Communication in a Poisson Field of Interferers—Part II: Channel Capacity and Interference Spectrum

Pedro C. Pinto, Student Member, IEEE, and Moe Z. Win, Fellow, IEEE

Abstract—In Part I of this paper, we presented a mathematical model for communication subject to both network interference and noise, where the interferers are scattered according to a spatial Poisson process, and are operating asynchronously in a wireless environment subject to path loss, shadowing, and multipath fading. We determined the distribution of the aggregate interference and the error performance of the link. In this second part, we characterize the capacity of the link subject to both network interference and noise. Then, we put forth the concept of spectral outage probability (SOP), a new characterization of the aggregate radio-frequency emission generated by communicating nodes in a wireless network. We present some applications of the SOP, namely the establishment of spectral regulations and the design of covert military networks. The proposed framework captures all the essential physical parameters that affect the aggregate network emission, yet is simple enough to provide insights that may be of value in the design and deployment of wireless networks.

Index Terms—Stochastic geometry, Poisson field, aggregate network emission, channel capacity, spectral outage, stable laws.

I. INTRODUCTION

The application of the spatial Poisson process to cellular networks was investigated in [1], and later advanced in [2]–[4]. However, these studies focus mostly on error performance metrics, and do not attempt a characterization of the channel capacity and interference spectrum. Furthermore, they often ignore random propagation effects (e.g. shadowing and fading) [1]; assume perfect synchronization between different interferers at the symbol or slot level [3]; or restrict the node locations to a disk in the two-dimensional plane [4], [5], which complicates the analysis and provides limited insights into the effect of network interference. In [6], [7], the authors analyze coexistence issues in narrowband and ultrawideband networks, but consider only a small, fixed number of interferers.

This paper was presented, in part, at the IEEE Global Telecommunications Conference, San Francisco, CA, November 2006.

P. C. Pinto and M. Z. Win are with the Laboratory for Information and Decision Systems (LIDS), Massachusetts Institute of Technology, Room 32-D674, 77 Massachusetts Avenue, Cambridge, MA 02139, USA (e-mail: [ppinto, moewin]@mit.edu).

Digital Object Identifier 10.1109/TWC.2010.07.071283

In Part I of this paper [8], we introduced a framework where the interferers are scattered according to a spatial Poisson process, and are operating asynchronously in a wireless environment subject to path loss, shadowing, and multipath fading. Under this scenario, we determined the statistical distribution of the aggregate interference, and the corresponding error performance of the link. In this second part, we characterize the capacity of the link subject to both network interference and noise. Then, we put forth the concept of spectral outage probability (SOP), a new characterization of the aggregate radio-frequency (RF) emission generated by communicating nodes in a wireless network. Lastly, we quantify these metrics as a function of important system parameters, such as the signal-to-noise ratio (SNR), interference-to-noise ratio (INR), path loss exponent of the channel, and spatial density of the interferers. Our analysis easily accounts for all the essential physical parameters that affect the aggregate network emission. Furthermore, the concept of SOP can be used (e.g., in commercial or military applications) to evaluate and limit the impact of network interference on any given receiver operating in the same frequency band.

This paper is organized as follows. Section II briefly reviews the system model introduced in Part I. Section III analyzes the channel capacity of the system, and presents numerical examples to illustrate its dependence on important network parameters. Section IV derives the power spectral density (PSD) of the aggregate interference, introduces the concept of spectral outage probability, and provides numerical examples of both metrics. Section V summarizes important findings.

II. MODEL SUMMARY

We briefly review the model introduced in Part I. As shown in [8, Fig. 1], we consider the interfering nodes to be spatially scattered in the two-dimensional infinite plane, according to a homogeneous Poisson process with density \( \lambda \) (in nodes per unit area) [9]. The random distance of interfering node \( i \) to the origin is denoted by \( R_i \). For analytical purposes, we introduce a probe link which is composed of two nodes: the probe receiver (located at the origin), and the probe transmitter (node \( i = 0 \)).

In terms of transmission characteristics, we consider that all interfering nodes employ the same two-dimensional modulation and transmit at the same power \( P \). For generality, however, we allow the probe transmitter to employ an arbitrary two-dimensional modulation and arbitrary power \( P_0 \), not...
necessarily equal to that used by the interfering nodes. We consider that all nodes employ the same symbol rate 1/T, but the signal received from node i is shifted by a random delay D_i, where D_i ∼ U(0, T). The probe receiver performs coherent demodulation of the desired signal using a conventional in-phase/quadrature (IQ) detector.

The wireless propagation channel introduces path loss, log-normal shadowing, and multipath fading. Specifically, the overall effect of the channel on node i is accounted for by the random phase φ_i ∼ U(0, 2π), and the amplitude factor √R_i/|H_i|. The term |H_i| accounts for the path loss; α_i is due to the multipath fading, and has an arbitrary distribution with E{|α_i^2|} = 1; and e^{σ_G i} is due to the log-normal shadowing, with G_i ∼ N(0, 1). In the rest of the paper, we consider the scenario where the location {R_i}^∞_{i=1} and shadowing {G_i}^∞_{i=1} of the interferers (succinctly denoted by P), as well as the shadowing G_0 affecting the probe transmitter, remain approximately constant during the interval of interest. This models a quasi-static scenario where the movement of the nodes during the interval of interest is negligible. In such case, we condition the analysis on P in order to derive a capacity outage probability and a spectral outage probability, which are more meaningful than the corresponding P-averaged metrics. Other fast-varying propagation effects, such as multipath fading due to local scattering, are averaged out in the analysis.

III. CHANNEL CAPACITY

In Part I of this paper, we focused on error performance metrics. We now build on the results of Part I and analyze the capacity of the link between the probe transmitter and probe receiver in [8, Fig. 1], subject to aggregate network interference and additive white Gaussian noise (AWGN). Unlike the simple AWGN channel, here the capacity depends on the information available about the channel at the probe transmitter and receiver. As in Part I, we assume that the probe receiver can perfectly estimate the fading (α_i and φ_i) affecting its own link, thus ensuring that coherent demodulation of the desired signal is possible. The probe transmitter, on the other hand, is not able to estimate the channel. This corresponds to the scenario where the receiver has perfect knowledge of the channel state information (CSI).

A. Capacity Outage Probability

We start with the complex baseband characterization of the probe link, obtained in Part I by projecting all signals onto a cosine-sine orthonormal set. Thus, the complex channel output Z can be written as

\[ Z = \alpha_0 e^{\sigma_G i} R_0^{-b} S + \tilde{W}, \]  \hspace{1cm} (1)

where S is the complex channel input, and \( \tilde{W} \) is the combined aggregate interference and thermal noise, given by

\[ \tilde{W} = \sum_{i=1}^{\infty} e^{\sigma_G i} X_i R_i^{-b} + W, \]  \hspace{1cm} (2)

with \( W \sim \mathcal{N}(0, N_0) \). These are essentially the same baseband equations as those given in Part I, except that the transmitted constellation symbol \( a_0 e^{j\theta_0} \) has been replaced by a generic input symbol S, with an arbitrary distribution f_S(s). This emphasizes the fact that to analyze the channel capacity, we need to maximize the mutual information over all possible input distributions f_S(s), and thus cannot restrict S to belong to a specific constellation, such as M-PSK or M-QAM. In addition, we impose an average energy constraint on the input symbol by requiring that \( \mathbb{E}(|S|^2) \leq E_S \).

Considering that the interfering nodes are coded and operating close to capacity, then the signal transmitted by each interferer is Gaussian, such that \( X_i \sim \mathcal{N}(0, 2V_X) \). The resulting aggregate interference is thus Gaussian when conditioned on \( P \), and the distribution of \( \tilde{W} \) in (2) is given by

\[ \tilde{W} \sim \mathcal{N}(0, 2AV_X + N_0), \]  \hspace{1cm} (3)

where

\[ A = \sum_{i=1}^{\infty} e^{2\sigma_G i} R_i^{-b}. \]  \hspace{1cm} (4)

Note that since A in (4) depends on \( P \) (i.e., \( \{R_i\}^\infty_{i=1} \) and \( \{G_i\}^\infty_{i=1} \)), it can be seen as a random variable (r.v.) whose value is different for each realization of \( P \). It was shown in Part I that the r.v. A has a skewed stable distribution [11] given by

\[ A \sim S \left( \alpha_A = \frac{1}{b}, \beta_A = 1, \gamma_A = \lambda \pi C_1^{-1/6} e^{2\sigma_G^2/b^2} \right), \]  \hspace{1cm} (5)

where \( b > 1 \), and \( C_x \) is defined as

\[ C_x \triangleq \begin{cases} \Gamma(2-x) \cos(\pi x/2) & \text{if } x \neq 1, \\ \frac{2}{\pi} & \text{if } x = 1, \end{cases} \]  \hspace{1cm} (6)

with \( \Gamma(x) = \int_0^\infty t^{x-1} e^{-t} dt \) denoting the gamma function.

Because of the conditioning on \( G_0 \) and \( P \), equations (1)-(4) describe a simple Gaussian channel depicted schematically in Fig. 1. The capacity of this energy-constrained, fast fading channel with receiver CSI can be written as [12]

\[ C = \max_{\alpha_0 \in [0, 2]} I(S; Z|\alpha_0), \]  \hspace{1cm} (7)

4We use \( \mathcal{N}(0, \sigma^2) \) to denote a circularly symmetric (CS) complex Gaussian distribution, where the real and imaginary parts are independent identically distributed (i.i.d.) \( \mathcal{N}(0, \sigma^2/2) \).

5Alternatively, we can follow the same approach as in Part I and argue that \( X_i \sim \mathcal{N}(0, 2V_X) \) in a scenario where the interferers employ an arbitrary two-dimensional modulation (this is the Gaussian approximation introduced in [8, Eq. (11)]). In such case, \( V_X \) is a function of the constellation of the interferers, as shown in [8, Eq. (14)].

6We use \( X \sim \mathcal{N}(0, \sigma^2) \) to denote the distribution of X conditional on Y.

7We use \( S(\alpha, \beta, \gamma) \) to denote a real stable distribution with characteristic exponent \( \alpha \in (0, 2] \), skewness \( \beta \in [-1, 1] \), and dispersion \( \gamma \in [0, \infty) \). The corresponding characteristic function is

\[ \phi(w) = \left\{ \begin{array}{ll} \exp \left[ -|\gamma| w^\alpha \left( 1 - j \beta \text{sign}(w) \tan \frac{\pi \alpha}{2} \right) \right] & \text{if } \alpha \neq 1, \\ \exp \left[ -|\gamma| w \left( 1 + j \frac{\beta}{\alpha} \text{sign}(w) \ln |w| \right) \right] & \text{if } \alpha = 1. \end{array} \right. \]
where $I(S;Z|\alpha_0)$ is the conditional mutual information between $S$ and $Z$ given $\alpha_0$. The optimal input distribution that maximizes the mutual information is therefore $\mathcal{N}_c(0, E_S)$. With this input distribution,

$$I(S;Z|\alpha_0 = \tilde{\alpha}_0) = \log_2 \left( 1 + \frac{\tilde{\alpha}_0^2 e^{2\sigma_Z^2 G_0 E_S}}{r_0^{2b}(2AVX + N_0)} \right)$$

in bits per complex symbol, and thus we obtain the capacity of the channel as

$$C(G_0, P) = \mathbb{E}_{\alpha_0} \left\{ \log_2 \left( 1 + \frac{\tilde{\alpha}_0^2 e^{2\sigma_Z^2 G_0 E_S}}{r_0^{2b}(2AVX + N_0)} \right) \right\}$$

(7)

in bits per complex symbol, where we have explicitly indicated the conditioning of $C$ on the random interferer positions and shadowing. For a Rayleigh fading channel, $\alpha_0^2$ is exponentially distributed with mean 1 and we can further express (7) in terms of the exponential integral function $Ei(x) = -\int_{-\infty}^{\infty} e^{-t}/t \, dt$ as

$$C(G_0, P) = -\frac{\exp(-2\sigma_Z^2)}{\ln(2)} \cdot \frac{1}{\ln(2)} \cdot \frac{1}{\exp(-2\sigma_Z^2)} \cdot Ei\left(-\frac{\sqrt{2}}{\eta}\right)$$

(8)

in bits per complex symbol, where

$$\eta = \frac{e^{2\sigma_Z^2 G_0 E_S}}{r_0^{2b}(2AVX + N_0)}$$

(9)

is the received signal-to-interference-plus-noise ratio (SINR), averaged over the fast fading.

In the proposed quasi-static model, the maximum rate of reliable communication for a given realization of $G_0$ and $P$ is given by (8)-(9). Such quantity is a function of the random user positions and shadowing, and is therefore random. Then, with some probability, $G_0$ and $P$ are such that the capacity is below the desired transmission rate $\rho$, thus making the channel unusable for communication at that rate with arbitrarily low error probability. The system is said to be in outage, and the capacity outage probability is

$$P_c^{\text{out}} = \mathbb{P}_{G_0, P} \{ C(G_0, P) < \rho \}$$

(10)

or, substituting (8) into (10),

$$P_c^{\text{out}} = \mathbb{P}_{\eta} \left\{ -\frac{\exp(-2\sigma_Z^2)}{\ln(2)} \cdot \frac{1}{\ln(2)} \cdot \frac{1}{\exp(-2\sigma_Z^2)} \cdot Ei\left(-\frac{\sqrt{2}}{\eta}\right) < \rho \right\}.$$ 

(11)

B. Numerical Results

Figures 2 and 3 quantify the capacity outage probability and illustrate its dependence on the various parameters, such as the signal-to-noise ratio $\text{SNR} = E_S/N_0$, the interference-to-noise ratio $\text{INR} = E/N_0$, and spatial density $\lambda$ of the interferers. For simplicity, we consider a case study where all interfering nodes transmit equiprobable symbols, belonging to a constellation that is symmetric with respect to the origin of the IQ-plane (e.g., $M$-PSK and $M$-QAM). In this particular case, it is shown in [8, Eq. (14)] that $V_X = E/3$, and thus (9) reduces to

$$\eta = \frac{e^{2\sigma_Z^2 \text{SNR}}}{r_0^{2b} (\frac{2A}{\lambda} \text{INR} + 1)}.$$ 

(12)

To evaluate the corresponding $P_c^{\text{out}}$, we resort to a hybrid approach where we employ the analytical result given in (11)-(12), but perform a Monte Carlo simulation of the stable r.v. $A$ according to [13]. Nevertheless, we emphasize that the expressions derived in this paper completely eliminate the need for simulation of the interferers’ positions and waveforms in the network, in order to obtain the capacity.

IV. SPECTRAL CHARACTERIZATION OF THE AGGREGATE NETWORK EMISSION

The spectral properties of the aggregate RF emission generated by all the nodes in a network is an important consideration in the design of wireless systems. This is useful in military applications, for example, where the communication designer must ensure that the presence of the deployed network is not detected by the enemy. If, for example, a sensor network is to be deployed in enemy territory, then the characterization of the aggregate network emission is essential for the design of a covert system. In commercial applications, on the other hand, the goal is to ensure that the RF emission of the network does not cause interference to other systems operating in overlapping frequency bands. To prevent interference, many commercial networks operate under restrictions which often take the form of spectral masks, imposed by a regulatory
agency such as the US Federal Communications Commission (FCC).

In the previous sections, we have so far derived the error probability and capacity of a link subject to both network interference and thermal noise. We now determine the PSD of the aggregate interference process \( \mathbf{Y}(t) \), measured at the origin of the two-dimensional plane in [8, Fig. 1]. The spectral characteristics of \( \mathbf{Y}(t) \) can be inferred from the knowledge of its PSD.

A. Power Spectral Density of the Aggregate Network Emission

The aggregate network emission at the probe receiver can be characterized by the complex baseband random process \( \mathbf{Y}(t) \), defined as

\[
\mathbf{Y}(t) = \sum_{i=1}^{\infty} \mathbf{Y}_i(t),
\]

where \( \mathbf{Y}_i(t) \) is the received process associated with each emitting node \( i \). The signal \( \mathbf{Y}_i(t) \) can in turn be expressed for all time \( t \) as

\[
\mathbf{Y}_i(t) = \frac{e^{\sigma G_i}}{R_i^e} \int h_i(t, \tau) \mathbf{X}_i(t - \tau) d\tau,
\]

where \( \mathbf{X}_i(t) \) is the complex baseband transmitted signal, and \( h_i(t, \tau) \) is time-varying complex baseband impulse response of the multipath channel associated with node \( i \). The system model described by (14) is depicted in Fig. 4. It corresponds to a generalization of the model introduced in Part I of this paper, where we considered a two-dimensional modulation and a flat Rayleigh fading channel. Since now we are interested in analyzing the spectral properties of \( \mathbf{Y}(t) \), we incorporate in the model a generic transmitted waveform \( \mathbf{X}_i(t) \), not necessarily associated with a two-dimensional modulation, as well as a generic multipath channel \( h_i(t, \tau) \), not necessarily associated with flat Rayleigh fading. Also, since in this section we are only interested in the aggregate emission of the network, we can ignore the existence of the probe link depicted in [8, Fig. 1]. In the remainder of this paper, we carry the analysis in complex baseband, although it can be trivially translated to passband frequencies.

In what follows, we consider that the transmitted signal \( \mathbf{X}_i(t) \) is a wide-sense stationary (WSS) process, such that its autocorrelation function has the form \( R_{\mathbf{X}_i}(t_1, t_2) \equiv \mathbb{E}\{\mathbf{X}_i^*(t_1)\mathbf{X}_i(t_2)\} = R_X(\Delta t) \), where \( \Delta t = t_2 - t_1 \). We define the PSD of the process \( \mathbf{X}_i(t) \) as \( \Phi_{\mathbf{X}_i}(f) = \mathcal{F}_{\Phi_{\mathbf{X}_i}} \{ R_X(\Delta t) \} \). Since different nodes operate independently, the processes \( \mathbf{X}_i(t) \) are also independent for different \( i \), but the underlying second-order statistics are the same (i.e., the autocorrelation function and the PSD of \( \mathbf{X}_i(t) \) do not depend on \( i \)). As we will show in the case study of Section IV-C, if \( \mathbf{X}_i(t) \) is a train of pulses with a uniformly distributed random delay (which models the asynchronism between emitting nodes), then it is a WSS process.

To model the multipath effect, we consider a wide-sense stationary uncorrelated scattering (WSSUS) channel [14]–[18], so that the autocorrelation function of \( h_i(t, \tau) \) can be expressed as

\[
R_{h_i}(t_1, t_2, \tau_1, \tau_2) \equiv \mathbb{E}\{h_i^*(t_1, \tau_1)h_i(t_2, \tau_2)\} = P_h(\Delta t, \tau_2)\delta(\tau_2 - \tau_1),
\]

for some function \( P_h(\Delta t, \tau) \). Such channel can be represented in the form of a densely-tapped delay line, as a continuum of uncorrelated, randomly-scintillating scatterers having WSS statistics. The functions \( h_i(t, \tau) \) are considered to be independent for different nodes \( i \), but the underlying second-order statistics are the same (i.e., the autocorrelation function of \( h_i(t, \tau) \) does not depend on \( i \)). WSSUS channels are an important class of practical channels which simultaneously exhibit wide-sense stationarity in the time variable \( t \) and uncorrelated scattering in the delay variable \( \tau \). They are the simplest non-degenerate channels which exhibit both time and frequency fading, and also serve as a good model for many radio channels.

We are now interested in determining the PSD of the aggregate RF emission \( \mathbf{Y}(t) \) of the network. The result is given in the following theorem.

**Theorem 4.1 (WSS and WSSUS Channels):** Let \( \mathbf{h}(t, \tau) \) denote the time-varying complex baseband impulse response of a multipath channel, whose autocorrelation function is given by \( R_h(t_1, t_2, \tau_1, \tau_2) \). Let \( \mathbf{u}(t) \) denote the complex baseband WSS process which is applied as input to the channel, and \( \mathbf{z}(t) \) denote the corresponding output process of the channel.

1) If the channel \( \mathbf{h}(t, \tau) \) is WSS, i.e., \( R_h(t_1, t_2, \tau_1, \tau_2) = R_h(\Delta t, \tau_2) \), then the output \( \mathbf{z}(t) \) is WSS and its PSD

\[
\Phi_{\mathbf{z}}(f) = \Phi_{\mathbf{u}}(f) \sum_{i=1}^{\infty} \frac{1}{R_i^e} \Phi_{\mathbf{X}_i}(f).
\]
B. Spectral Outage Probability

In the previous section, we derived the PSD of the aggregate network emission, \( S_Y(f, \mathcal{P}) \), and showed that it is a function of the random node positions and shadowing, \( \mathcal{P} \). Then, with some probability, \( \mathcal{P} \) is such that the spectrum of the aggregate emission is too high in some frequency band of interest, thus causing an outage in that frequency band. This leads to the concept of spectral outage probability (SOP), which we denote by \( P_{\text{out}}(f) \) and generally define as

\[
P_{\text{out}}^a(f) \triangleq \mathbb{P}_P\{S_Y(f, \mathcal{P}) > m(f)\},
\]

where \( S_Y(f, \mathcal{P}) \) is the random PSD of the aggregate network emission \( Y(t) \), and \( m(f) \) is some spectral mask determining the outage (or detection) threshold at the receiver. The SOP is a frequency-dependent quantity and, in the case of slow-varying positions \( \mathcal{P} \), is a more insightful metric than the PSD averaged over \( \mathcal{P} \).

Note that this definition is applicable in general to any emission model: the spectral outage probability \( P_{\text{out}}^a(f) \) represents the probability that the PSD of the aggregate network emission, measured at an arbitrary location in the plane and at a particular frequency \( f \), exceeds some predetermined mask \( m(f) \).

In commercial applications, the concept of SOP can provide a radically different way to establish spectral regulations. Current regulations and standards (e.g., FCC Part 15 or IEEE 802.11) impose a spectral mask on the PSD at the transmitter, and the type of mask often depends on the environment in which the devices are operated (e.g., indoor or outdoor). The purpose of this mask is to limit RF emissions generated by a terminal, and to protect other services that operate in dedicated bands (e.g., Global Positioning System, public safety, and cellular systems). However, the transmitted PSD is usually not representative of the aggregate PSD at the victim receiver, due to the random propagation effects (multipath fading and shadowing) and the random position of the emitting nodes. Thus, spectral regulations that are based only on the transmitted PSD do not necessarily protect a victim receiver against interference.

In the proposed framework, we follow a radically different approach, in the sense that the spectral mask is defined at the victim receiver, not at the transmitter. In effect, the mask \( m(f) \) introduced in (20) represents the outage threshold with respect to the accumulated PSD at the receiver, not the individual PSD at the transmitter (this follows from the fact that \( S_Y(f, \mathcal{P}) \) is measured at an arbitrary location in the plane, whereas a probe receiver could be located). Therefore, the received aggregate spectrum \( S_Y(f, \mathcal{P}) \) and the corresponding \( P_{\text{out}}^a(f) \) can be used to characterize and control network's RF emissions more effectively, since they not only consider the aggregate effect of all emitting nodes at an arbitrary receiver location, but also incorporate the random propagation effects and random node positions. Furthermore, the use of different masks for indoor or outdoor environments is no longer necessary, since the environment is already accounted for in our model by parameters such as the amplitude loss exponent \( b \), the spatial density \( \lambda \) of the emitting nodes, and the shadowing coefficient \( \sigma \).

In military applications, on the other hand, the goal is to ensure that the presence of the deployed network is not detected by the enemy. If, for example, a surveillance network is to be deployed in enemy territory, then the characterization of its aggregate emission is essential for the design of a covert network with low probability of detection. In such application, the function \( m(f) \) in (20) can be interpreted as the frequency-dependent mask which determines the detection threshold (not the outage threshold as before). In other words, if the aggregate spectral density \( S_Y(f, \mathcal{P}) \) measured at a given location exceeds the mask \( m(f) \), then the presence of the deployed network could be detected by the enemy.

For the signal model considered in this paper, \( P_{\text{out}}^a(f) \) can be derived by substituting (19) into the general definition of

\[\ldots\]
the outage probability $P$.

where $\mathbb{P}$ is the cumulative distribution function (c.d.f.) of $\nu$. Note that the process $X_i(t)$ in (22) is WSS, as required by Theorem 4.1.12

The PSD of $X_i(t)$ is then given by $[21]–[23]$.

To model the multipath effect, we consider for simplicity that $\mathbf{h}(t, \tau)$ is time-invariant such that it does not introduce any Doppler shifts, i.e., $D_\theta(\nu) = \delta(\nu)$. Substituting the expressions for $S_X(f)$ and $D_\theta(\nu)$ in (21), we obtain the SOP as

$$P_{\text{out}}^n(f) = 1 - F_A \left( \frac{m(f)}{P(G(f))^2} \right).$$

Figure 5 shows that for a fixed spectral mask $m(f)$, the SOP can be highly dependent on the pulse shape $g(t)$, such as square or root raised-cosine (RRC) pulse. In fact, $P_{\text{out}}^n(f)$ is a nonlinear function of $|G(f)|$, where the nonlinearity is determined in part by the c.d.f. $F_A(\cdot)$ of the stable r.v. $A$, as shown in (24). The SOP can be used as a criterion for designing the pulse shape: for example, we may wish to determine the baseband pulse $g(t)$ and transmitted power $P$ such that $\max_f P_{\text{out}}^n(f) \leq \rho^*$, where $\rho^*$ is some target outage probability which must be satisfied at all frequencies.

SOP in (20), leading to

$$P_{\text{out}}^n(f) = \mathbb{P} \left\{ A > \frac{m(f)}{D_h(f) * S_X(f)} \right\} = 1 - F_A \left( \frac{m(f)}{D_h(f) * S_X(f)} \right),$$

where $F_A(\cdot)$ is the cumulative distribution function (c.d.f.) of the stable r.v. $A$, whose distribution is given in (5).

C. Numerical Results

In this section, we quantify the spectral density and outage probability associated with a particular case study. We also illustrate their dependence on the various parameters involved, such as the transmitted pulse shape, spectral mask, transmitted power, and spatial density of the emitting nodes. For all numerical examples, we consider that the emitting nodes employ a two-dimensional modulation (e.g., $M$-PSK or $M$-QAM), such that transmitted signal $X_i(t)$ can be written for all $t$ as

$$X_i(t) = \sum_{n=0}^{+\infty} a_{i,n} g(t - nT - D_i),$$

where the sequence $\{a_{i,n}\}_{n=-\infty}^{+\infty}$ represents the stream of complex symbols transmitted by node $i$, assumed to be i.i.d. in $n$ and zero-mean, for simplicity; $g(t)$ is a real, baseband, unit-energy shaping pulse, defined for all values of $t$; $T$ is the symbol period; and $D_i \sim U(0, T)$ is a random delay representing the asynchronism between different emitting nodes.

The type of constellation employed by the emitting nodes is captured by the statistics of the symbols $\{a_{i,n}\}_n$. Note that the process $X_i(t)$ in (22) is WSS, as required by Theorem 4.1.12.

The PSD of $X_i(t)$ is then given by $[21]–[23]$.

$$S_X(f) = P(G(f))^2,$$

where $P = \mathbb{E}\{|a_{i,n}|^2\}/T$ is the power transmitted by each emitting node, and $G(f) = F_A(g(t))$.

To model the multipath effect, we consider for simplicity that $\mathbf{h}(t, \tau)$ is time-invariant such that it does not introduce any Doppler shifts, i.e., $D_\theta(\nu) = \delta(\nu)$. Substituting the expressions for $S_X(f)$ and $D_\theta(\nu)$ in (21), we obtain the SOP as

$$P_{\text{out}}^n(f) = 1 - F_A \left( \frac{m(f)}{P(G(f))^2} \right).$$

Figure 5 shows that for a fixed spectral mask $m(f)$, the SOP can be highly dependent on the pulse shape $g(t)$, such as square or root raised-cosine (RRC) pulse. In fact, $P_{\text{out}}^n(f)$ is a nonlinear function of $|G(f)|$, where the nonlinearity is determined in part by the c.d.f. $F_A(\cdot)$ of the stable r.v. $A$, as shown in (24). The SOP can be used as a criterion for designing the pulse shape: for example, we may wish to determine the baseband pulse $g(t)$ and transmitted power $P$ such that $\max_f P_{\text{out}}^n(f) \leq \rho^*$, where $\rho^*$ is some target outage probability which must be satisfied at all frequencies.

Figure 6 shows that for a fixed pulse shape $g(t)$, $P_{\text{out}}^n(f)$ can significantly depend on the spectral mask $m(f)$ (e.g., piecewise-linear, Gaussian, or constant mask). Since $P_{\text{out}}^n(f)$ accounts for both $G(f)$ and $m(f)$, it quantifies the compatibility of the transmitted pulse shape with the spectral restrictions imposed through $m(f)$.

Figures 7 and 8 illustrate, respectively, the dependence of the outage probability $P_{\text{out}}^n(f)$ on the transmitted power $P$ and spatial density $\lambda$ of the emitting nodes. Specifically, as $P$ or $\lambda$ increase, the aggregate network emission becomes stronger, and thus $P_{\text{out}}^n(f)$ deteriorates at all frequencies, approaching the maximum value of 1.

11Note that each complex symbol $a_{i,n} = a_{i,n} e^{j \theta_{i,n}}$ can be represented in the IQ plane by a constellation point with amplitude $a_{i,n}$ and phase $\theta_{i,n}$.

12This can be shown in the following way: first, if we deterministically set $D_i$ to zero in (22), the resulting process $X_i(t)$ is wide-sense cyclosta-
tionary (WSSC) with period $T$ [20]; then, since $X_i(t) = X_i(t - D_i)$, with $D_i \sim U(0, T)$ and independent of everything else, it follows that $X_i(t)$ is WSS.

13For typical node speeds or channel fluctuations, the frequencies of the Doppler shifts are on the order of few kHz. As a consequence, when the con-
sidered $X_i(t)$ is an ultrawideband signal, $D_\theta(\nu)$ can be well approximated by a Dirac-delta function.
D. Generalizations

We now extend the results to an heterogeneous scenario with $K$ different networks, where a given emitting node belongs to the network $k \in \{1 \ldots K\}$ with probability $p_k$, independently of everything else. Using the splitting property of Poisson processes [24], we know the emitting nodes from each network $k$ form a spatial Poisson process, which is independent of the processes of other networks and has spatial density $\lambda_k = \lambda p_k$. Therefore, we can write the aggregate emission from all nodes in all networks as

$$Y(t) = \sum_{k=1}^{K} Y^{(k)}(t),$$

where $Y^{(k)}(t) = \sum_{i=1}^{\infty} Y_{k,i}(t)$ is the aggregate emission from the individual network $k$, and

$$Y_{k,i}(t) = \frac{e^{\sigma G_{k,i}}}{R_{k,i}^b} \int h_{k,i}(t,\tau) X_{k,i}(t-\tau) d\tau, \quad k = 1 \ldots K,$$

where $X_{k,i}(t)$ and $h_{k,i}(t,\tau)$ are, respectively, the transmitted signal and the impulse response of the multipath channel associated with node $i$ from network $k$. We consider that $X_{k,i}(t)$ and $h_{k,i}(t,\tau)$ are independent in both $k$ and $i$. Then, the aggregate emission $Y^{(k)}(t)$ is also independent for different networks $k$ when conditioned on the positions $\mathcal{P}$, and thus $S_Y(f) = \sum_{k=1}^{K} S_{Y^{(k)}}(f)$. We can generalize (19) and write the conditional PSD of the aggregate emission $Y(t)$ in this heterogeneous scenario as

$$S_Y(f,\mathcal{P}) = \sum_{k=1}^{K} A_k \left[D_{h_k}(f) \ast S_{X_k}(f)\right],$$

where $D_{h_k}(f)$ and $S_{X_k}(f)$ are, respectively, the Doppler power spectrum and the PSD of the transmitted signal associated with network $k$; and the r.v.’s $\{A_k\}$ are i.i.d. in $k$ and given by

$$A_k = \sum_{i=1}^{\infty} e^{2\pi G_{k,i}} R_{k,i}^{-b},$$
with distribution
\[ A_k \sim S\left( \alpha_A = \frac{1}{b}, \beta_A = 1, \gamma_A = \pi \lambda_b c_1^{-1} b^{2\sigma^2/b^2} \right). \]

V. CONCLUSIONS

This two-part paper investigates a mathematical model for communication subject to both network interference and AWGN, where the spatial distribution of the nodes is captured by a Poisson field in the two-dimensional plane. We specifically address the cases of slow and fast-varying node positions, as well as homogeneous and heterogeneous networks, in a realistic wireless environment subject to path loss, multipath fading and shadowing. In Part I, we determined the statistical distribution of the aggregate interference at the output of a conventional linear receiver, which leads directly to the characterization of the error performance (in terms of outage and average probabilities).

In this second part, we characterized the capacity of the link when subject to both network interference and noise, and derived the PSD of the aggregate RF emission of the network. Then, we put forth the concept of spectral outage probability, and described some possible applications, namely the establishment of spectral regulations and the design of covert military networks. In particular, the SOP can be used as a criterion for designing pulse shapes or controlling interference in wireless networks, and as a measure of the network’s covertness. Our framework clearly shows how the aggregate network emission can be characterized in terms of important network parameters, thereby providing insights that may be of value to the network designer.

APPENDIX A

DERIVATION OF THEOREM 4.1

The derivation of Theorem 4.1 relies on the general theory of linear time-varying systems and Bello system functions [14]–[17]. Let \( h(t, \tau) \) denote a time-varying complex baseband impulse response of a multipath channel. When the complex baseband process \( u(t) \) is applied as input to the channel, the output process \( z(t) \) is given by the integral
\[ z(t) = \int h(t, \tau) u(t - \tau) d\tau. \]

We define the autocorrelation function of the input \( u(t) \) as \( R_u(t_1, t_2) \triangleq \mathbb{E}\{u^*(t_1) u(t_2)\} \), and the autocorrelation function of the channel \( h(t, \tau) \) as \( R_h(t_1, t_2, \tau_1, \tau_2) \triangleq \mathbb{E}\{h^*(t_1, \tau_1) h(t_2, \tau_2)\} \). The autocorrelation of the output \( z(t) \) is generally given by
\[ R_z(t_1, t_2) = \int \int R_h(t_1, t_2, \tau_1, \tau_2) R_u(t_1 - \tau_1, t_2 - \tau_2) d\tau_1 d\tau_2. \] (25)

Since the input process \( u(t) \) is WSS, \( R_u(t_1, t_2) = R_u(\Delta t) \), where \( \Delta t = t_2 - t_1 \).

We first consider a WSS channel \( h(t, \tau) \) such that \( R_h(t_1, t_2, \tau_1, \tau_2) = R_h(\Delta t, \tau_1, \tau_2) \). Then, we can rewrite \( R_z(t_1, t_2) \) in (25) as
\[ R_z(t_1, t_2) = \int \int R_h(\Delta t, \tau_1, \tau_2) R_u(\Delta t + \tau_1 - \tau_2) d\tau_1 d\tau_2 \triangleq R_u(\Delta t). \] (26)

Since \( R_u(t_1, t_2) \) is a function only of \( \Delta t \), the output \( z(t) \) is also WSS. The PSD of \( z(t) \) can be written as
\[ S_z(f) = F_{\Delta t \rightarrow f}\{R_u(\Delta t)\} \]
\[ = \int \int R_h(\Delta t, \tau_1, \tau_2) R_u(\Delta t + \tau_1 - \tau_2) \times e^{-j2\pi f \Delta t} d\tau_1 d\tau_2 \]
\[ = \int P_s(\nu, \tau_1, \tau_2) \mu = f \frac{1}{2} [S_u(f)] e^{j2\pi f (\tau_1 - \tau_2)} d\tau_1 d\tau_2, \] (27)

where \( P_s(\nu, \tau_1, \tau_2) \) is the Doppler power spectrum of the channel \( h(t, \tau) \), and \( S_u(f) \) is the PSD of \( u(t) \). This is the result in Theorem 4.1, eq. (15).

We now further constrain the channel \( h(t, \tau) \) to be WSSUS such that \( R_h(t_1, t_2, \tau_1, \tau_2) = P_h(\Delta t, \tau_2) \delta(\tau_2 - \tau_1), \) for some function \( P_h(\Delta t, \tau) \). Then, \( R_u(t_1, t_2) \) in (26) can be further simplified as follows:
\[ R_z(t_1, t_2) = \int P_h(\Delta t, \tau_2) \delta(\tau_2 - \tau_1) R_u(\Delta t + \tau_1 - \tau_2) d\tau_1 d\tau_2 \]
\[ = \int P_h(\Delta t, \tau) R_u(\Delta t) d\tau \]
\[ = R_u(\Delta t) \int P_h(\Delta t, \tau) d\tau \triangleq R_u(\Delta t). \] (28)

The output \( z(t) \) is therefore WSS, and its PSD can be written as
\[ S_z(f) = F_{\Delta t \rightarrow f}\{R_u(\Delta t)\} \]
\[ = F_{\Delta t \rightarrow f}\{R_u(\Delta t)\} \ast F_{\Delta t \rightarrow f}\left\{ \int P_h(\Delta t, \tau) d\tau \right\} \]
\[ = S_u(f) \int P_s(\nu, \tau) d\tau \triangleq S_u(f) \ast D_h(\nu), \] (29)

where \( P_s(\nu, \tau) \) is the Doppler power spectrum of the channel as \( D_h(\nu) \triangleq \int P_s(\nu, \tau) d\tau \), then (29) can be succinctly written as
\[ S_z(f) = S_u(f) \ast D_h(\nu), \] (30)

which is the result in Theorem 4.1, eq. (16).

From (30), we conclude that \( S_z(f) \) depends on the Doppler power spectrum of the channel, \( \int P_s(\nu, \tau) d\tau \), but not on its power delay profile \( \int P_s(\nu, \tau) d\nu \). This is intuitively satisfying since all delayed replicas of the WSS process \( u(t) \) have the same PSD. Furthermore, if the channel \( h(t, \tau) \) is time-invariant, then \( D_h(\nu) = \delta(\nu) \) and thus \( S_z(f) = S_u(f) \), i.e., the channel does not affect the PSD of the input. On the other hand, if the channel is time-varying in such a way that it introduces a Doppler shift of \( f_0 \) Hz, then \( D_h(\nu) = \delta(\nu - f_0) \) and thus \( S_z(f) = S_u(f - f_0) \), i.e., the output PSD is simply the input PSD shifted by \( f_0 \) Hz, as expected.

Pedro C. Pinto (S’04) received the Licenciatura degree with highest honors in Electrical and Computer Engineering from the University of Porto, Portugal, in 2003. He received the M.S. degree in Electrical Engineering and Computer Science from the Massachusetts Institute of Technology (MIT) in 2006. Since 2004, he has been with the MIT Laboratory for Information and Decision Systems (LIDS), where he is now a Ph.D. candidate. His main research interests are in wireless communications and signal processing. He was the recipient of the MIT Claude E. Shannon Fellowship in 2007, the Best Student Paper Award at the IEEE International Conference on Ultra-Wideband in 2006, and the Infinon Technologies Award in 2003.

Moe Z. Win (S’85-M’87-SM’97-F’04) received both the Ph.D. in Electrical Engineering and M.S. in Applied Mathematics as a Presidential Fellow at the University of Southern California (USC) in 1998. He received an M.S. in Electrical Engineering from USC in 1989, and a B.S. (magna cum laude) in Electrical Engineering from Texas A&M University in 1987.

Dr. Win is an Associate Professor at the Massachusetts Institute of Technology (MIT). Prior to joining MIT, he was at AT&T Research Laboratories for five years and at the Jet Propulsion Laboratory for seven years. His research encompasses developing fundamental theory, designing algorithms, and conducting experimentation for a broad range of real-world problems. His current research topics include location-aware networks, time-varying channels, multiple antenna systems, ultra-wide bandwidth systems, optical transmission systems, and space communications systems.

Professor Win is an IEEE Distinguished Lecturer and elected Fellow of the IEEE, cited for “contributions to wideband wireless transmission.” He was honored with the IEEE Eric E. Sumner Award (2006), an IEEE Technical Field Award for “pioneering contributions to ultra-wide band communications science and technology.” Together with students and colleagues, his papers have received several awards including the IEEE Communications Society’s Guglielmo Marconi Best Paper Award (2008) and the IEEE Antennas and Propagation Society’s S. A. Schelkunoff Transactions Prize Paper Award (2003). His other recognitions include the Laurea Honoris Causa from the University of Ferrara, Italy (2008), the Technical Recognition Award of the IEEE Comsoc Radio Communications Committee (2008), Wireless Educator of the Year Award (2007), the Fulbright Foundation Senior Scholar Lecturing and Research Fellowship (2004), the U.S. Presidential Early Career Award for Scientists and Engineers (2004), the AIAA Young Aerospace Engineer of the Year (2004), and the Office of Naval Research Young Investigator Award (2003).

Professor Win has been actively involved in organizing and chairing a number of international conferences. He served as the Technical Program Chair for the IEEE Wireless Communications and Networking Conference in 2009, the IEEE Conference on Ultra Wideband in 2006, the IEEE Communication Theory Symposium of ICC-2004 and Globecom-2000, and the IEEE Conference on Ultra Wideband Systems and Technologies in 2002; Technical Program Vice-Chair for the IEEE International Conference on Communications in 2002; and the Tutorial Chair for ICC-2009 and the IEEE Semiannual International Vehicular Technology Conference in Fall 2001. He was the chair (2004-2006) and secretary (2002-2004) for the IEEE Communications Society, Radio Communications Committee. Dr. Win is currently an Editor for IEEE TRANSACTIONS ON WIRELESS COMMUNICATIONS. He served as Area Editor for Modulation and Signal Design (2003-2006), Editor for Wideband Wireless and Diversity (2003-2006), and Editor for Equalization and Diversity (1998-2003), all for the IEEE TRANSACTIONS ON COMMUNICATIONS. He was Guest-Editor for the PROCEEDINGS OF THE IEEE (Special Issue on UWB Technology & Emerging Applications) in 2009 and IEEE JOURNAL ON SELECTED AREAS IN COMMUNICATIONS (Special Issue on Ultra-Wideband Radio in Multiaccess Wireless Communications) in 2002.
