu_H &= -i Q, \quad \mu_B = r^{-\ln(\tau_B)/4} \sqrt{\tau_B} Q.
\end{align*}
\]

with \( r \in \{1/2, 2\} \), and \( r = 1 \) corresponding to the central-value curves. The exponent of \( r \) for cases (b) and (c)
is chosen such that for $\tau_B = e^{-4}$ the scales $\mu_B$ or $\mu_S$ vary by factors of 2, with smaller variations for increasing $\tau_B$ and no variation for $\tau_B \to 1$. In this limit, there should only be a single scale $|\mu_H| = \mu_B = \mu_S$, and thus the only scale variation should be case (a). For the integrated cross section we replace $\tau_B$ in Eq. (7) with $\tau_B^{\text{cut}}$. In both Figs. 3 and 4, we see good convergence of the perturbative series and a substantial reduction in the perturbative uncertainties at NNLL. The convergence is improved appreciably by the summation of the $\pi^2$ terms.

In Fig. 5, we plot percent differences for several cross sections relative to the NNLL result. All results are integrated up to $\tau_B^{\text{cut}} = 0.1$ and are plotted versus $Q$. The dark orange bands show the NNLL perturbative uncertainties and the light yellow bands the 90% C.L. PDF + $\alpha_s$ uncertainties using the procedure from Ref. [10]. The dashed line shows the NNLL result without the gluon contribution to the quark beam function, $I_{qg}$ in Eq. (5). The gluon contribution is significant at the LHC and less prominent at the Tevatron, because the gluon PDF is more important for $p\bar{p}$ than $pp$ collisions. In the dotted line we further neglect all terms in the quark contribution $I_{qq}$ that are subleading in the threshold limit $x \to 1$. Except for the Tevatron at large $Q$ the threshold result is a poor approximation to the full result, being well outside the perturbative uncertainties. The dark band and solid line show the NLO result with the perturbative uncertainties from varying the common scale between $Q/2$ and $2Q$. Its difference from the resummed NNLL result is generically large and not captured by the fixed-order perturbative uncertainties, showing that the resummation is important not only to get an improved central value but also to obtain reliable perturbative uncertainties.

Beam thrust in Drell-Yan production provides an experimentally and theoretically clean measure of ISR in $q\bar{q} \to \ell^+\ell^-$, similar to how thrust measures final-state radiation in $e^+e^- \to q\bar{q}$. The experimental measurement of beam thrust will contribute very valuable information to our understanding of ISR at hadron colliders and could be used to test and tune the initial-state parton shower and underlying event models in Monte Carlo programs. Restricting beam thrust $\tau_B \ll 1$ implements a theoretically well-controlled jet veto, which has important applications in other processes, for example, Higgs production [11]. The measurement of beam thrust in Drell-Yan production provides a clean environment to test the application of beam thrust as a central jet veto.
