We report first results from an analysis based on a new multi-hadron correlation technique, exploring jet-medium interactions and di-jet surface emission bias at the BNL Relativistic Heavy Ion Collider (RHIC). Pairs of back-to-back high-transverse-momentum hadrons are used for triggers to study associated hadron distributions. In contrast with two- and three-particle correlations with a single trigger with similar kinematic selections, the associated hadron distribution of both trigger sides reveals no modification in either relative pseudorapidity $\Delta \eta$ or relative azimuthal angle $\Delta \phi$ from d + Au to central Au + Au collisions. We determine associated hadron yields and spectra as well as production rates for such correlated back-to-back triggers to gain additional insights on medium properties.

Di-hadron correlation measurements in heavy-ion collisions have advanced the studies of hot and strongly interacting matter at the BNL Relativistic Heavy Ion Collider (RHIC). The effects of jet-medium interactions are reflected in the broad away-side distributions of associated hadrons in di-hadron azimuthal correlations and their softened transverse momentum \(p_T\) spectra [1–4]. For associated hadrons with transverse momentum between \(1.0 < p_T < 2.0\) GeV/c in addition to the overall broadening of the away side \((\Delta \phi \sim \pi)\), a dip at \(\pi\) is reported in [4–6]. Various scenarios and different mechanisms of jet-medium interactions have been proposed to explain the experimental observations [7–10]. On the near-side \((\Delta \phi \sim 0)\), the modification of the correlation structure is also observed [2,11–13]. In [12] the same-side peak is described by two components: the ridge, a long-range \(\Delta \eta\) plateau, and the small-\(\Delta \eta\) jet-like peak. It is argued that the ridge might arise from jet-medium interactions. However, recent three-particle analyses report possible decoupling of the jet and ridge features [14]. The existing three-particle correlation analyses do not specifically identify the away-side jet, hence the pseudorapidity correlation relative to the away-side jet cannot be studied.

Di-hadron azimuthal correlations of two high-\(p_T\) hadrons have been observed to exhibit jet-like peaks in both near and away sides [15,16]. Little modification is apparent in the shape of the peaks, but the amplitude of the away-side peak shows a strong suppression in central Au + Au collisions with respect to d + Au collisions. The data may be interpreted in two scenarios: in-medium energy loss followed by in-vacuum fragmentation and finite probability to escape the medium without interactions. As jet-medium interactions manifest themselves via shape changes of correlation structures predominantly in the softer momentum range (below 2 GeV/c), we investigate the modification dynamics using a new three-particle \((2 + 1)\) correlation technique, which measures the degree of correlation of a softer particle with a di-hadron trigger. The technique utilizes a second high-\(p_T\) trigger on the away side of the highest-\(p_T\) particle in the event as an estimate of the away-side jet axis direction.

The analysis presented in this letter used data collected by the STAR (Solenoideal Tracker at RHIC) experiment [17] in the years 2003 and 2004. Data samples consist of 5.5 M d + Au, 14 M minimum bias Au + Au, and 18 M central triggered Au + Au events from collisions with the center-of-mass per-nucleon-pair energy of 200 GeV. Based on the charged track multiplicity at midrapidity \(|\eta| < 0.5\) recorded by the STAR Time Projection Chamber (TPC) [18], the minimum bias Au + Au data are divided into 4 centrality bins. They correspond to 0%–20%, 20%–40%, 40%–60%, and 60%–80% of the total geometric cross section. The central-trigger data represent approximately 12% of the total cross section. To express centrality dependencies we calculate via the Monte Carlo Glauber model the number of participating nucleons \(N_{\text{part}}\) and the number of binary collisions \(N_{\text{coll}}\) for each centrality bin used in the analysis. The track selection for the analysis is identical to [5].

We select the highest-\(p_T\) particle in an event as the main (first) trigger and require \(p_T^{\text{trig1}}\) to be between 5 to 10 GeV/c. The second trigger \(p_T^{\text{trig2}}\) is selected to be above 4 GeV/c. We consider two high-\(p_T\) particles to be a di-jet-like pair if they conform to the requirement of relative azimuthal difference of \(|\phi^{\text{trig1}} - \phi^{\text{trig2}} - \pi| < \alpha\). The \(\alpha\) is chosen to be 0.2 corresponding approximately to 1\(\sigma\) of the away-side peak width in relative azimuth for two high-\(p_T\) hadrons [15]. We construct the associated hadron distributions in \(\Delta \phi\) and \(\Delta \eta\) coordinates with respect to each trigger direction. The associated soft particle yield is measured relative to both triggers using the following expression:

\[
\frac{d^2N}{d\Delta \eta d\Delta \phi} = \frac{1}{N_{\text{trig}} \epsilon_{\text{pair}}} \left( \frac{d^2N_{\text{raw}}}{d\Delta \eta d\Delta \phi} - a_{\text{yam}} \frac{d^2N_{\text{bg}}}{d\Delta \eta d\Delta \phi} \right),
\]

where \(N_{\text{trig}}\) is the number of trigger pairs, corrected for a dilution effect due to randomly associated pairs, and \(d^2N_{\text{raw}}/(d\Delta \eta d\Delta \phi)\) is the associated hadron distribution for all hadrons in triggered events. The associated hadrons \(p_T\) (1.5 GeV/c < \(p_T^{\text{assoc}}\) < \(p_T^{\text{trig1}}\)) is selected to coincide with the range where the away-side dip in di-hadron correlations is reported. The “raw” distribution is corrected for single-track efficiency and acceptance effects. The correction factor \(\epsilon_{\text{pair}}\) includes the single-track reconstruction efficiency, which depends on \(\eta, \phi, p_T\), and multiplicity. It also corrects for the pair acceptance obtained by the mixed-event technique. \(d^2N_{\text{bg}}/d\Delta \eta d\Delta \phi\) represents the total background, which consists of multiple terms. The dominant background contribution is from combinatorics and is accounted for by mixing trigger pairs and associated hadrons from different events, selected to have similar multiplicity and primary vertex position. The initially uniform distribution (apart from efficiency and acceptance effects) is then modulated by the flow term

\[
f(\Delta \phi) = 1 + \frac{2v_2^{\text{assoc}1} v_2^{\text{assoc}2}}{1 + 2v_2^{\text{assoc}1} v_2^{\text{assoc}2} \sin(2\alpha) / 2\alpha} \cos(2\Delta \phi),
\]

where \(v_2^{\text{assoc}1}\), \(v_2^{\text{assoc}2}\), and \(v_2^{\text{assoc}}\) are sample-averaged values of the elliptical flow coefficient for primary and secondary triggers and associated hadrons, respectively, to account for elliptical flow effects, which we consider independent of \(\eta\) in the range studied [19,20]. The multiplicity and \(p_T\) dependence of the elliptical flow coefficients \(v_2\) for triggers and associated particles are obtained from averaging the results from the event-plane and four-particle cumulant methods [19]. The background due to randomly associated triggers in the initial selection of the trigger pairs is also considered [6]. We use di-hadron correlations for the appropriate kinematic selections to determine the shape of the related background distribution, and the signal-to-noise ratio from the trigger-trigger correlation to estimate the per-trigger contribution for such pairs. The overall background level \(a_{\text{yam}}\) is estimated with the zero-yield at minimum (ZYAM) method [6,21,22]. For the \(2 + 1\) correlation we choose the zero-yield region to be more than 3\(\sigma\) (corresponding to 1.3 radians) away from both jet-like peaks. We also use a double Gaussian plus a \(v_2\)-modulated background fit to estimate the systematic error due to the ZYAM method. To obtain the transverse momentum spectra for associated hadrons we follow the same procedure selecting the hadrons within 0.5 radians in relative azimuth and 0.5 in relative pseudorapidity of the respective trigger direction.
Various sources of systematic uncertainties on measured yields are evaluated. Single-track reconstruction efficiency contributes 5% overall normalization uncertainty for the associated hadron yields. This error does not affect same-side to away-side comparison for the correlated yields of the same data sample. The systematic uncertainty in the pair-acceptance correction due to finite statistics of the mixed-events is estimated to be less than 5%. The uncertainty due to the elliptical flow correction is estimated from the difference in the v2 results from the event-plane and cumulant methods. The uncertainty is found to be 5% in most-central, less than 1% in most-peripheral, and 9% in mid-central Au + Au events. This uncertainty is largely correlated between same- and away-side distributions and is not applicable to d + Au events. Systematic uncertainty due to ZYAM normalization of the background level was estimated by varying the Δφ range for the minimum yield region, and is found to be ~10% in the Au + Au data and less than 5% in d + Au events. The related uncertainty is correlated between same and away sides. Systematic uncertainty due to correlated background subtraction from the di-jet sample is determined to be less than 3% for both d + Au and Au + Au events. This error is correlated between the same and away sides, and was estimated by varying background normalization for the trigger-trigger correlation in a similar manner as for 2 + 1 correlation. Finally, the uncertainty in the di-hadron distributions used for estimating the correlated background term arises mainly from the uncertainty in v2 and ZYAM normalization. We evaluate these in a similar manner and estimate that the resulting effect varies from less than 1% in d + Au events to about 5% in central Au + Au data.

Figure 1 shows Δφ and Δη projections (symmetrized about 0) of the correlation function defined above, measured for central and mid-central Au + Au collisions and compared with the corresponding measurement from minimum bias d + Au data. The Δφ projection [Fig. 1(a)] reveals jet-like peaks on both the same and away sides. The observed structures from Au + Au data of all centralities are consistent within errors with the ones in d + Au collisions. This constitutes an observation of the away-side correlation structure peaked in both Δφ and Δη for the associated hadrons in this kinematic regime.

FIG. 1. (Color online) Projections of 2 + 1 correlation on Δφ (a) and Δη (b) for 200 GeV top 12% central-triggered (squares) and mid-central (band) Au + Au and minimum bias d + Au (circles) data. Errors shown are statistical. The kinematic selection is as follows: 5 < p_{trig1}T < 10 GeV/c, 4 GeV/c < p_{trig2}T < p_{assoc}T, and 1.5 GeV/c < p_{assoc}T < p_{trig1}T. (c) Transverse momentum distributions per trigger pair for the same- and away-side hadrons associated with di-jet triggers (|Δφ| < 0.5, |Δη| < 0.5). Errors are the quadrature sum of the statistical and systematic uncertainties. Inclusive charged hadron distribution 10% most-central Au + Au data [23] are shown for comparison.

FIG. 2. (a) Relative production rates for jets and di-jets in Au + Au collisions of different centralities with respect to d + Au data. (b) Calculations of the Glauber-based core-corona model that accommodates inclusive hadron suppression and single-jet production rate results. (c) Conditional di-jet survival probability in Au + Au data compared to the d + Au reference. The band shows the expectations from Glauber-based core-corona model described in the text. Error bars in (a) and (c) are the quadrature sum of the statistical and systematic uncertainties.
range. These results differ significantly from earlier di-hadron correlation observations, where substantial differences in both yields and shapes on both the same and away sides were observed between Au + Au and d + Au data [5]. We observe no evidence of the Mach-cone effect by looking at Δη projections for di-jet-triggered correlations for same-side as well as away-side triggers [Fig. 1(b)]. We find that the same-side integrated yields at 0.5 < Δη < 1.5 are consistent with zero; however, statistical limitations ban exclusion of the ridge magnitudes reported in [12]. The 2 + 1 results provide no evidence of a long-range “ridge” associated with the direction of either of the high-p_T triggers, consistent with lack of medium-induced effects on those di-jets selected by this analysis. The possible effects of radial flow on Mach-cone-like and ridge signals in di-hadron correlations have been studied in [24]. We expect no such radial flow-related effects for tangentially emitted trigger pairs.

We further explore the associated hadron spectra to complement the correlation shape analysis. Figure 1(c) shows same- and away-side-associated hadron yields plotted vs transverse momentum in d + Au and 12% central Au + Au collisions. Within the uncertainties no difference is observed between associated hadron spectra on same side or away side Au + Au or d + Au data samples. Earlier measurements from di-hadron correlations in a similar kinematic range have shown significant softening of the away-side-associated hadron spectra [2].

To check for the possible away-side softening which is indicative of energy deposition in the medium, we estimated the jet energy difference between same and away sides. We sum the transverse momentum of trigger particle and jet energy in the fiducial range. We then calculate the jet energy difference between same and away sides. We observe the same result in all centrality for single triggers is consistent with the suppression factors observed in inclusive charged hadron measurements [23], while correlated trigger pair production rates are suppressed even further.

To examine if these results are consistent with the purely tangential jet production scenario, Monte Carlo Glauber calculations to find the spatial distribution of hard scattering were performed for each centrality bin. We assume a simplistic scenario where the interaction zone in heavy-ion collisions consists of a completely opaque core (full jet attenuation) surrounded by a permeable corona (no jet-medium interactions). Similar ideas were previously explored in application to RHIC data in, for example, [27]. Energy loss fluctuations as discussed in [28] have not been taken into account. Participant eccentricity for the medium core shape has been used. This has been found most suitable for elliptical flow results [29].

The size of the core is estimated directly from the R_AA suppression measurements [3,23] and the calculated core eccentricity. The total size of the interaction area is calculated in a similar way, requiring the integrated collision density inside this area to be 99% of the total N_coll. We further assume that all observed trigger hadrons come from the corona. Core and corona sizes that accommodate the inclusive hadron suppression results are shown in Fig. 2(b). The gray band shows propagation of uncertainties in the published R_AA values into our calculations. Figure 2(c) displays the conditional di-jet survival rates. The expected rates are shown as a band, where the width reflects the uncertainty in the published R_AA data.

To estimate the conditional di-jet survival probability in the data, we use the double ratio \( I_{d+Au}^{Au+Au} = \frac{R_{d+Au(trigger pairs)}}{R_{d+Au(single triggers)}} \), which reflects any changes in probability to find an away-side trigger for each primary trigger in Au + Au data relative to d + Au. For the 12% most-central Au + Au data, the likelihood of finding an away-side trigger for each primary trigger, which might be interpreted as conditional di-jet survival probability, is approximately 20% ± 2%(stat) ± 4.5%(syst) compared to d + Au. This ratio is shown as symbols in Fig. 2(c) for comparison with the above model. However, we must point out that core emission where neither of the di-jets interacted with the medium cannot be ruled out by this analysis.

To summarize, we attempt to investigate mechanisms of jet-medium interactions in ultrarelativistic heavy-ion collisions using a technique involving three-particle (2 + 1) correlations of hadrons associated with a correlated pair of back-to-back high-p_T particles. Both same-side and away-side peaks of di-jet-triggered correlations from central Au + Au data are found to be similar to the structures observed in d + Au collisions at the same energy. We observe the same result in all centrality bins of minimum bias Au + Au data. We measure associated hadron spectra on each side of a di-jet primary trigger and find that spectral shapes and integrated yields in central Au + Au data are similar on the same side and away side and are consistent with those measured in d + Au data. In contrast with earlier measurements with a single trigger, we observe no modification in correlations of associated hadrons in the momentum range of \( p_T^{assoc} > 1.5 \text{ GeV}/c \) with the kinematic
selection studied. Systematic assessment of di-jet production rates supports tangential emission bias in a simplistic core-corona scenario, showing no evidence for di-jets interacting with the core.
