(Received 6 November 2010; published 8 March 2011)

Weinberg’s seminal prediction of the cosmological constant relied on a provisional method for regulating eternal inflation which has since been put aside. We show that a modern regulator, the causal patch, improves agreement with observation, removes many limiting assumptions, and yields additional powerful results. Without assuming necessary conditions for observers such as galaxies or entropy production, the causal patch measure predicts the coincidence of vacuum energy and present matter density. Their common scale, and thus the enormous size of the visible Universe, originates in the number of metastable vacua in the landscape.

Introduction.—The smallness of the cosmological constant, $\Lambda$, has long posed a hierarchy problem: why is the energy of the vacuum at least 60 orders of magnitude smaller than the natural value expected from the standard model [1–3]? The actual magnitude of the cosmological constant was measured more recently [4–6]; it poses, in addition, a coincidence problem. The vacuum energy, $\rho_{\Lambda} = \frac{\Lambda}{8\pi} = 1.4 \times 10^{-123}$, is comparable in magnitude to the present matter density. (We use Planck units, with $c = \hbar = G = 1$.) This constitutes a coincidence of two a priori unrelated time scales, $t_\Lambda \sim \rho_{\Lambda}^{-1/2}$, the time at which vacuum energy begins to dominate, and $t_{\text{obs}}$, the time at which observers exist.

In a theory that contains a sufficiently dense discretuum of values of $\Lambda$, anthropic selection can explain the smallness of $\Lambda$. Weinberg [7] argued that observers require galaxies, which form only if $t_\Lambda \approx t_{\text{gal}}$, where $t_{\text{gal}}$ is the time at which density perturbations grow nonlinear. This approach successfully predicted a nonvanishing cosmological constant, and it explains the coincidence that $t_\Lambda \sim t_{\text{gal}}$. It has the following limitations. (i) It does not explain the coincidence $t_{\text{obs}} \sim t_\Lambda$. There is no reason a priori why $t_{\text{obs}}$ should not vastly exceed $t_{\text{gal}}$. (ii) It applies only to observers whose existence depends on the formation of galaxies. (iii) It actually favors values of $\Lambda$ a few orders of magnitude larger than the observed value. (iv) It explains one unnaturally large time scale, $t_\Lambda$, in terms of another, $t_{\text{gal}}$. The fundamental origin of either scale remains unclear. (v) The prediction was based on a cosmological measure, observers per baryon, that has been ruled out phenomenologically [8].

The causal patch measure transcends these limitations. It explains the coincidence $t_\Lambda \sim t_{\text{obs}}$ from geometric properties, assuming only that observers are made of matter or radiation, and it relates the absolute scale, $10^{-123}$, to the size of the landscape.

Results.—Our first result, $t_\Lambda \sim t_{\text{obs}}$, solves the coincidence problem and predicts that observers are most likely to find themselves at the onset of vacuum domination. Our second result, $t_\text{c} \sim t_{\text{obs}}$, predicts another coincidence: that the time scale associated with spatial curvature is comparable to $t_{\text{obs}}$. Our third result, $t_{\text{obs}} \sim N^{1/2}$, explains the origin of the enormous phenomenological scales governing the visible Universe, such as its size and age, in terms of the number of landscape vacua that can be cosmologically produced and which contain observers, $\mathcal{N}$. It can be regarded as a prediction for $\mathcal{N}$.

These results hold true under a simple qualitative assumption about the landscape distribution of the time scale of observers. No specific anthropic conditions are assumed to be necessary for observers. We stress that $N$ will be smaller than $\mathcal{N}$, the total number of vacua, due to anthropic and cosmological selection effects, neither of which we will consider in this Letter. Intriguingly, preliminary analyses [9,10] suggest $\log(\mathcal{N}^{1/2}) \sim O(100)$ for a class of vacua [11]. If this class dominates the landscape, then our prediction implies that $\log\mathcal{N}$ is not very much smaller than $\log\mathcal{N}$, and that the fundamental origin of hierarchy lies in the number of topological cycles of complex three-manifolds.

Relation to other work.—Polchinski [2] first articulated the question of the ultimate origin of the scale of the cosmological constant in the context of the landscape. Refs. [3,12] anticipated the answer reached in the present Letter but not its derivation. Less general derivations have been proposed for special classes of vacua [13,14], or under the assumption that observers arise in proportion to the entropy produced [15,16].
arguments employed the causal diamond, a measure that is somewhat less well-defined than the causal patch.

No specific anthropic assumptions are made, and our results apply to arbitrary observers in arbitrary vacua. Parameters like the masses of leptons [17], or the time scales of structure formation [13], may be correlated with $t_{\text{obs}}$, but they are defined only in small portions of the landscape and will not be considered here. Here, we restrict to vacua with $\Lambda > 0$. In a separate publication, we will consider other measures and vacua with negative cosmological constant.

Derivation.—The relative probability for two outcomes of a cosmological measurement is given by $p_1/p_2 = N_1/N_2$, where $N_I$ is the expected number of times each outcome occurs in the Universe. Thus, the $N_I$ play the role of an unnormalized probability distribution. A distribution $dp/dx$ over a continuous parameter $x$ can be computed as the number $dN$ of outcomes occurring in the range $(x, x + dx)$.

The landscape of string theory contains long-lived de Sitter vacua which give rise to eternal inflation [9]. Globally, every experiment and every possible outcome occurs infinitely many times: $N_I = \infty$. To obtain well-defined relative probabilities, we use the causal patch measure [12,18], which computes $N_I$ in the causal past of a point on the future boundary of spacetime (Fig. 1).

Consider an arbitrary observer who lives in an FRW (homogeneous and isotropic) universe at FRW time of order $t_{\text{obs}}$. What order of magnitude for $t_\Lambda$ and $t_c$ is he likely to observe? This is described by the probability distribution over $\log t_\Lambda$ and $\log t_c$ at fixed $\log t_{\text{obs}}$, which can be written as

$$\frac{dp}{d\log t_\Lambda d\log t_c} = \frac{d\tilde{p}}{d\log t_\Lambda d\log t_c} n_{\text{obs}}.$$  \hspace{1cm} (1)

We will begin by computing this distribution; later we will allow $t_{\text{obs}}$ to vary as well.

The first factor in Eq. (1) is the “prior probability”; it corresponds to the expected number of times a vacuum with specified values of $\log t_\Lambda$ and $\log t_c$ is nucleated in the causal patch [19]. This is proportional to the number of such vacua in the landscape multiplied by the rate at which they are produced cosmologically from specified initial conditions. But this rate will be independent of $t_\Lambda$ and $t_c$ in the regime of interest ($t_\Lambda \gg 1$). In the string landscape, a decay changes $\Lambda$ enormously compared to the energy scales associated with $t_\Lambda$ and $t_c$ in the daughter vacuum. Thus, the decay chains leading to the vacua of interest have no information about the eventual values of $t_\Lambda$ and $t_c$.

Vacua with $\Lambda \sim 1$ contain only a few bits of causally connected information [20], and hence no complex systems of any kind. Thus, we may restrict attention to vacua with $\Lambda \ll 1$ and keep only the leading order in a Taylor expansion of the density of vacua near $\Lambda = 0$, $dN/d\Lambda = \text{const}$ [7]. With $t_\Lambda \sim \Lambda^{-1/2}$, this implies

$$\frac{d\tilde{p}}{d\log t_\Lambda d\log t_c} = t_\Lambda^2 g(\log t_c).$$  \hspace{1cm} (2)

Here $g$ encodes the prior probability distribution over the time of curvature domination.

The second factor in Eq. (1) is the number of observers present within the causal patch at the time $t_{\text{obs}}$, averaged over all vacua with the given values of $(\log t_\Lambda, \log t_c, \log t_{\text{obs}})$ using the prior distribution. It can be written as

$$n_{\text{obs}}(\log t_\Lambda, \log t_c, \log t_{\text{obs}}) = M_{\text{CP}} h,$$  \hspace{1cm} (3)

where $M_{\text{CP}}(\log t_\Lambda, \log t_c, \log t_{\text{obs}})$ is the total matter mass present within the causal patch at the time $t_{\text{obs}}$, and $h(\log t_\Lambda, \log t_c, \log t_{\text{obs}})$ is the number of observers per unit matter mass, again averaged over vacua with the given values of the parameters using the prior distribution. We will argue below that $h$ is trivial in the only regime where it could possibly affect our result.

We now turn to the computation of $M_{\text{CP}}$. Vacua are cosmologically produced as open FRW universes [21] with metric $ds^2 = -dt^2 + a(t)^2(dx^2 + \sinh^2 \chi d\Omega_5^2)$, embedded in an eternally inflating parent vacuum. The boundary of the causal patch coincides with the event horizon for long-lived metastable de Sitter vacua: $\chi_{\text{CP}}(t) = \int_0^t dt'/a(t')$.

If $t_\Lambda \approx t_c$, the Universe contains a curvature dominated era. The evolution of the scale factor is governed by the Friedmann equation, $\dot{a}^2/a^2 = t_c/a^3 + a^{-2} + \Lambda a^2$, where $t_c/a^3 \sim \rho_m$ is the energy density of pressureless matter. The remaining terms encode the curvature and the cosmological constant. (The inclusion of a radiation term, or the assumption that observers are made from radiation rather than matter, would not affect our results qualitatively.) A piecewise approximate solution is

$$a(t) \sim \begin{cases} \frac{1}{2} t^{2/3}, & t < t_c \\ t_c, & t_c < t < t_\Lambda \\ t_\Lambda e^{(t-t_\Lambda)/t_c}, & t_\Lambda < t. \end{cases}$$  \hspace{1cm} (4)
Integration yields the comoving radius of the causal patch:

$$\chi_{\text{CP}}(t) \sim \begin{cases} 
1 + \log(t_\Lambda/t_c) + 3 \left[ 1 - \left( \frac{t}{t_c} \right)^{1/3} \right], & t < t_c \\
1 + \log(t_\Lambda/t), & t_c < t < t_\Lambda \\
e^{-t/t_c}, & t_\Lambda < t.
\end{cases}$$

(5)

In the regime where curvature never dominates, \( \chi_{\text{CP}} \) can be obtained by setting \( t_c \rightarrow t_\Lambda \) in Eq. (5).

The mass inside the causal patch at the time \( t_{\text{obs}} \) is \( M_{\text{CP}} = p_m a^3 V_{\text{com}} = t_c V_{\text{com}}(\chi_{\text{CP}}(t_{\text{obs}})) \). The comoving volume inside a sphere in hyperbolic space, \( V_{\text{com}} \), can be approximated by \( \chi^3 \) for \( \chi \lesssim 1 \) (in the regime \( t_\Lambda < t_{\text{obs}} \)), and by \( e^{2t} \) for \( \chi \gtrsim 1 \) (i.e., for \( t_\Lambda > t_{\text{obs}} \)). Substituting into Eqs. (1)–(3), we find the probability distribution \( d\rho/d\log t_c d\log t_\Lambda \) is

$$gh \times \begin{cases} 
1/t_c, & t_\text{obs} < t_c < t_\Lambda \quad \text{I} \\
t_c/t_{\text{obs}}, & t_\text{obs} < t_c < t_\Lambda \quad \text{II} \\
(t_c/t_\Lambda)^{3/2} e^{-3t_{\text{obs}}/t_c}, & t_c < t_\Lambda < t_{\text{obs}} \quad \text{III} \\
1/t_\Lambda, & t_\text{obs} < t_\Lambda < t_c \quad \text{IV} \\
n^{-1} e^{-3t_{\text{obs}}/t_\Lambda}, & t_\Lambda < t_\text{obs}, t_\Lambda < t_c \quad \text{V}
\end{cases}$$

(6)

For the moment, let us ignore the unknown functions \( g \) and \( h \); i.e., set \( gh \) constant. Then the probability distribution is a function of powers and exponentials of \( t_c \) and \( t_\Lambda \). Hence, it depends at least exponentially on the variables \( \log t_c \) and \( \log t_\Lambda \), so it will be dominated by its maximum. In Fig. 2, arrows indicate whether \( \log t_c \) and \( \log t_\Lambda \) prefer to increase or decrease (or neither). The arrows do not reflect the precise direction and strength of the gradient. For example, in region III, the probability grows with \( t_c \), and since the exponential dominates, it also grows with \( t_\Lambda \); this is indicated by a diagonal arrow pointing towards larger \( \log t_c \) and \( \log t_\Lambda \). (Recall that we are holding \( t_{\text{obs}} \) fixed for now.) By following the arrows, we recognize that the probability density is maximal not at a point, but along two degenerate half-lines of stability: \( \log t_\Lambda = \log t_{\text{obs}} \), \( \log t_c = \log t_{\text{obs}} \), and \( \log t_c = \log t_{\text{obs}} \), \( \log t_\Lambda = \log t_{\text{obs}} \).

Let us now include the effects of the two prefactors we have so far neglected, beginning with \( h \), the number of observers per unit mass. Crucially, \( h \) cannot depend on \( t_\Lambda \) for \( t_\Lambda \gg t_{\text{obs}} \), and it cannot depend on \( t_c \) for \( t_c \gg t_{\text{obs}} \). This is because in these regimes, curvature or vacuum energy have no dynamical effect prior to the time \( t_{\text{obs}} \), so they cannot be measured by anything, including \( h \). (One might imagine that \( h \) is correlated with \( t_c \), due to the prior distribution; here we assume this is not the case.) For \( t_c \ll t_{\text{obs}} \), we will assume that \( h \) is an increasing function of \( t_c \); similarly, for \( t_\Lambda \ll t_{\text{obs}} \), we will assume that \( h \) is an increasing function of \( t_\Lambda \). This assumption is weak; it states that the disruption of structure formation by curvature or vacuum energy, on average over many vacua, does not increase the number observers per unit mass.

We thus arrive at a key intermediate result of this Letter: the “anthropic factor” \( h \) is irrelevant. Its only possible effect is to further suppress the probability distribution in a regime whose integrated probability is already negligible, namely, for \( t_c \ll t_{\text{obs}} \) or \( t_\Lambda \ll t_{\text{obs}} \). Near the half-lines of maximal probability, which dominate the distribution, \( h \) will at most contribute factors of order unity, which we neglect here in any case, and which will not lift the degeneracy along the two half-lines, because they can only depend on the variable orthogonal to each line.

The other prefactor, \( g(\log t_c) \), encodes the prior probability distribution over the time of curvature domination. We will assume that \( g \) decreases mildly, like an inverse power of \( \log t_c \). (If slow-roll inflation is responsible for flatness, then \( \log t_c \) corresponds to the number of \( e \) foldings. If \( g \) decreased more strongly, like an inverse power of \( t_c \), then inflationary models would be too rare in the landscape to explain the observed flatness.) This will tilt the arrows slightly left in regions IV and V, lifting the degeneracy along the horizontal half-line. Because of the logarithmic dependence, the peak at \( t_c \sim t_{\text{obs}} \) is very wide, so \( t_c \) could be large enough for curvature to be unobservable in vacua with \( t_\Lambda \sim t_{\text{obs}} \) [22].

The degeneracy along the vertical half-line \( t_c \sim t_{\text{obs}} \) would render the probability distribution unintegrable, unless the effective number of vacua in the landscape, \( \tilde{N} \), is finite. By “effective,” we mean that vacua without observers, and vacua that are very suppressed cosmologically, are not included in \( \tilde{N} \). The effective spectrum of \( \Lambda \) is discrete with spacing of order \( \tilde{N}^{-1} \). The smallest positive value of \( \Lambda \) will be of this order, so \( t_\Lambda r^{\text{max}}_\Lambda \sim \tilde{N}^{-1/2} \). This “discretuum cutoff” reduces the half-line of maximal probability to the interval

![FIG. 2. The probability distribution over the time scales of curvature and vacuum domination at fixed observer time scale \( t_{\text{obs}} \), before the prior distribution over \( \log t_c \) and the finiteness of the landscape are taken into account. Arrows indicate directions of increasing probability. The distribution is peaked along two degenerate half-lines (thick).](image-url)
\[ \log t_c = \log t_{\text{obs}}, \quad \log t_{\text{obs}} \leq \log t_A \leq \log t_{\text{max}}. \quad (7) \]

So far, we have treated the time scale of observers, \( t_{\text{obs}} \), as a fixed input parameter. We will now extend our analysis to determine the probability distribution over all three parameters, including \( \log t_{\text{obs}} \). Part of this work has already been done, since our calculation of the mass \( M_{\text{CP}} \) within the causal patch took into account the dependence on \( t_{\text{obs}} \) as well as on \( t_A \) and \( t_c \). The number of observers per unit mass, \( h \), also includes a \( t_{\text{obs}} \) dependence, though we have yet to make any assumptions about it. For the joint prior probability, we can write

\[ \frac{d^3 \hat{p}}{d \log t_A d \log t_c d \log t_{\text{obs}}} = f \frac{d \hat{p}}{d \log t_c d \log t_{\text{obs}}}, \quad (8) \]

where the last factor is given by Eq. (2), and \( f \equiv p(t_{\text{obs}} | t_A, t_c) \) is the conditional probability that observers exist at the time \( t_{\text{obs}} \) in a vacuum with parameters \( (t_A, t_c) \). We thus find a trivariate probability distribution simply by multiplying Eq. (6) by the function \( f \).

To analyze this distribution, we will first marginalize over \( t_A \) and \( t_c \) to determine the most probable value of \( \log t_{\text{obs}} \). Evaluating Eq. (6) at this value then predicts \( \log t_A \) and \( \log t_c \). We may restrict the integral over \( t_c \) and \( t_A \) to the neighborhood of the line interval (7), which contains nearly all of the probability at any fixed \( t_{\text{obs}} \), and in which we argued that neither \( f \) nor \( h \) can depend significantly on \( \log t_c \) or \( \log t_A \). With \( g \sim (\log t_c)^{-k}, \ k > 1 \), we find from Eq. (6) that the marginal probability distribution over \( \log t_{\text{obs}} \) is \( f h t_{\text{obs}}^k \), where \( k \) is a rational function of \( \log t_{\text{obs}} \). Let us assume that the product \( f h \) grows more strongly than linearly with \( t_{\text{obs}} \), i.e., that \( f h \sim t_{\text{obs}}^{\epsilon} \), with \( \epsilon > 0 \) [23]. With this assumption, the marginal distribution becomes \( t_{\text{obs}}^k f (\log t_{\text{obs}}) \). This favors large values for \( t_{\text{obs}}: \log t_{\text{obs}} \sim \log t_{\text{max}} \). At this value of \( t_{\text{obs}} \), the interval of maximum probability (7) for \( (\log t_A, \log t_c) \) shrinks to a single point, and we predict

\[ \log t_A = \log t_c = \log t_{\text{obs}} = \log (\tilde{N}^{1/2}). \quad (9) \]

We thus predict that the number of vacua that contain observers and can be cosmologically produced is \( \tilde{N} \sim 10^{125} \). The relation between \( \tilde{N} \) and the total number of vacua in the landscape is not trivial. String theory contains infinitely many stable supersymmetric vacua, for example, vacua of the form \( \text{AdS}_p \times S^l \), with arbitrary integer flux. Since we do not live in such a vacuum, it must be the case that they either cannot contain any observers, or that their integrated cosmological production rate is finite, for example, because the production of very large flux values is highly suppressed. If the speculation that ten-to-the-millions of vacua arise from \( F \)-theory constructions [24] holds up, then similar considerations would have to apply to explain why \( \log \tilde{N} \) is so much smaller.

\[ \begin{align*}
[23] & We will not consider specific anthropic models or otherwise attempt to support this assumption further; it can be regarded as a prediction of our approach. However, we note that general considerations, due to Roni Harnik, support the weaker statement that both \( h \) and \( f \) should increase with \( t_{\text{obs}} \) when averaged over many vacua with \( t_{\text{obs}} \sim t_c \). The density of matter at the time \( t_{\text{obs}} \) is of order \( t_{\text{obs}}^4 \), which implies that the maximum number of nonoverlapping quanta per unit mass grows as \( t_{\text{obs}}^{3/2} \) [16]. Supposing that a system of sufficient complexity to function as an observer requires a fixed minimum amount of quanta, this implies that more observers can be produced per unit mass, on average. Similarly, the fraction of vacua containing observers should increase with \( t_{\text{obs}} \), since the number of elementary interactions that can take place in the Universe, and hence, the probability for successful evolution of observers, increases with time. \\
\end{align*} \]
