(Received 20 September 2010; accepted 7 February 2011; published online 25 February 2011)

In recent quenching heat transfer studies of nanofluids, it was found that deposition of nanoparticles on a surface raises its Leidenfrost point (LFP) considerably [Kim et al., Int. J. Multiphase Flow 35, 427 (2009) and Kim et al., Int. J. Heat Mass Transfer 53, 1542 (2010)]. To probe the physical mechanism underlying this observation, the effects of surface properties on LFP of water droplets were studied, using custom-fabricated surfaces for which roughness height, wettability, and porosity were controlled at the nanoscale. This approach reveals that nanoporosity is the crucial feature in efficiently increasing the LFP by initiating heterogeneous nucleation of bubbles during short-lived solid-liquid contacts, which results in disruption of the vapor film. © 2011 American Institute of Physics. [doi:10.1063/1.3560060]

When a liquid droplet is placed on a surface held at a temperature much higher than the liquid’s boiling point, it hovers on a vapor cushion without wetting the surface. This phenomenon is called film boiling and occurs at surface temperatures beyond the so-called “Leidenfrost point (LFP).” If the surface temperature is at or above the LFP, heat transfer from the surface to the liquid takes place by conduction and radiation through the vapor layer, thus the liquid takes a significantly longer time to evaporate than it would on a surface held at lower temperature. Therefore, higher LFP is desirable for rapid cooling of overheated components in high-power-density thermal systems, such as nuclear reactors during hypothetical accidents.

In recent film boiling heat transfer studies with nanofluids, it was demonstrated that deposition of nanoparticles on a surface significantly increases the nominal LFP up to ~500 °C under atmospheric and saturated conditions, considerably accelerating the transient cooling of overheated objects.1,2 However, such a high LFP could not be explained by the traditional LFP models based on hydrodynamic instability of the vapor film, e.g., Berenson’s3 and Henry’s4 models. This suggested that the vapor film is destabilized and disrupted by a different mechanism associated with the thin nanoparticle deposition layer. Characterization of the deposition layer suggested changes in roughness, wettability, and nanoporosity as plausible causes for such a high LFP. Nevertheless, it was not possible to identify the exact physical mechanism of LFP enhancement because nanoparticle deposition in those experiments changed roughness height, wettability, and porosity simultaneously. Therefore, we decided to investigate LFP phenomena with custom-fabricated surfaces for which we can precisely separate the effects of roughness height, wettability, and nanoporosity, as explained next.

Surface roughness height was controlled by fabricating cylindrical posts of 15 μm height and 5 μm diameter on a nanosmooth silicon wafer (Rg<0.5 nm; thickness 380 μm) [Fig. 1(b)]. The posts were fabricated with a deep reactive-ion etching process, and were arranged on a square array of large pitch (500 μm), to prevent secondary effects, such as capillarity. Next, the surface intrinsic wettability was controlled by depositing a nanosmooth thin layer of gold (100 nm thick) or silicon oxide (20 nm thick) with a sputtering technique; the resulting contact angles for de-ionized water droplets were found to be 83° on the gold surface and 19° on the silicon oxide surface (see the insets of Fig. 1). Note that the presence of the microposts does not affect wettability [compare insets of Figs. 1(a) and 1(b)], which was expected, given the large pitch of the post array. Finally, to explore the effect of nanoporosity, we used a thin nanoporous layer (about 600 nm thick) made of silicon oxide nanoparticles (23 nm), deposited according to the layer-by-layer (LBL) process.

FIG. 1. SEM images of fabricated samples for LFP tests: (a) smooth Au layer; (b) 15 μm posts on smooth Au layer; (c) 15 μm posts on smooth SiO2 layer; (d) LBL SiO2 layer. Insets show static equilibrium contact angle on the fabricated samples for 10 μL water droplets on (a) smooth Au (83°), (b) Au with microposts (83°), (c) SiO2 layer (19°), and (d) nanoporous SiO2 layer (~0°).
ably closed to the values found in the literature. The LFP on the smooth gold surface without microposts is significantly higher than that on the smooth silicon oxide surface without microposts. The upper block has a through-hole in the shape of an inverted cone to place a droplet on the silicon wafer. The temperature difference between the two blocks was controlled to keep the evaporating droplet on the silicon wafer. The temperature corresponding to the maximum evaporation time is the LFP. The LFP on the smooth silicon oxide surface without microposts is the longest evaporation time is the LFP. The LFP on the smooth silicon oxide surface without microposts is

A common technique used for determining the LFP consists in measuring the evaporation times of liquid droplets over a heated surface. The test surface is sandwiched between two independently heated and controlled copper blocks. The upper block has a through-hole in the shape of an inverted cone to place a droplet on the silicon wafer and keep the evaporating droplet on the silicon wafer. The temperature difference between the two blocks was controlled to be less than 1 K during the experiments. A water droplet of ~2.9 mm in diameter is released on the test surface from a height of 1.5 mm using a syringe, and the evaporation time is measured with a stopwatch. The uncertainty in the evaporation time measurement was found to be ~0.4 s from a set of tests at representative conditions.

The data obtained from the droplet experiments are displayed as droplet evaporation time versus surface temperature in Fig. 2. In this curve, the temperature corresponding to the longest evaporation time is the LFP. The LFP on the smooth gold surface without microposts is ~264 °C, reasonably closed to the values found in the literature. The LFP is slightly higher (~274 °C) for the smooth silicon oxide surface without microposts but is significantly higher (~359 °C) for the porous silicon oxide surface without microposts. This result suggests that nanoporosity has a stronger effect than intrinsic surface wettability on the LFP. The effect of roughness height (microposts) is shown by the data designated with the empty symbols in Fig. 2; everything else being the same, the presence of the microposts consistently enhances the LFP on all surfaces tested in this study but the magnitude of the enhancement is distinctively higher on the nanoporous surface. As a result, the nanoporous surface with microposts can be considered an optimum (within the limits of our study), exhibiting the highest LFP at 453 °C, which is even beyond the critical point of water (374 °C) (Table I).

Why do nanoporosity and microposts result in such a high LFP? High-speed imaging of the evaporating droplets shed light on the mechanisms, when we focused on the intermittent solid-liquid contacts in film boiling, as suggested by previous researches. Actually, we observed thin liquid filaments intermittently connecting the droplet to the solid surface on the samples with microposts [Fig. 3(b)], whereas the filaments were not observed on the surfaces without microposts [Fig. 3(a)]. However, even in the presence of liquid filaments, the evaporation process was quite different depending on whether the surface was nanoporous or not. The gold and silicon oxide surfaces without nanoporosity stably sustained the liquid filaments, typically for a few milliseconds, without triggering any perturbation [Figs. 3(b) and 3(c)]. By contrast, the nanoporous surfaces instantaneously reacted to the filament contacts with violent splashes of tiny droplets around the large evaporating droplet [Fig. 3(d)]. This splashing severely disturbed the liquid-vapor interface and prevented the establishment of a stable vapor film at nominal surface temperatures as high as ~453 °C.

Biare et al. derived an analytical solution for the film thickness of a stationary evaporating droplet of radius, \( R \), smaller than the capillary length, \( R < a = \sqrt{\sigma/\rho g} \), for a given surface superheat, \( \Delta T \),

\[
e = C \left( \frac{k \Delta T \mu g}{h_f \rho_c \sigma^2} \right)^{1/3} R^{4/3},
\]

where \( C \), \( \sigma \), \( k \), \( \mu \), \( \rho \), \( \rho_c \), and \( h_f \) are, respectively, an adjustable coefficient, surface tension, thermal conductivity, dynamic viscosity, density of liquid, density of vapor, and la-

tent heat of evaporation. For an evaporating droplet of $2R \approx 2.9 \text{ mm}$ on a surface of $400 \text{ °C}$ ($\Delta T = 300 \text{ °C}$), the initial film thickness is estimated to be approximately $36 \mu m$ and then decreases monotonically as $R^{3/2}$. Thus, at $15 \mu m$ height, the microposts can initiate solid-liquid contacts, as shown in Fig. 3.

Once the liquid filaments are established, heterogeneous nucleation of bubbles can occur at the contact points, if there are cavities available for nucleation. Bernardin and Mudawar’s heterogeneous nucleation model of the LFP focuses on the surface superheat temperature required to initiate the growth of hemispherical vapor bubbles from the pre-existing surface cavities. The nanosized pores act as cavities for heterogeneous nucleation of bubbles. The pressure drop across a spherical bubble interface of radius $r$ can be estimated using Young–Laplace equation as

$$P_g - P_f = \frac{2\sigma}{r}. \quad (2)$$

In combination with the Clausius–Clapeyron equation, Eq. (2) gives the following expression for the temperature required to initiate the nucleation of a hemispherical vapor bubble,$^{15}$

$$T_{nuc} = T_{sat} \exp \left( \frac{2\sigma \rho g}{r h_f g} \right). \quad (3)$$

There exists a large difference in temperature for heterogeneous nucleation of bubbles between the nanoporous and nonporous surfaces, i.e., $T_{nanoporous} \approx 218 \text{ °C}$ versus $T_{nonporous} \approx 336 \text{ °C}$, where nucleation diameter of $23 \text{ nm}$ and $1 \text{ nm}$ were assumed, respectively.$^{12,13}$ Therefore, bubbles more easily nucleate on the nanoporous surface and very rapidly grow in the highly superheated liquid. Starting from the Rayleigh equation for the inertia-controlled phase of bubble growth, it can be shown that $\Delta P \sim \rho V^2$, where $V$ is the velocity of the expanding vapor interface and $\Delta P$ is the value of the pressure difference across the interface at the point of nucleation. For a bubble with a diameter of $23 \text{ nm}$, the estimated velocity, $V$, is of the order of $10 \text{ m/s}$. When the vapor phase velocity is greater than the critical velocity of Kelvin–Helmholtz instability, the liquid-vapor interface can be disrupted. For the steam and water at atmospheric pressure, the critical velocity is approximately $8 \text{ m/s}$.\textsuperscript{14} Therefore, the velocity of the expanding vapor interface for the $23 \text{ nm}$ diameter bubble is fast enough to generate the splashes shown in Fig. 3(d). In this regard, it is concluded that nanoporosity (not solely high surface wettability) is an essential feature to enhance the LFP, and such enhancement occurs via prevention of the stable vapor film establishment, caused by heterogeneous nucleation of bubbles. The microposts on the surface intensify such effects by promoting intermittent liquid-surface contacts.

This work was partially supported by the Korea Science and Engineering Foundation (KOSEF) grant funded by the Korea government (MEST) (Grant No. 2010-0018761). The authors acknowledge the financial support of the DOE–NEUP fellowship program for Mr. Bao Truong. We also thank Mr. Eric Forrest for assisting in the preparation of the LBL coatings of the test samples in Professors M. Rubner and R. Cohen’s laboratory at MIT.

8. The reported value of LFP is the nominal temperature of the test surface. Obviously, the local temperature at which the liquid-solid contact occurs must be below the critical point.
12. Note that these values of nucleation superheat are much higher than those normally encountered on engineering surfaces where microcavities are present.
13. The calculated value of the heterogeneous nucleation superheat temperature at $d = 1 \text{ nm}$ is higher than the homogeneous nucleation temperature ($\sim 300 \text{ °C}$ for water at atmospheric pressure) because the size of the vapor embryos responsible for homogeneous nucleation is of the order of a few nanometers. Therefore, the fluid nucleates homogeneously before it does so heterogeneously.
