(Received 14 September 2010; published 21 March 2011)

We present detailed numerical simulations of a class of material systems that strongly discriminate light based primarily on the angle of incidence, over a broad range of frequencies, and independent of the polarization. Unique properties of these systems emerge from exploring photonic crystals whose constituents have an anisotropic dielectric response.

DOI: 10.1103/PhysRevA.83.035806
PACS number(s): 42.70.Qs, 88.40.F—, 88.40.H—

Materials and structures that strongly discriminate electromagnetic radiation based on one, or more of its properties (e.g., polarization, frequency) play an enabling role for a wide range of physical phenomena. For example, polarizers can selectively transmit light based on its polarization [1] over a wide range of frequencies; photonic crystals [2] (PhCs) can reflect light of certain frequencies irrespective of the angle of incidence and irrespective of the polarization. A material system that could transmit light based primarily on the angle of incidence might also enable a variety of novel physical phenomena. Light incident at a prescribed range of angles would be nearly perfectly transmitted, while light from other angles of incidence would be nearly perfectly reflected [Fig. 1(a)]. Ideally, such an angular selectivity would apply independent of the incoming polarization and over a broad range of frequencies. Structures with such strong angular selectivity do not currently exist. For example, PhCs exhibit some angular discrimination of light, but this discrimination is always strongly dependent on frequency, as illustrated in Fig. 1(b). In this Brief Report, we present a material system that opens the desired angular gaps, as shown in Fig. 1(c).

For example, using realistic constituent material parameters, we present numerical calculations demonstrating an angular photonic band gap (PBG) material system in which light experiences fractional frequency band gap. The key to these interesting physical phenomena is always strongly dependent on frequency, as illustrated in Fig. 1(b). In this Brief Report, we present a material system that could transmit light based primarily on the angle of incidence, over a broad range of frequencies, and independent of the polarization.

From Eqs. (1) and (2), we see that TE light is affected only by $\varepsilon$ and $\mu$ of each bilayer [4]), and made out of an isotropic material with $\varepsilon_{\text{rod}} = 12.25$ [5]. To the right of the inset of Fig. 2(a), we show a schematic diagram of normally incident TM- (in blue) and TE- (in red) polarized light incident on the above-described multilayer. Since $E$ lies in the $xy$ plane, both polarizations experience $n_{A} = n_{B} = \sqrt{1/23}$, so because of the absence of any contrast in the refractive index, there is no photonic band gap and normally incident light of all frequencies and both polarizations gets transmitted, apart from the small reflections at boundaries between the structure and air. As seen in Fig. 2(b), the situation changes with oblique incidence: TM-polarized light now has $E_{\text{inc}} \neq 0$, and thus experiences an index contrast ($n_{A}^{TM} \neq n_{B}^{TM} = \sqrt{1/23}$); therefore, a photonic band gap opens, with strong reflections for TM light. In contrast, TE-polarized light incident at oblique angle still has $E_{\text{inc}} = 0$ and thus experiences no index contrast as shown [Fig. 2(b): $n_{A} = n_{B} = \sqrt{1/23}$]; therefore, it gets transmitted for all frequencies. Thereby, TM light is transmitted for small $\theta_{\text{inc}}$ and reflected for large $\theta_{\text{inc}}$. This structure works only for a certain frequency range [9.3% in the case of Fig. 2(b)].

It is useful to look at analytical expressions for the effective refractive index $n_{A}$ of the anisotropic layer. A simple calculation starting from Maxwell’s equations [6] yields the following refractive indices ($n = c/\epsilon_{\text{phase}}$) experienced by TE and TM light, respectively, in the anisotropic layer $A$:

\[ n_{A}^{TE} = \frac{1}{\sqrt{\mu_{Axx}^{\phi} \epsilon_{Ayy}^{\phi} / \mu_{Azz}^{\phi} + \sin^{2} \theta_{A}^{TM} / \mu_{Azz}^{\phi}}}, \]  

\[ n_{A}^{TM} = \frac{1}{\sqrt{\mu_{Axx}^{\phi} \epsilon_{Ayy}^{\phi} / \mu_{Azz}^{\phi} + \sin^{2} \theta_{A}^{TE} / \mu_{Azz}^{\phi}}}, \]

where $\theta_{A}^{TE}$ and $\theta_{A}^{TM}$ are the refraction angles for TE and TM polarizations in layer $A$, as described by Snell’s law:

\[ n_{A}^{TE} \sin \theta_{A}^{TE} = n_{A}^{TM} \sin \theta_{A}^{TM} = n_{\text{inc}} \sin \theta_{\text{inc}}, \]

\[ n_{A}^{TM} \sin \theta_{A}^{TM} = n_{\text{inc}} \sin \theta_{\text{inc}}. \]

From Eqs. (1) and (2), we see that TE light is affected only by $\varepsilon_{A}^{\phi}$, $\mu_{Axx}^{\phi}$, and $\mu_{Azz}^{\phi}$, while TM light is affected only by $\mu_{Axx}^{\phi}$ and $\varepsilon_{A}^{\phi}$.
\( \mu_A, \varepsilon_A^{xx}, \) and \( \varepsilon_A^{zz} \). In particular, TM light is affected by \( \varepsilon_A^{zz} \), in contrast to the TE polarization. We also note that for near-normal incidence, \( \sin \theta_A \approx 0 \), so \( n_A \) increases only slightly with increasing anisotropy. However, for incidence angles not close to the normal, \( n_A \) increases more rapidly with increasing anisotropy, and therefore higher anisotropy in \( \varepsilon \) or \( \mu \) results in higher index contrast and wider frequency gaps at those angles.

To achieve a simultaneous band gap for both TE and TM polarizations, we consider a multilayer structure with anisotropy in both permittivity and permeability tensors: \( \varepsilon_B = \mu_A = \gamma_B \) while \( \varepsilon_A = \mu_B = (\gamma_A, \gamma_A, \gamma_A) \) [7]. For simplicity, we consider the case \( \varepsilon_A^{xx} = \mu_A = \gamma_A \) here. TM light with oblique incidence from air experiences a photonic band gap, because \( n_B^{TM} = \sqrt{\gamma_B} \) while \( n_A^{TM} = \sqrt{\gamma_A} \) [Eq. (2)]. On the other hand, TE incidence at the same angle also experiences an index contrast because \( n_A^{TE} = \sqrt{\gamma_A} \) while \( n_B^{TE} = \sqrt{\gamma_B} \) [Eq. (1)]. The relative size of the TE (and also TM) gap as a function of \( \theta_{inc} \) and the degree of anisotropy \( \gamma_A/\gamma_B \) was obtained from the TMM [8] and is shown in Fig. 3; the thicknesses of layers \( A \) and \( B \) were chosen to be equal \( (h_A = h_B = 0.5a) \) so that the structure discriminates angles equally, over the same frequency interval and for both polarizations simultaneously [9]. From the contour plot, we observe that the size of the fractional gap increases only slightly with increasing anisotropy \( \gamma_A/\gamma_B \) beyond \( \gamma_A/\gamma_B \approx 2 \), which can also be seen by inspection of Eqs. (1) and (2) and noticing that the achievable index contrast “saturates” for large \( \gamma_A/\gamma_B \) anisotropy values. Therefore, materials with very large anisotropy do not necessarily lead to much larger band gaps in these structures. This is somewhat contrary to conventional PhCs where large index contrasts typically lead to larger band gaps. Note also that the size of the fractional frequency gap increases with \( \theta_{inc} \).

Having proposed a structure that opens an angular gap for both polarizations over a certain frequency range, we now discuss a method by which one might enlarge the frequency range over which this angular discrimination is exhibited. Since we are concerned with the largest fractional frequency gap that occurs simultaneously for both polarizations, we operate at quarter-wave condition. We use anisotropic \( \varepsilon_A = \mu_A \) (as opposed to the previously considered case when we had anisotropic \( \varepsilon_A = \mu_B \)). We start with a single stack consisting of 130 homogeneous bilayers with \( \varepsilon_A = \mu_A = (1.23, 1.23, 2.43) \) and \( \varepsilon_B = \mu_B = 1.23 \). The size of each bilayer in this stack is \( a \). Light incident at 22.5\(^\circ\) (from air) on this stack experiences a simultaneous TE and TM photonic band gap having a fractional frequency width of 1.64\% (at the quarter-wave condition). To widen this fractional frequency range, we consider a multilayer consisting of 71 such stacks, each stack being made out of 130 bilayers. However, the period of each stack is graded, so that frequency gaps of different stacks are contiguous and merge together, resulting in a much larger frequency gap (\( \approx 71 \) times the size of the gap in the single-gap case). More specifically, we choose the period \( a_i \) of the \( i \)th stack \( (i = 1, 2, \ldots, 71) \) to be \( a_i = 1.0164^{i-1}a \), where \( a \) is the period of the first stack facing the incident light. We also choose the thickness \( h_A \) of layer \( A \) in the \( i \)th stack to be 0.494\( a \), so that the quarter-wave condition (which maximizes the relative size of the frequency gap) is satisfied. In Fig. 4(a), TMM results for the transmission spectrum at 22.5\(^\circ\) incidence on the 71-stack multilayer show a reflection window of relative frequency size of \( \approx 107\% \) for both TE and TM polarizations. In Fig. 4(b), we show TMM results for light incident at 45\(^\circ\) on this same structure: nearly complete reflection occurs inside the reflection window for 22.5\(^\circ\) incidence [Fig. 4(a)], indicating a large angular band gap. In fact, this proposed structure exhibits an angular gap (for \( \theta_{inc} \) between 22.5\(^\circ\) and 90\(^\circ\)) for both polarizations simultaneously over a 107\% wide frequency range [Fig. 4(c)].

The applicability of the angular PBG concept we propose for a given situation of interest will depend on the availability of anisotropic materials in the frequency range of interest.
FIG. 2. (Color) (a) Transmission spectra [obtained from the transfer matrix method (TMM) \cite{11}] for TE- (red) and TM- (blue) polarized light normally incident from air on 30 bilayers of the structure shown in the inset. (b) Schematic diagrams showing TM- (inset, left) and TE- (inset, right) polarized light incident at nonzero angle from air ($n_{\text{inc}} = 1$). The physical structure considered in this figure is always the same; however, TM light incident at nonzero angle “sees” a structure of different optical properties than the structure “seen” by either TM light incident normally or TE light incident at any angle. Transmission spectra (obtained from the TMM) for TE- (red) and TM- (blue) polarized light incident at 45° from air on 30 bilayers of the structure shown in the inset. Green curve: Transmission spectrum (obtained from the finite-difference time-domain method \cite{19}) for TM-polarized light incident at 45° from air on 30 bilayers of the structure in the inset, in the case when anisotropic layer $A$ is not made from a homogeneous material, but is a metamaterial implemented from a square lattice of dielectric rods. A TM photonic band gap opens and closely overlaps with the TM gap obtained from the TMM for the uniform dielectric case; as expected, the TMM is a good approximation for analyzing structures of this type.

In addition to the dielectric metamaterials for TM-polarized light [cf. Fig. 2(a)], amorphous photonic crystals could be of interest \cite{10,11}. To achieve polarization independence (where anisotropic $\mu$ is needed), one can exploit metalo-dielectric metamaterials \cite{12}. Another option is to split incoming light according to polarization before it enters the structure, rotate TE polarization into TM polarization, and only then allow it to continue onto our structure \cite{13}.

In summary, we presented a class of material systems capable of discriminating light primarily based on the angle of incidence. Angular PBG material systems of this type could potentially find uses in applications where radiation is incoming from a known, defined direction, and it is desirable to prevent subsequent “escape” of radiation energy. As an avenue of further research, it would be interesting to explore whether material systems of similar properties could one day be useful for solar-energy applications. Sunlight has a well-defined angle of incidence. A portion of sunlight is reflected from solar-energy conversion devices, while a portion

FIG. 3. (Color) The relative size of the TE gap as a function of $\theta_{\text{inc}}$ and $\gamma_2/\gamma_1$ for a multilayer structure that has $\varepsilon_A = \mu_B = (\gamma_1, \gamma_1, \gamma_1)$, $\varepsilon_B = \mu_A = \gamma_1$. The light is incident from a medium of $\varepsilon_{\text{inc}} = \mu_{\text{inc}} = \gamma_1$. The TM gap is identical to the TE gap.

is reradiated (either because of radiative recombination, or in solar-thermal \cite{14} systems because of thermal emission); this represents losses, which can often be substantial. If one could suitably place a material system that would allow light at one particular angle (that coming from the sun) to get perfectly through, while light emerging from the device (most of which typically propagates at different angles) would be reflected back to the device, the efficiency of the solar-energy conversion could be improved \cite{15–18}.

FIG. 4. (Color) Transmission spectra of the graded-periodicity multilayer stack at various incident angles: (a) 22.5° and (b) 45°.

[4] Since we know that a TM reflection window opens at $45^\circ$, we choose the relative thickness $h_A$ of layer $A$ such as to maximize the size of the TM fractional gap, which happens at the quarter-wave condition $[h_A n_A \cos(\theta_{TM}) \omega_0/\epsilon = h_B n_B \cos(\theta_{TM}^B) \omega_0/c]$, $\omega_0$ being the central frequency of the gap. This results in $h_A = 0.46a$.
[5] In a 2D square lattice of dielectric rods, modes having their $E$ field along the rods are substantially more concentrated inside the rods and therefore experience the high $E$ of the rods. On the other hand, modes having their $E$ field in the periodicity plane experience average $E$ smaller than that along the rods; hence the anisotropy in effective $\epsilon$. Our frequency domain simulations (not discussed here) show that in the low-frequency limit, the metamaterial indeed has effective $\epsilon = (1.23,1.23,2.43)$.
[7] Note that a structure having $\epsilon_A = \mu_A = (\gamma_1,\gamma_1,\gamma_2)$ and $\epsilon_B = \mu_B = \gamma_1$ would work equally well. However, the structure that we analyze in Fig. 3 offers somewhat more flexibility in the material choice, in the sense that equal anisotropic $\epsilon$ and $\mu$ do not have to occur in the same material.
[8] Pochi Yeh, *Optical Waves in Layered Media*, Chap. 5 (Ref. [3]), pp. 102–110; Chap. 6, pp. 118–128. In the TMM, we model each layer as being uniform; e.g., in the case of layer $A$ of Fig. 2, uniform $\epsilon = (1.23,1.23,2.43)$.
[9] Note that this choice of $h_A = h_B$ does not result in the largest possible fractional gap for either polarization, which actually occurs at the quarter-wave condition, satisfied nonsimultaneously for the two different polarizations when $\epsilon_A = \mu_B = (\gamma_1,\gamma_1,\gamma_2)$.
