Abstract
Prions are self-perpetuating aggregated proteins that are not limited to mammalian systems but also exist in lower eukaryotes including yeast. While much work has focused around chaperones involved in prion maintenance, including Hsp104, little is known about factors involved in the appearance of prions. De novo appearance of the [PSI+] prion, which is the aggregated form of the Sup35 protein, is dramatically enhanced by transient overexpression of SUP35 in the presence of the prion form of the Rnq1 protein, [PIN+]. When fused to GFP and overexpressed in [ps+] [PIN+] cells, Sup35 forms fluorescent rings, and cells with these rings bud off [PSI+] daughters. We investigated the effects of over 400 gene deletions on this de novo induction of [PSI+]. Two classes of gene deletions were identified. Class I deletions (bug1Δ, bem1Δ, art1Δ, and hog1Δ) reduced the efficiency of [PSI+] induction, but formed rings normally. Class II deletions (las17Δ, vps5Δ, and sac6Δ) inhibited both [PSI+] induction and ring formation. Furthermore, class II deletions reduced, while class I deletions enhanced, toxicity associated with the expanded glutamine repeats of the huntingtin protein exon 1 that causes Huntington’s disease. This suggests that prion formation and polyglutamine aggregation involve a multi-phase process that can be inhibited at different steps.

Introduction
Prions are associated with transmissible spongiform encephalopathies, a family of neurological diseases that include Creutzfeldt-Jakob disease in humans, Scrapie in sheep, and the well-publicized “Mad Cow” disease. Transmission of prions occurs when a normally folded protein is converted to an alternate conformation that has the ability to further convert additional molecules of the normal protein into the misfolded infectious form. Prions also exist in Saccharomyces cerevisiae. The well characterized cytoplasmically transferred elements [URE3], [PSI+], and [PIN+] (see reviews [1–4]), as well as several other recently characterized elements [5–9], have been identified as yeast prions. Prions occur spontaneously in laboratory strains, although at very low frequency [10–12]. De novo appearance of prions can be facilitated by overexpression of either the whole prion protein or distinct regions that are required for propagation, called prion domains [13–19]. Most known yeast prion domains are glutamine (Q) and asparagine (N) rich [3,5–9,20]. In the case of de novo appearance of the prion form of the Sup35 translational termination factor, [PSI+], overexpression of Sup35 or its prion domain (Sup35PD) dramatically increases the appearance of [PSI+]. However, this increase requires either Q/N-rich domains that are simultaneously overexpressed [21,22] or the presence of another Q/N-rich prion, like the prion form of the Rnq1 protein, [PIN+] (also called [RNQ+]; [22–24]).

Similar to prion strains found in mammals (reviewed in [25]), yeast prions have also been shown to exist in different conformations called “variants” [14,26–30]. The introduction of in vitro generated Sup35 amyloid fibers into yeast not only infects the cells with the prion, proof of the “protein-only” hypothesis, but also demonstrates that distinct forms of the in vitro made amyloid cause the appearance of distinct variants that are heritable [31–32].

To further understand how prions are formed and maintained, recent studies have focused on specific host factors that affect the propagation and appearance of yeast prions. Chaperones, which are normally involved in proper protein folding, play a role in prion maintenance and appearance. Hsp104 and Sis1 break prion aggregates into smaller pieces that efficiently segregate into daughter cells, a requirement for prion transmission [33–41]. Deletion of the N-terminal activation domain of Hsf1, a heat shock transcription factor, prevents [PSI+] formation, while deletion of the Hsf1 C-terminal region promotes [PSI+] appearance [42]. Furthermore, disruption of the non-essential human Hsp110 ortholog, SSE1, or overexpression of HSP82 and HSC82 that encode members of the Hsp90 family of chaperones, dramatically reduces, but does not eliminate, the induction of [PSI+] caused by the overexpression of Sup35PD [43].

Two Gene Classes Control Prion and PolyQ Formation

Author Summary

Certain proteins that exist in functional unaggregated conformers can also form self-perpetuating infectious aggregates called prions. Here we investigate factors involved in the initial switch to the prion form. De novo appearance of the [PSI+] prion, which is the aggregated form of the Sup35 protein, is dramatically enhanced by overexpression of the SUP35 gene in the presence of the prion form of the Rnq1 protein, [PIN+]. When tagged with green fluorescent protein and transiently overexpressed in [psi-] [PIN+] cells, Sup35 forms fluorescent rings, and cells with these rings give rise to daughter cells that are [PSI+]. Here, we investigate factors required for this induction of [PSI+]. Analyses of over 400 gene deletions revealed two classes that reduce [PSI+] induction: one class forms fluorescent rings normally, and the other does not. Interestingly, the former class enhanced, while the latter class reduced, toxicity associated with the expanded polyglutamine repeats of the huntingtin protein exon 1 that causes Huntington’s disease. These results suggest that prion formation and polyglutamine aggregation involve a multi-phase process that can be inhibited at different steps.

Factors that affect [PSI+] induction are not limited to chaperones. Deletion of actin cytoskeletal genes, such as SLA1 or SLA2, reduces [PSI+] induction [44], suggesting that the actin cytoskeleton may play a role in prion appearance. Deletion of the ubiquitin-conjugating enzyme, Ubc4, enhances the de novo appearance of [PSI+] [45], and exposure to environmental stress can also alter the frequency of [PSI+] appearance [46].

Here, we identify deletions of several genes (bug1Δ, bend1Δ, arf1Δ, hog1Δ, las17Δ, vps5Δ, and sac6Δ) that reduce the efficiency with which overexpression of Sup35PD can induce the de novo appearance of [PSI+]. Deletion of LAS17, VPS5, or SAC6, which are associated with endocytosis and the actin cytoskeleton, not only inhibit [PSI+] induction, but also suppress the toxicity and aggregation associated with the expanded glutamine repeats of the huntingtin protein exon 1 that causes Huntington’s disease.

Results

Deletions of BUG1, BEM1, ARF1, HOG1, LAS17, VPS5, and SAC6 show low or no induction of [PSI+] but maintain propagation of [PSI+] and [PIN+]

Our goal was to identify genes that influence the induction of the [PSI+] prion. Previous work approached this problem by making use of the observation that overexpression of Sup35PD-GFP in [PSI+] [PIN+] cells causes toxicity due to excessive sequestration of essential Sup35 into large aggregates [46,47]. When Sup35PD-GFP is highly expressed in [psi-] [PIN+] cells, the frequent induction of [PSI+] results in an intermediate level of toxicity, because only cells that have switched to the [PSI+] state are sick [23,46]. Therefore, genes whose deletions enhance or reduce the toxicity associated with overexpression seemed likely to increase or decrease [PSI+] induction frequency, respectively [46]. We tested 238 deletion strains that enhanced toxicity, 131 that reduced toxicity, and nine other strains studied in Tyedmers et al. [46] (Table S1; Tyedmers and Lindquist, unpublished) for their effects on [PSI+] induction.

First, to distinguish the inability to induce [PSI+] from the inability to propagate [PSI+] we tested if the 398 deletions could maintain weak and strong variants of [PSI+] in a propagating culture after cytoduction with [PSI+]. A plasmid encoding a copper inducible Sup35PD-GFP fusion was plasmiduced into the deletion strains simultaneously with the cytoduction of weak or strong [PSI+]. After over 50 generations of growth, we scored for maintenance of [PSI+] by overexpressing Sup35PD-GFP and examining cells for the presence of fluorescent aggregates. All deletion strains cytoduced with either weak or strong [PSI+] contained fluorescent aggregates, indicative of [PSI+], except for hsp104Δ, which had the characteristic diffuse fluorescence of [psi-] cells (data not shown). Additionally, we have previously shown that [PIN+] is maintained in all strains of the deletion library except rda1Δ and hsp104Δ [48].

Next, we used a standard nonsense suppression assay for [PSI+] to screen the 398 yeast deletion library strains, in the BY4741 background, for their effects on induction of stable propagating [PSI+]. To do this, the [PIN+] prion, the Sup35PD-GFP plasmid, and a plasmid containing a wrn3-14 nonsense allele to score for [PSI+] cells [49] were simultaneously cytoduced into the 398 deletion strains as described previously [48]. Following overexpression of Sup35PD-GFP to induce [PSI+], cells were plated on -Ura where suppression of the plasmid borne wrn3-14 nonsense allele allowed [PSI+], but not [psi-], cells to grow.

Six novel deletion strains: bem1Δ, def1Δ, sup160Δ, rpp1aΔ, rpp4Δ, and pre9Δ, as well as the expected rda1Δ and hsp104Δ deletions, failed to grow on -Ura (Table 1). Previous work has shown that in the presence of the SUP35 R2E2 allele, which increases the appearance of [PSI+] without SUP35 overexpression, bem1Δ and pre9Δ decreased [PSI+] appearance [46]. In addition, 29 other deletions showed either low or extremely low induction of [PSI+] (Figure 1, Table 1). While strains carrying deletions of SPT4 or TML1010C-B failed to express Sup35PD-GFP, all other deletion strains expressed Sup35PD-GFP at similar levels (data not shown).

Deletion strains that decrease the efficiency of [PSI+] induction (Table 1) were from both enhanced and reduced toxicity groups. This makes sense if we consider that toxic side effects of the deletions could overlay the positive effect on growth rate due to the

Table 1. Yeast deletion library strains that show no, very low, or low induction of [PSI+].

reduced [PSF] induction. Furthermore, in some deletions, even the overexpression of YFP alone (without the Sup35 prion domain) causes strong toxicity that must be, therefore, completely unrelated to prion induction frequency [46].

To eliminate the effects of secondary mutations known to have accumulated in library strains [50,51], multiple independent deletions of nineteen of the best candidates that showed no or reduced induction of [PSF] (Table 1) were re-engineered in a wildtype 74-D694 [PIN+] strain. This 74-D694 genetic background contains a [PSF] suppressible ade1-14 allele that provides the ability to directly score for [PSF] by examining growth on -Ade. Of the 19 re-engineered deletions, only the six deletions (bre1Δ, bug1Δ, bem1Δ, arf1Δ, pre9Δ, and hg1Δ) that reproducibly reduced the frequency of [PSF] induction, relative to the wildtype induction frequency of approximately 7.5 X 10^-3 (Figure 2), were pursued further. Since a slow growth phenotype complicates the scoring for [PSF], deletions that significantly inhibited growth in the 74D-694 background, like lat1Δ and sac6Δ (data not shown), were eliminated from further analysis.

In addition to the above deletions, we made a deletion of LAS17, which was previously shown to inhibit the aggregation of the polyglutamine 103Q repeat [52]. We also made deletions of VPS5 and SAC6, because they, like Las17 and other proteins shown to affect the appearance of [PSF], are associated with endocytosis and the actin cytoskeleton. Even though prion propagation was unaffected in these three deletion strains because they were all able to maintain [PSF] over many generations after cytoduction (data not shown), tag3Δ caused a significant decrease in prion induction, and las17Δ and sac6Δ strains completely failed to induce [PSF] (Figure 2).

To eliminate deletions that reduced [PSF] induction by altering the levels of Sup35, Sup35PD-GFP, or chaperones, we examined these levels in all strains. None of the deletions caused significant changes in Hsp104, Ssa1, Sis1, Sse1, or Ssb1/2 (data not shown). Since Sup35PD-GFP levels were reduced in bre1Δ strains and Sup35 endogenous levels were decreased in pre9Δ strains (Figure S1), these deletions were dropped from further study.

To eliminate the possibility that the reduced [PSF] induction was due to the loss of [PIN+] during the construction of any of the deletion strains, we showed that the maintenance of [PIN+] was unaffected by the deletions. Each independently constructed deletion was crossed to a [pin+] strain carrying a plasmid with the CUP1 controlled RNQ1-GFP fusion. When grown on medium containing copper, induction of the resulting diploid containing the RNQ1-GFP construct caused the appearance of punctate dots indicative of [PIN+] (data not shown). Furthermore, we showed that [PIN+] was maintained in deletion strains by the presence of [PIN+] characteristic SDS-resistant oligomeric species after 24 hours of Sup35PD-GFP overexpression (Figure S2). Differences in the migration of Rnq1 SDS-resistant oligomers have been shown to be associated with different [PIN+] variants [53]. We observed similar migration of Rnq1 oligomeric species in the deletion strains, suggesting that the [PIN+] prion variants were not altered during construction of the strain or by Sup35PD-GFP overexpression. These results and other properties of the deletions investigated further below are summarized in Table 2.
Reduced \([PS\]') formation is not always associated with reduced ring formation

Transient overexpression of Sup35PD-GFP in \([psi^-]\) \([PIN']\) cells leads to the appearance of cytoplasmic fluorescent rings and lines [54]. Daughter cells derived from micromanipulated cells that contain such rings or lines, where overexpression of Sup35PD-GFP is turned off but where endogenous SUP35 is tagged with GFP, always contained fluorescent puncta indicative of \([PS\]') [55]. In contrast, mother cells without ring or line aggregates always gave rise to daughter cells with diffuse fluorescence, indicative of \([psi^-]\) [44, 54–56]. Thus the appearance of rings/lines, while not necessarily a direct intermediate in the formation of \([PS\]'), is nonetheless a hallmark of the potential appearance of induced \([PS\]'). No such rings have ever been observed during spontaneous appearance of \([PS\]') in the absence of Sup35PD overexpression (unpublished).

To determine the deletions that inhibit the induction of \([PS\]') and also prevent ring formation, we compared the number of cells that contained rings after 24 hours of expressing Sup35PD-GFP in the seven deletion strains. Ring containing cells in four of the deletions, \(bug1\Delta\), \(bem1\Delta\), \(af1\Delta\), and \(hog1\Delta\), appeared at levels similar to wildtype (30%, Figure 3A). The \(rnl1\Delta\) strains, which are \([pin]\), always displayed diffuse fluorescence (Figure 3A), as expected, since \([PIN']\) has been previously shown to be required for ring formation [54].

Interestingly, when measured after 24 hrs of Sup35PD-GFP induction, the three deletions associated with endocytosis and organization of the actin cytoskeleton, \(sac6\Delta\), \(las17\Delta\), and \(vps5\Delta\), all showed a significant reduction in cells containing rings. Since by 25 hrs of induction, wildtype, \(sac6\Delta\), and \(vps5\Delta\) strains were in stationary phase, where ring formation peaks [54], the inhibition of ring formation in \(sac6\Delta\) and \(vps5\Delta\) was not the result of a failure of these cultures to reach stationary phase (Figure S3). Also, since \(las17\Delta\) cells reached saturation phase only after 36 hours, we also measured ring formation in \(las17\Delta\) cultures following 50 hrs of induction, well after the culture reached stationary phase. These cultures still showed a 50% reduction in ring formation relative to the wildtype cultures (data not shown).

Ring-associated toxicity

Ring formation is associated with \([PS\]') appearance [54]. However, it has been shown that cells that contain rings have a higher rate of cell death than those that have diffuse fluorescence [44, 47, 54]. Therefore, we asked if the deletions might be more toxic to ring bearing cells, which would result in a decrease in \([PS\]') induction. To test this, we micromanipulated individual ring containing cells from selected deletion strains and assessed whether they were viable. Similar to previous findings [47], only 36% of wildtype ring containing cells were viable, whereas 95% of wildtype cells with diffuse cytoplasmic fluorescence were viable (Figure 3B). In general, the viability of ring containing wildtype, \(bem1\Delta\), and \(hog1\Delta\) cells appeared to be similar (Figure 3B) and therefore cannot explain the strong reduction of de novo induction of \([PS\]'). Ring containing \(af1\Delta\) cells had reduced viability (21%), which could account for the decrease in \([PS\]') induction (Figure 2). In contrast, \(bug1\Delta\) ring cells showed an increase in viability (59%),

Figure 2. Nine deletions show reduced \([PS\]') appearance. Genes were disrupted in the 74D-694 \([PIN']\) strain background. Deletion strains, transformed with the Sup35PD-GFP plasmid, were grown in 10 ml of plasmid selective media supplemented with copper for 24 hours at 30°C and plated on SD-Ade in order to determine \([PS\]') induction frequency. Induction frequency and standard error were calculated with at least one transformant from each independent knock out (see Table S3) for a total of three transformants per deletion. The exception was \(pre9\Delta\) which was calculated from three transformants from a single independent knock out. Only deletion strains that showed a significant difference in induction frequency compared to wildtype strains (\(p<0.05\) unpaired t-test) were included in the figure.

All strains contain the [PIN] prion. Deletion strains were assessed compared to wildtype. (-) indicates a lower degree compared to wildtype. Whether strains exhibited enhanced or reduced toxicity during Sup35PD overexpression in Tyedmers et al. [46] is listed under ‘Toxicity with Sup35PD overexpression’. ‘Reaches stationary phase after 24 hours’ indicates which deletion strains containing Sup35PD-GFP, when induced with copper for 24 hours, reach stationary phase (Figure S3). Strains carrying a deletion of LAS17 took 36 hours to reach stationary phase. Maintains [PIN] and Maintains [PSI] indicate strains that can propagate the respective prion after cytoduction. ‘[PSI] induction’ indicates the relative induced frequency of [PSI] formation (Figure 2). ‘Detection of Sup35PD-GFP rings’ indicates the fraction of cells containing rings after 24 hours of Sup35PD-GFP overexpression (Figure 3A), whereas the ‘viability of ring cells’ refers to toxicity associated with ring containing cells (Figure 3B). The frequency of cells with bright 103Q-GFP aggregates accumulating after one to two hours of induction (Figure 4B) are summarized under ‘103Q bright aggregates.’ The effect of 103Q-GFP overexpression on the growth of deletions strains are under ‘Growth of [PIN] 103Q-GFP expressing cells.’

*a aggregates were reduced, but faint aggregates on diffuse background were increased.
b sorted previously by [52].

Figure 3. Ring formation and viability.

A. PIN+ cells containing Sup35PD-GFP were induced in copper containing liquid media for 24 hours. The percentage of cells containing rings was determined by counting more than 300 cells from at least one transformant from each independent knockout line (see Table S3) for a total of three transformants per deletion. Bars indicate standard error and (*) indicates deletion strains that showed a significant difference in the percentage of cells containing rings compared to wildtype (p<0.01 unpaired t-test).

B. Ring containing cells (purple bars) or cells with diffuse cytoplasmic fluorescence (green bars) were isolated by micromanipulation, placed on rich media and assayed for growth. At least 20 ring containing cells and 10 diffuse cells, from at least one transformant from each independent knockout line for a total of three transformants, were tested. Bars indicate standard error and (*) indicates the deletion strains that showed a significant difference in viability compared to wildtype strains (p<0.01 unpaired t-test).

doi:10.1371/journal.pgen.1001386.g003
but apparently these cells did not efficiently give rise to [PS\textsuperscript{I}] cells. In the absence of rings, there appeared to be no effect on the viability of any of the deletion strains (Figure 3B, green bars).

Since isolating ring cells in strains with low ring formation was difficult, we focused on one example and found that of the small population of cells in \textit{psi3\Delta} strains that formed rings, a majority were inviable (Figure 3B). This suggests that rings in the absence of \textit{VPS5} may be harmful to the cell and likely explains the decreased percentage of rings observed in Figure 3A.

**Deletion strains affect aggregation and toxicity of polyglutamine**

We next asked if our deletion strains also affect the [\textit{PIN}\textsuperscript{\text{+}}] dependent aggregation of the polyglutamine (polyQ) expanded repeat found in the mutant huntingtin protein associated with Huntington’s disease. Since \textit{las17A} strains, carrying a galactose inducible expanded polyQ repeat (103Q) fused to GFP, were previously shown to delay 103Q-GFP aggregate formation compared to wildtype strains [32], we tested our other deletions for similar aggregation patterns. When wildtype [\textit{PIN}\textsuperscript{\text{+}}] cells expressed 103Q-GFP for approximately one to two hours, 62% of cells displayed strong fluorescent puncta, while [\textit{pin}] cells showed mostly cells with diffuse fluorescence (73%) and a minor population that contained a faint fluorescent foci on a diffuse background (27%; Figure 4A and 4B). Similar analyses of [\textit{PIN}\textsuperscript{\text{+}}] strains with \textit{bug1\Delta}, \textit{bem1\Delta}, \textit{arf1\Delta}, and \textit{hog1\Delta} deletions resulted in a reduced number of cells that contained strong fluorescent puncta (Figure 4B, green bars) and an increased number of cells that had faint fluorescent foci with a diffuse background (Figure 4B, purple bars). As in the previous study [32], [\textit{PIN}\textsuperscript{\text{+}}] \textit{las17A} strains had barely any strong fluorescent foci. Examination of [\textit{PIN}\textsuperscript{\text{+}}] \textit{psi3\Delta} and [\textit{PIN}\textsuperscript{\text{+}}] \textit{sac6\Delta} strains also showed a strong reduction in cells having bright foci and a similar distribution of cells with faint foci vs. no foci as seen in wildtype [\textit{pin}\textsuperscript{\text{+}}] strains.

We next examined the effect of these deletions on toxicity associated with expression of the expanded polyglutamine protein in the presence of the [\textit{PIN}+] prion [57]. Our controls verified earlier findings [57] that wildtype [\textit{PIN}\textsuperscript{\text{+}}] cells carrying a galactose inducible 103Q-GFP plasmid show toxicity compared to cells carrying the non-toxic 25Q-GFP plasmid. As expected, polyglutamine expressing cells that are either [\textit{pin}] or \textit{rug1\Delta} did not exhibit toxicity, whereas wildtype [\textit{PIN}\textsuperscript{\text{+}}] cells were sick (Figure 4C). Since previous studies have correlated the presence of polyQ aggregates with cell toxicity [57], the lack of strong polyQ fluorescent foci in the class of deletions that also reduced ring formation after Sup35PD-GFP overexpression (\textit{las17A}, \textit{psi3\Delta}, and \textit{sac6\Delta}; Figure 4A and B) nicely explained the observed decrease in polyQ toxicity. Interestingly, the class of deletions that reduced [PS\textsuperscript{I}] induction, but not ring formation (\textit{bug1\Delta}, \textit{bem1\Delta}, \textit{arf1\Delta}, and \textit{hog1\Delta}), increased the frequency of cells containing faint polyQ-GFP fluorescent foci on diffuse backgrounds and clearly enhanced 103Q toxicity.

**Discussion**

We scored 398 gene deletions, previously identified by their ability to increase or decrease toxicity caused by overexpression of Sup35PD-GFP [46], for effects on the induction of [PS\textsuperscript{I}] and established effects for four of the deletions (see Table 2 summarizing all results). Since there is not always a strong correlation between the toxicity associated with \textit{SUP35} overexpression and the induction of [PS\textsuperscript{I}], we tested all of the enhanced and reduced toxicity candidates found in the previous study [46] for [PS\textsuperscript{I}] induction. We observed that induction of [PS\textsuperscript{I}] was inhibited by deletions that either reduced (\textit{arf1\Delta} and \textit{bem1\Delta}) or enhanced (\textit{bug1\Delta} and \textit{hog1\Delta}) toxicity. Possibly the rings or other less visible aggregates have an altered property in the presence of \textit{bug1\Delta} or \textit{hog1\Delta} that inhibits detectable [PS\textsuperscript{I}] appearance and causes toxicity. It has been shown that rings cause toxicity by titrating Sup35 and/or Sup45 (the essential release factor that binds to Sup35) into aggregates and away from the ribosome [46].

The toxicity associated with \textit{bug1\Delta} and \textit{hog1\Delta} during [PS\textsuperscript{I}] induction could be an enhancement of this effect or could be by the formation of a different type of toxic [PS\textsuperscript{I}] intermediate.

We also examined three deletions (\textit{las17A}, \textit{psi3\Delta}, and \textit{sac6\Delta}), which were chosen for their association with endocytosis and the actin cytoskeleton, and found that they reduce [PS\textsuperscript{I}] induction. While \textit{las17A} and \textit{psi3\Delta} were not included in the library originally scored for SUP35PD-GFP toxicity, the \textit{sac6\Delta} BY4741 library strain was not associated with changes in toxicity [46]. We found that \textit{sac6\Delta} inhibits [PS\textsuperscript{I}] induction in both the deletion library (BY4741; data not shown) and the 74-D694 (Figure 2) backgrounds. This suggests that other non-essential deletions that inhibit [PS\textsuperscript{I}] induction were likely missed in the toxicity screen.

All seven of our deletion strains reduce [PS\textsuperscript{I}] induction caused by overexpression of Sup35PD-GFP. While a deletion of \textit{BEM1} was previously shown to reduce the spontaneous appearance of [PS\textsuperscript{I}] associated with the SUP35 \textit{R2E2} expanded repeat [46], it is unknown whether our deletions affect the spontaneous appearance of [PS\textsuperscript{I}] without overexpression or mutated alleles (e.g. \textit{R2E2}) of Sup35. Since the spontaneous appearance of [PS\textsuperscript{I}] is very infrequent and Mendelian suppressors with the phenotype of [PS\textsuperscript{I}] [58] appear at a higher rate than [PS\textsuperscript{I}], scoring for mutations that lower the appearance of [PS\textsuperscript{I}] is challenging.

**Prion and polyglutamine formation and maturation**

Time lapse examination of individually micromanipulated [\textit{psi}] [\textit{PIN}\textsuperscript{\text{+}}] cells, containing an endogenously tagged Sup35-GFP fusion and transiently overexpressing Sup35PD-GFP from a plasmid, previously showed that a fluorescent ring initially forms at the cell periphery and then internalizes around the vacuole. Later, such cells with rings give rise to [PS\textsuperscript{I}] daughter cells with fluorescent foci (Figure 5A) [44,55].

In this paper, we identified two classes of gene deletions that reduce the \textit{de novo} induction of stable [PS\textsuperscript{I}] but differ in effects on ring formation. Class I deletions (\textit{bug1\Delta}, \textit{bem1\Delta}, \textit{arf1\Delta}, and \textit{hog1\Delta}) form Sup35PD-GFP rings at approximately wildtype levels (Figure 3). Class II deletions (\textit{las17A}, \textit{psi3\Delta}, and \textit{sac6\Delta}) have a significantly reduced number of cells with Sup35PD-GFP rings (Figure 3).

The existence of these two deletion classes suggests that the prion formation pathway can be inhibited at different steps. In the case of class I deletions, problems in peripheral and internal ring formation were not detected (data not shown), suggesting that these genes are important for ring containing cells to transmit heritable [PS\textsuperscript{I}] aggregates to daughter cells (Figure 5A). In the case of class II deletions, peripheral rings form infrequently, suggesting that these genes are important in the initial formation of the ring even in the presence of [\textit{PIN}+] (Figure 5A). While rings contained in \textit{psi3\Delta} (class II) cells have reduced viability, it is unlikely that ring formation is so toxic that cells die before the ring appears because there is no corresponding increase in toxicity in non-ring containing cells (Figure 3B).

The formation of polyglutamine aggregates, upon overexpression of Q103GFP in a [\textit{PIN}\textsuperscript{\text{+}}] strain, is not associated with ring formation. Instead, large bright aggregates are observed within one to two hours of induction [52]. All of our deletions affected polyglutamine aggregation, but the type of effect differed based on
Figure 4. Aggregation and toxicity of 103Q in deletion strains. A. Log phase wildtype \([PIN^+]\) cells containing the 103Q-GFP plasmid were induced in galactose containing media for one to two hours and then visualized. Within the population, most cells exhibited strong fluorescent aggregates on a non-fluorescent background (bottom), some cells had faint fluorescent foci on a cloudy fluorescent background (middle), and a very small population of cells had diffuse cytoplasmic fluorescence (top). B. Deletions containing 103Q-GFP were induced and scored for the different cell types indicated in (A). The percentages of cells containing strong fluorescent aggregates (green bars), faint foci (purple bars), and diffuse cytoplasmic...
Class I deletions, 

\[ \text{bem1}^{D}, \text{bug1}^{D}, \text{arf1}^{D}, \text{and hog1}^{D} \]

caused a decreased level of bright fluorescent aggregates and an increase in diffuse cells with faint foci (Figure 4A and 4B). Interestingly, these deletions enhanced the toxicity associated with 103Q-GFP (Figure 4C). In the presence of the class II deletions, 

\[ \text{las17}^{D}, \text{vps5}^{D}, \text{and} \text{ sac6}^{D} \]

103Q-GFP usually remained diffuse, and

\[ \text{bem1}^{D}, \text{bug1}^{D}, \text{arf1}^{D}, \text{and hog1}^{D} \]

caused a decreased level of bright fluorescent aggregates and an increase in diffuse cells with faint foci (Figure 4A and 4B).

**A. Steps of [PSI+] formation**

Class I deletions affect Sup35 transition from functional protein to non-functional aggregates. Class II deletions are important for ring formation. As the ring matures, diffuse Sup35 diminishes in intensity. The peripheral ring then collapses to surround the vacuole. The daughters of the ring containing cell contain multiple Sup35:GFP aggregates characteristic of [PSI+]. Class I deletions interfere with transitioning to [PSI+] after the ring appears.

**B. 103Q formation**

Class II deletions are important for initial oligomer formation, while Class I deletions are important for large aggregate formation. Diffuse monomer transitions into toxic soluble polyglutamine oligomers, and finally into formation of large aggregates that sequester some toxic oligomers.

**Figure 5. Proposed effects of class I and II genes on the multistep pathways of de novo prion and polyglutamine aggregate formation.** A. Induction of [PSI+] by transient overexpression of Sup35PD-GFP in a [psi-] [PIN+] strain with endogenous Sup35 tagged with GFP. As described in Mathur et al., [55] the first stages of [PSI+] induction involve the formation of a peripheral fluorescent ring. Class II deletions appear to inhibit this step. As the ring matures, diffuse Sup35 diminishes in intensity. The peripheral ring then collapses to surround the vacuole. The daughters of the ring containing cell contain multiple Sup35:GFP aggregates characteristic of [PSI+]. Class I deletions interfere with transitioning to [PSI+] after the ring appears. B. Hypothetical model of 103Q aggregation in [PIN+] cells. Class II proteins function in the initial formation of small toxic 103Q oligomers (left), since class II gene deletions result in diffuse fluorescence and suppression of toxicity. Class I proteins most likely facilitate incorporation of these small oligomers into large protective aggregates (right).
very few cells had bright aggregates (Figure 4B). Additionally, all class II deletions suppressed polyglutamine toxicity (Figure 4C).

The formation of large huntingtin aggregates in mammals was initially thought to be the cause of huntingtin-mediated cell death (reviewed in [59]), but emerging evidence suggests that these large aggregates are neuroprotective ([60], reviewed in [61]) and toxicity is due to a soluble pool of oligomeric conformers ([62-63]). Also in yeast, small multiple foci of 103Q appear to be more toxic than a large aggregate ([64,65]). Thus, we propose that class I genes are important for the formation of large protective aggregates but not small toxic oligomers (Figure 4B), and that when a class I gene product is absent, the reduction of large protective aggregates permits the increased propagation of deadly soluble oligomers.

In contrast, in cells with class II deletions, 103Q-GFP toxic oligomers or aggregates may form only rarely. While the [PSF] and polyglutamine formation pathways are not directly comparable, we propose that class II genes affect the initial steps of polyglutamine formation, and the formation of large protective aggregates (promoted by class I genes) is a downstream event (Figure 5B).

**Actin and prion formation**

Although endocytosis is relatively unaffected in bem1Δ, bag1Δ, ady1Δ, bag1Δ, las17Δ, psi5, and sac6Δ strains, six out of seven of our deletion mutants display fragmented vacuoles (Figure S4) [66,67]. Possibly, vacuole fragmentation may affect the perivacuolar deposition site for aggregated proteins, called IPOD [68], which has been suggested to play a role in prion formation [55,56]. Some of the deletion library strains we screened induced [PSF] normally but had fragmented vacuoles (Table S1, asterisk; [66]), suggesting that intact vacuoles are not necessarily a requirement for efficient prion appearance. Vacuole fragmentation has been shown to be associated with microtubular defects [69] as well as fluctuations in prion appearance. Vacuole fragmentation has been shown to be associated with microtubular defects [69] as well as fluctuations in prion appearance. Vacuole fragmentation has been shown to be associated with microtubular defects [69] as well as fluctuations in prion appearance.

Actin and prion formation involves a multi-step process that is dependent upon actin organization. Interestingly, six of the seven proteins identified here have mammalian homologues (Table 2), suggesting that similar mechanisms may be involved in aggregation and oligomerization of QN-rich proteins in higher eukaryotes. Further elucidation of how actin nucleation contributes to prion induction will not only shed light on how toxic oligomeric species are formed, but also could provide clues to the molecular mechanisms underlying many human aggregating neurodegenerative diseases.

**Methods**

**Plasmids and strains**

In this work, 398 yeast deletion library strains (parent strain BY4741; MATα ura3Δ his3Δ1 leu2Δ1 met15Δ; Open Biosystems, Huntsville, AL; Table S1) previously obtained from an earlier toxicity screen ([46]; Tyedmers and Lindquist unpublished) were scored for effects on [PSF] induction in a wildtype Sup35 background. The “karl plasmid donor” strain (GF667; MATα CEN1-16::Gal1-CEN1-16-Ura3Δ kar1Δ15 lys2 ade5-535 leu2-3,112 can1-100 his3-11,15 trpl-1 cyhΔ6) was used to introduce plasmids and prions into the deletion library strains via cytoduction, as described in Manogaran et al. [48]. A plasmid containing a copper inducible prion and middle domain of Sup35 (Sup35PD) fused to green fluorescent protein (Sup35PD-GFP; p1181; CEN2 HIS3 on ARS AmpR pCap1-Sup35PD-GFP) was used to induce [PSF] in deletion strain derivatives of BY4741, while a LEU2 version of the plasmid (p1182) was used in 74-D694 (L1749; [33]; MATα ade1-14 leu2-3,115 his3Δ200 ura3-52 trpl-289 high [PEN]). To score for [PSF] in the BY4741 strains, a plasmid containing the [PSF] suppressible ura3-14 allele ([49]; p1513; CEN2 LEU2 ura3-14 on ARS AmpR) was used. A tester strain (L12147; MATα leu2 ura2 his3 [psn]) transformed with a copper inducible RNQ1 fused to GFP (p1186; CEN LEU2 on ARS AmpR pCuPI-RNQ1::GFP) was used to confirm the presence of [PEN] in 74D694 deletion strains (see below). Plasmids p1572 and p1838 [52], which contain a fusion of GFP to the galactose inducible 25Q or 103Q repeats in exon 1 of the huntingtin gene, respectively, were used to examine polyglutamine aggregation and toxicity. These fusion constructs do not contain the proline-rich region of the huntingtin exon 1 [52].

**Cultivation procedures**

Yeast strains were cultivated using standard media and growth protocols [71] and grown at 30°C except when indicated. Complex media contained 2% dextrose (YPD), and synthetic complete media contained the required amino acids and 2% dextrose (SD) or 2% galactose (SGal).

**Curing of BY4741 deletion strains**

Pre-existing prions were cured by growing strains on media containing low levels of guanidine hydrochloride (GuHCl), which cures through the inactivation of Hsp104 [72,73]. Strains were spotted onto YPD plates containing 5mM GuHCl and repeated two to three additional times to ensure that prions were cured.

**Preparation of the karl plasmid donor and introduction of plasmids and prions into deletion strains**

Prions and plasmids were introduced into the karl plasmid donor strain. To make a [PSF] karl plasmid donor strain to test for [PSF] maintenance in the deletion strains, the karl plasmid donor strain was crossed to either a weak [PSF] (L1759) or strong [PSF] (L1765) strain containing Sup35PD-GFP. karl plasmidcitants containing [PSF] were chosen as described in Manogaran et al. [48], and confirmed to contain [PSF] by the formation of Sup35PD-GFP aggregates after 16 hours. The [PSF] karl plasmid donor was mated to the BY4741 deletion strains, deletion strain cytoductants were confirmed by testing for auxotrophic markers, and the presence of [PSF] Sup35PD-GFP aggregate formation was examined as described above [54].

To test for the induction of [PSF], prions and plasmids were introduced into the karl plasmid donor strains by crossing to either a [PEN] (L1749 high [PEN]) or [pse] strain (L2910) containing the Sup35PD-GFP and ura3–14 plasmids. [PEN] karl plasmid donor

strains were confirmed as above and tested for the presence of [PIN+] by the formation of Sup35PD-GFP fluorescent rings after 24 hours of induction on copper [54]. Cytoduction of plasmids and prions into the BY4741 library deletion strains has been described previously [46]. To ensure reproducibility, cytoductions were performed in duplicate.

Induction of [PSF+] in cytoduced deletion strains

Cytoduced BY4741 deletion strains, containing [PIN+] and both Sup35PD-GFP (HIS3) and nmt3–14 (LEU2) plasmids, were spotted onto plasmid selective SD-His-Leu plates plus 50 μM copper sulfate and grown for approximately two days. Strains were resuspended in 300 μl of sterile water and either spotted onto SD-Leu (grown two days) to assess growth, or SD-Leu-Ura (grown at room temperature for five to seven days) to score for [PSF+] induction. Induction experiments on all 398 yeast deletion library strains were repeated six times to ensure reproducibility. Spots that exhibited no or reduced growth on SD-Leu-Ura, compared to controls, were chosen as candidate genes that affect [PSF+] appearance (Table 1).

Re-engineering of candidate strains

Genetic recombination was used to replace candidate genes (Table 1) with HIS3 in [PIN+] 74-D694. Primers (Table S2), adjacent to sequences flanking the 5' or 3' ends of the candidate gene, were used to PCR amplify the HIS3 gene. PCR products were transformed and His+ transformants were confirmed for insertion of the HIS3 gene in the correct locus. Two to three independent knockout lines (Table S3) were obtained for each deletion, except for pnuA. To confirm the presence of [PIN+], deletion strains were mated to a [pnu] tester strain containing a RNQ1-GFP plasmid. Diploids were checked for the formation of fluorescent RNQ1-GFP aggregates after induction overnight. To test whether las17A, spo5A, or sac6A maintain [PSF+], the deletions were cytoduced with [PSF+] and checked for growth on –Ade.

Scoring the induction frequency of [PSF+]

Re-engineered deletion strains were transformed with the Sup35PD-GFP (LEU2) plasmid and grown in SD-Leu plus copper sulfate liquid media for 24 hours. After induction, approximately 10,000 cells were plated on SD–Ade, and a 50-fold dilution of cells was plated on SD+12. Colony counts were obtained from at least one transformant from each independent knock out (see Table S3) on SD+12 vs. SD–Ade. Colony counts from at least three transformants were used to determine the induction frequency.

Sup35PD-GFP ring formation in re-engineered deletion strains

After 24 hours of induction, cells were examined for the formation of GFP fluorescent rings [34] using a Zeiss Axiolop2 deconvolution workstation equipped with either a X40 Plan-Neofluar or X100 Plan-Apochromat objective lens (Zeiss). Approximately 300 cells were counted from at least one transformant from each independent knock out, for a total of three transformants.

Determining cell viability of ring-containing cells

Ring containing cells were simultaneously visualized and micromanipulated onto 2% sterile Noble Agar slabs. Slabs were transferred onto YPD media and grown for one to two days.

Aggregation and toxicity of polyglutamine in re-engineered deletion strains

Strains containing the galactose inducible 25Q or 103Q GFP fusion plasmids were grown overnight in SD-Ura and then washed in water approximately four times to remove residual glucose. To score for aggregation, washed cells were grown in liquid Gal-Ura for one to two hours with shaking and then examined for GFP aggregates. To score for toxicity, log phase uninduced washed cells were serially diluted 20-fold and spotted onto SD-Ura or SGal-Ura.

Supporting Information

Figure S1 Certain deletion strains have decreased levels of Sup35 and Sup35PD-GFP. [PIN+] wildtype or deletion strains containing Sup35PD-GFP were grown for 22 hours to an approximate OD600 3.0 at 30°C in the presence of 50 μM copper. All strains are in the 74D-694 background except sac6Δ, which is in the BY4741 background. Equivalent amounts of cell lysates were loaded per lane and subjected to SDS-PAGE (see Text S1). Lanes in the left panel were run on the same gel. Blotted proteins were incubated either with anti-GFP antibody, anti-Sup35 C-terminal antibody, or anti-PGK antibody (as indicated).

Found at: doi:10.1371/journal.pgen.1001386.s001 (0.24 MB TIF)

Figure S2 The [PIN+] variant in the deletion strains appears to be unaffected. [PIN+] wildtype and deletion strains, containing Sup35PD-GFP, were grown for 24 hours in copper media, and equivalent amounts of protein were loaded on a 1.5% agarose gel and subjected to SDD-AGE [53]. Blotted proteins were incubated with an antibody against the Rnq1 protein.

Found at: doi:10.1371/journal.pgen.1001386.s002 (0.62 MB TIF)

Figure S3 All deletion strains reach saturation after 24 hours of induction, except las17A. Deletion and wildtype strains containing Sup35PD-GFP and [PIN+] were grown in plasmid selective media with copper at 30°C. OD600 readings were taken at the indicated time points to assess growth.

Found at: doi:10.1371/journal.pgen.1001386.s003 (0.27 MB TIF)

Figure S4 Vacuole formation is altered in deletion strains, except hog1Δ. A. Wildtype and deletion strains were incubated with 5 μM FM4-64 for 20 minutes in YPD, washed and then allowed to incubate for 60 minutes before visualizing internalization of the dye. B. Wildtype cells were treated either with DMSO (gray bars) or various concentrations of Nocodazole (purple bars) during overnight induction of Sup35PD-GFP. Percent of rings were calculated after 24 hours of induction. C. Untreated cells (DMSO) or cells treated with 50 μg/ml of Nocodazole from (B) were plated in 20 fold serial dilutions on SD-Ade media to score for [PSF+] induction. Growth on SD-Ade indicates there is no growth defect.

Two Gene Classes Control Prion and PolyQ Formation
