Contributed by Gerald N. Wogan, July 19, 2010 (sent for review April 27, 2010)

Helicobacter pylori is a human carcinogen, but the mechanisms evoked in carcinogenesis during this chronic inflammatory disease remain incompletely characterized. We determined whether chronic H. pylori infection induced mutations in the gastric mucosa of male and female gpt delta C57BL/6 mice infected for 6 or 12 mo. Point mutations were increased in females infected for 12 mo. The mutation frequency in this group was 1.6-fold higher than in uninfected mice of both sexes (P < 0.05). A:T-to-G:C transitions and G:C-to-T:A transversions were 3.8 and 2.0 times, respectively, more frequent in this group than in controls. Both mutations are consistent with DNA damage induced by oxidative stress. No increase in the frequency of deletions was observed. Females had more severe gastric lesions than males at 6 mo postinfection (MPI; P < 0.05), but this difference was absent at 12 MPI. In all mice, infection significantly increased expression of IFNγ, IL-17, TNFα, and iNOS at 6 and 12 mo, as well as H. pylori–specific IgG1 levels at 12 MPI (P < 0.05) and IgG2c levels at 6 and 12 MPI (P < 0.01 and P < 0.001). At 12 MPI, IgG2c levels in infected females were higher than at 6 MPI (P < 0.05) and also than those in infected males at 12 MPI (P < 0.05). Intensity of responses was mediated by sex and duration of infection. Lower H. pylori colonization indicated a more robust host response in females than in males. Earlier onset of severe gastric lesions and proinflammatory, Th1-biased responses in female C57BL/6 mice may have promoted mutagenesis by exposing the stomach to prolonged oxidative stress.

gpt delta mouse • Helicobacter • inflammation • mutagenesis • sexual dimorphism

Acting through multiple, complex mechanisms that are incompletely understood, chronic inflammation is a significant risk factor for several major human malignancies, including stomach cancer. Chronic inflammation induced by Helicobacter pylori infection increases lifetime risk of developing gastritis, duodenal and gastric ulcers, mucosa-associated lymphoid tissue lymphoma, mucosal atrophy, and gastric carcinoma (1, 2). Indeed, H. pylori has been classified by International Agency for Research on Cancer as a human carcinogen on the basis of its impact on gastric cancer incidence, the second most frequent cause of cancer-related death worldwide (3). Among postulated mechanisms through which infection may contribute to increased cancer risk are overproduction of reactive oxygen and nitrogen species (RONS) by inflammatory cells, and the subsequent induction of mutations critical for tumor initiation in cells of infected tissues (4). The inflammatory response to infection results in increased production of RONS, including superoxide (O2·−), hydrogen peroxide (H2O2), nitric oxide (NO), peroxynitrite (ONO2−), and nitrous anhydride (N2O3), in vitro (5, 6) and in vivo (7–9). H. pylori can also directly activate RONS-producing enzymes, such as inducible NO synthase (iNOS) and spermide oxidase, in gastric epithelial cells, causing DNA damage and apoptosis (5, 6). Chronic inflammatory states increase levels of DNA adducts, such as etheno adducts, 8-oxoG, and other mutagenic precursors, in vitro and in vivo (10–12), but tend not to alter the frequency of deletions (13). RONS also can damage DNA indirectly by creating adduct-forming electrophiles via lipid peroxidation (14, 15). RONS have been shown to induce mutations in H. pylori by inducing a hypermutation state in the bacteria (16).

A widely used experimental model is the H. pylori SS1-infected C57BL/6 mouse, which is susceptible to chronic infection and develops robust gastritis and premalignant lesions similar to those occurring in humans (17, 18). To date, limited investigation has focused on genetic damage associated with infection in these animals, but available data are still incomplete. Enhanced DNA fragmentation was observed in gastric cells of infected mice (19), in which dsDNA breaks were also detected by TUNEL assay (20, 21). Mutagenicity in reporter genes recovered from gastric DNA of male and female Big Blue transgenic mice 6 mo after infection with H. pylori or Helicobacter felis has also been reported (22). In H. pylori-infected male mice, point mutation frequency was increased at 6 mo post infection (MPI), but decreased to control levels by 12 MPI, suggesting that the animals may have adapted to infection (22). Female mice infected with H. felis also had an increased frequency of point mutations at 7 MPI, compared with uninfected controls (23). Mutagenesis resulting from infection has also been associated with p53 status. Mutations were found in the lacI reporter genes of a small number of H. felis-infected female TSG−/− mice harboring either one (p53+/−) or two (p53−/−) WT p53 alleles (23). A 2-fold increase in mutations was found in DNA from the gastric mucosa of infected p53+/− mice, and also in uninfected p53−/− mice; the mutation frequency in infected p53+/− mice was further increased by approximately threefold. The intensity of inflammation was estimated to be significantly higher in infected p53+/− mice than in infected p53−/− animals, and gastric epithelial proliferation was similarly increased with infection in both latter treatment groups. By contrast, in another study, infection of Big Blue transgenic mice (sex not specified) with the SS1 strain of H. pylori for 3.5 mo resulted in no significant increase in gastric mutations over uninfected controls (13).

We used the gpt delta mouse to measure the accumulation of gastric mutations associated with H. pylori SS1 infection in male and female animals at 6 and 12 MPI. This experimental system comprises λ-EG10–based transgenic C57BL/6 mice harboring tandem arrays of 80 copies of the bacterial gpt gene at a single site on chromosome 17. The model was specifically designed to facilitate the in vivo detection of point mutations by 6-thioguanine...
(6-TG) selection, and deletions up to 10 kb in length by selection based on sensitivity to P2 interference (Sph) (24). When phage DNA rescued from mouse tissues is introduced into appropriate Escherichia coli strains, both point mutations and large deletions can be efficiently detected (24). We also characterized histopathologic changes, expression of inflammatory cytokines, and expression of iNOS in gastric mucosa 6 and 12 mo after initial infection. In addition, we compared responses of male and female mice to assess the influence of sex. We found that Helicobacter pylori infection induced significant increases in the frequency of point mutations in the gastric mucosa of female, but not male, gpt delta mice. The accumulation of point mutations was therefore sex-dependent and was mediated by the duration of infection and the severity of disease.

Results and Discussion

Pathology, Cytokine and iNOS Expression, and Serologic Responses to H. pylori Infection and H. pylori Levels. Inflammatory histopathologic changes resulting from H. pylori infection were evaluated (Fig. S1) and gastric histological activity index (GHAI) scores calculated, with the following results. Scores were significantly increased in infected animals of both sexes at 6 and 12 MPI (female, \( P < 0.001 \) and \( P < 0.01 \), respectively; and male, \( P < 0.05 \) and \( P < 0.001 \), respectively; Fig. 1). Regarding specific types of lesions represented in the GHAI, infected females experienced higher levels of hyperplasia (\( P < 0.05 \)), epithelial defects (\( P < 0.001 \)), and dysplasia (\( P < 0.05 \)) compared with infected males at 6 MPI, and thus had correspondingly higher (\( P < 0.05 \)) GHAI scores at this time point. At 6 MPI, infected females, in both sexes, displayed mild to moderate inflammation, comprised chiefly of submucosal and mucosal infiltrates of mononuclear and granulocytic cells. In addition, in infected males, mucous metaplasia, intestinal metaplasia, oxyntic gland atrophy, and hyalinosis were all significantly elevated compared with controls (all \( P < 0.01 \); intestinal metaplasia, \( P < 0.001 \)); no significant increases occurred in foveolar hyperplasia, epithelial defects, or dysplasia. In infected females, inflammation (\( P < 0.05 \)), epithelial defects (\( P < 0.001 \)), mucous metaplasia (\( P < 0.01 \)), hyalinosis (\( P < 0.001 \)), as well as premalignant lesions of oxyntic gland atrophy (\( P < 0.001 \)), intestinal metaplasia (\( P < 0.05 \)), and dysplasia (\( P < 0.05 \)) were significantly elevated compared with uninfected controls. At 12 MPI, there were no differences in gastric lesion severity between infected males and females; both groups had similar mucosal changes. Infected male mice at 12 MPI displayed significantly increased epithelial defects but decreased intestinal metaplasia than infected males at 6 MPI (\( P < 0.01 \) and \( P < 0.001 \)).

Helicobacter pylori infection significantly increased transcription profiles at 6 and 12 MPI as follows (details in Fig. S2): IFN-\( \gamma \) (males, \( P < 0.001 \); females, \( P < 0.01 \) at 6 and 12 MPI); TNF-\( \alpha \) (males, \( P < 0.01 \) at 6 and 12 MPI; females, \( P < 0.01 \) and \( P < 0.05 \)); IL-17 (males, \( P < 0.05 \) and \( P < 0.001 \); females, \( P < 0.05 \) and \( P < 0.01 \)). iNOS expression was increased in male and female mice at 6 and 12 MPI (males, \( P < 0.05 \) and \( P < 0.01 \); females, \( P < 0.01 \) and \( P < 0.001 \)) compared with controls at 12 mo. IL-10 expression was not significantly affected by infection in animals of either sex (\( P > 0.05 \)).

Helicobacter pylori infection also resulted in a Th1-predominant IgG2c response in infected mice as previously reported (25, 26) (Fig. 2). Helicobacter pylori-specific IgG2c levels were higher in infected than in uninfected animals at 6 and 12 MPI (\( P < 0.01 \) and \( P < 0.001 \), respectively). At 12 MPI, infected females had significantly higher

![Fig. 1. H. pylori infection elicits more gastric pathologic processes in female mice at 6 mo. H. pylori infection increased the GHAI in both male and female C57BL/6 mice at 6 and 12 mo. At 6 mo of infection, infected females had significantly more pathologic processes than infected males. Uninfected males (○; 6 MPI, \( n = 7 \); 12 MPI, \( n = 3 \)), uninfected females (○; 6 MPI, \( n = 5 \); 12 MPI, \( n = 3 \)), infected males (●; 6 MPI, \( n = 4 \); 12 MPI, \( n = 5 \)) and infected females (●; 6 MPI, \( n = 4 \); 12 MPI, \( n = 6 \)). Bar represents the mean. *\( P < 0.05 \), **\( P < 0.01 \), and ***\( P < 0.001 \).](image-url)
IgG2c levels than infected males ($P < 0.05$). Duration of infection also increased IgG2c levels in infected females, with higher levels noted at 12 versus 6 MPI ($P < 0.05$). *H. pylori*-specific IgG1 (Th2) levels were higher in infected than in uninfected animals at 12 MPI ($P < 0.05$). Females had higher Th1/Th2 ratios than males: at 6 MPI, 8.58 vs. 4.01; and at 12 MPI, 12.9 vs. 7.51.

We and others have demonstrated that *H. pylori* levels are inversely correlated with the degree of pathology and the immune response as measured by antibody and cytokine production (25, 27). At 6 MPI, *H. pylori* was detectable by quantitative PCR in all infected males, but not in one female. At 12 MPI, there was a salient difference in levels of *H. pylori* colonization between males and females; *H. pylori* was undetectable in four infected females, but undetectable in only one male (Fig. 3).

**Frequency and Nature of Mutations.** We determined the frequency of gpt point mutations in gastric DNA isolated from infected and uninfected mice by selection of mutants based on 6-TG resistance. Recognizing the possible confounding effect of clonal expansion of sibling mutants (i.e., jackpot mutations), we sequenced the gpt genes from all 556 recovered mutants. Any mutation found to duplicate another at the same site within an individual sample was excluded from subsequent frequency calculations. After this adjustment, at 12 MPI the gpt mutation frequency in infected females ($7.5 \pm 2.0 \times 10^{-6}, P < 0.05$) was significantly (1.6-fold) higher than that in all control animals ($4.7 \pm 1.1 \times 10^{-6}$), whereas the frequency in infected males ($6.3 \pm 5.4 \times 10^{-6}, P = 0.49$) was not. At 6 MPI, gpt mutation frequency in infected animals of either sex ($5.6 \pm 2.0 \times 10^{-6}, P = 0.72$; males, $7.2 \pm 2.2 \times 10^{-6}$, $P = 0.57$) was not significantly different from that of controls ($6.2 \pm 3.0 \times 10^{-6}$; Fig. 4).

After sequencing and accounting for clonal expansion, 236 from infected and 156 mutants from uninfected mice were used to identify effects of *H. pylori* infection on types of mutations causing loss of gpt function, with the results summarized in Table 1 and Table S1. G:C-to-A:T transitions and G:C-to-T:A transversions were the most prevalent types of mutations in both infected and uninfected animals, representing 33% to 50% and 17% to 31%, respectively, of total mutations in various treatment groups; mutant frequencies varied from 2.1 to $3.0 \times 10^{-6}$ in these transitions and 0.9–1.8 $\times 10^{-5}$ in the transversions. The 1.6-fold higher total mutations observed in infected females compared with age-matched controls at 12 MPI was attributable mainly to two types of mutations: 3.8 times more A:T-to-G:C transitions ($P < 0.05$) and 2.0 times more G:C-to-T:A transversions ($P < 0.05$). These two mutations are consistent with the expected mutational spectrum induced by RONS (28) and have been found elevated in another animal model of chronic inflammation (13).

An increase in G:C-to-T:A transversions was also reported in a previous study documenting *H. pylori*-induced mutations (22).

A:T-to-G:C transitions can be formed by deamination of adenosine to hypoxanthine or creation of ethenoadenine. Deamination is mediated by N$_2$O$_3$, the autoxidation product of NO, which directly nitrosates primary amines on DNA bases (28, 29). Hypoxanthine resembles guanine and mispairs with cytosine, resulting in the observed mutation. Alternatively, A:T-to-G:C transitions can also be created indirectly by lipid peroxidation by RONS, forming etheno adducts in DNA such as highly mutagenic ethenoadenine (30, 31). G:C-to-T:A transversions have also been associated with increased iNOS expression levels, pointing to the involvement of RONS (32). Cells cocultivated with activated macrophages predominantly develop G:C-to-T:A transversions caused by exposure to NO, O$_2^\cdot$, and H$_2$O$_2$ (33). G:C-to-T:A transversions are also caused by adducts produced by oxidative stress or lipid peroxidation, such as 8-oxodG, edC, and M1G (34, 35). The presence of 8-oxodG, a major product of oxidative damage to DNA, results in mispairing of guanine with adenine during replication, thus inducing transversions (36). Although 8-oxodG is believed to be the main cause of this mutation, etheno adducts formed by lipid peroxidation may also play a significant role in mutagenesis observed in vivo (37).

**Fig. S3** shows the mutation spectrum detected in the gpt gene, of which the following features are noteworthy. In both uninfected and infected mice, hotspots occurred at nucleotides C64, G110, G115, and G418; C64, G110, and G115 are CpG sites and are known hotspots in this assay (38, 39). Hotspots occurring in infected mice were located at A8, G116, and G143; A8 and G116 were found predominantly in infected females at both 6 and 12 mo, whereas G143, located at a CpG site, was a hotspot in infected animals of both sexes. Uninfected mice had hotspots at G406, G416, and A419, one of which (G416) occurred mainly in males. Mutations in infected males were concentrated mainly in hotspots common to both uninfected and infected animals, whereas in infected females there was an increase in mutations throughout the gpt gene at non-G-C sites. This result suggests that the chemistry of DNA damage in mice with a stronger host response to infection may have differed from that in mice with mild or minimal gastritis.
Effect | Uninfected all (n = 6) | Infected male (n = 4) | Infected female (n = 8) | Uninfected all (n = 14) | Infected male (n = 5) | Infected female (n = 11) |

Data are mean (SD) of mutation frequency data from 411 mutants recovered from the gpt assay after excluding 155 mutants considered siblings. Control mice of both sexes were grouped for this analysis. The mutation frequency of A:T-to-G:C transitions and G:C-to-T:A transversions was significantly elevated in female mice infected with H. pylori for 12 mo. *P < 0.05.

Mutation analysis using the SpI\(^{-}\) assay revealed that the frequency of deletion mutations in gpt of gastric tissue DNA was not significantly affected by H. pylori infection (Fig. 5). Analyses of 57 samples from 32 mice showed that SpI\(^{-}\) mutant frequencies in infected mice at 6 MPI, 4.8 ± 2.5 \times 10^{-6}, \(P = 0.09\); females at 12 MPI, 5.0 ± 2.6 \times 10^{-6}, \(P = 0.30\); males at 6 MPI, 6.3 ± 2.5 \times 10^{-6}, \(P = 0.87\); and males at 12 MPI, 5.2 ± 1.4 \times 10^{-6}, \(P = 0.17\) were not significantly different from those of age-matched controls at either time point (all mice at 6 MPI, 2.9 ± 1.3 \times 10^{-6}; all mice at 12 MPI, 3.6 ± 1.8 \times 10^{-6}).

Current models of inflammation-driven carcinogenesis are based on chronic inflammation inducing mutations that lead to cancer (40, 41). Female mice at 6 MPI had more hyperplasia, epithelial defects, and dysplasia than infected males and age-matched controls, but this increase in pathologic findings was not accompanied by increased frequency of mutations. This was detected only in infected female mice at 12 MPI, which had experienced more severe gastritis for a longer period, suggesting that gastritis is necessary but not sufficient to induce mutagenesis. Similarly, duration of infection in itself was insufficient, as mutation frequency was not increased in male mice at 12 MPI. Based on the GHAI, infected male mice had a weaker response at 6 MPI compared with infected females, whereas by 12 MPI, the level of pathologic process was similar in both sexes. These data suggest that the delayed onset of severe gastric lesions in males reduced the duration of their exposure to chronic gastritis, protecting them from mutagenesis, highlighting the importance of severity and duration of the inflammatory response.

Our findings agree with current paradigms for the role of inflammation in carcinogenesis (4) and with the more severe pathology induced in female versus male C57BL/6 mice infected with Helicobacter spp. (42). Our observations in female gpt delta mice are consistent with previously reported data from female C57BL/6 Big Blue mice infected with H. felis, which induces more severe gastritis at earlier time points than H. pylori, effectively increasing the amount of DNA damage inflicted after infection (23, 43, 44). The higher mutation frequency found at 7 MPI in H. felis-infected female C57BL/6 Big Blue mice may be comparable to that occurring at 12 MPI in female gpt delta mice infected with H. pylori, based on increased inflammation and epithelial proliferation. In contrast, another study of DNA point mutations induced by H. pylori in male Big Blue mice reported that, although mutant frequency was increased at 6 MPI, it returned to control levels by 12 MPI (22). The decrease between 6 and 12 MPI was accompanied by loss of iNOS expression and reversion of the mutation spectrum to one indistinguishable from that of uninfected mice (22). Two possible explanations for these results are that (i) the increase in mutations at 6 MPI may have reflected Jackpot mutations, because clonal expansion was not assessed or (ii) loss of infection resulted in absence of iNOS expression and reversion of the mutation spectrum. An additional factor pertinent to comparisons of previous mutagenesis studies involving gastric infection by Helicobacter spp. is the endogenous Helicobacter status of the mouse colony (45). We recently reported that concurrent, subclinical infection in C57BL/6 mice with non-gastric Helicobacter bilis significantly reduced H. pylori-associated premalignant gastric lesions at 6 and 11 MPI (46). This immunomodulatory effect could affect observed mutagenic responses.
and it is unknown whether Big Blue mice used in previous studies were free of enteric Helicobacter spp.

Our observed sex-based effects on mutagenesis induced by H. pylori in mice has not been reported previously, but sex bias has been found in other responses to infection. In H. pylori–infected Mongolian gerbils, immune responses and cytokine production were reported to be affected by sex (47), and H. pylori preferentially induced cancer in male INS-GAS mice (48).

Greater female susceptibility to gastric Helicobacter infections has been noted previously in WT C57BL/6 mice (42), whereby females infected with H. felis experience an earlier onset of gastric inflammation, epithelial hyperplasia, atrophy, and apoptosis (42). Mechanisms responsible for the observed sex-based effects are incompletely understood, but findings to date collectively indicate that sex is an important variable, affecting strength of the host response to H. pylori infection, which in turn determines disease outcome.

The typical host response to Helicobacter infection is a proinflammatory Th1 response that causes chronic gastritis (49, 50). However, mouse strains such as BALB/c, which mount a strong antiinflammatory Th2 humoral immune response to H. pylori infection, develop less severe disease (51). We have previously shown that modulation of the Th1 response by an increased Th2 response reduces pathology associated with concurrent helminth infections (27). In the current study, the immune response of females to H. pylori infection was biased toward a greater Th1/Th2 ratio compared with males at both 6 and 12 mo. Higher Th1/Th2 ratios reflect a stronger inflammatory response to H. pylori infection. Furthermore, proinflammatory Th17 cells and regulatory T cells have been recently shown to modulate host responses to H. pylori (52, 53). H. pylori–specific Th17 immunity, mediated by IL-17 (54), increases inflammation unless it is suppressed by regulatory T cells, which are up-regulated by TGF-β and IL-10 (53). Higher levels of inflammation, epithelial defects, and atrophy were indeed observed in infected females at 6 MPI. At 12 MPI, the level of serum IgG2c was significantly elevated in infected females, reflective of increased proinflammatory cytokines in the gastric mucosa, and is consistent with the reduction in H. pylori colonization levels. The earlier onset of severe pathologic process caused by the Th1- and Th17-biased response to H. pylori was also associated with the increase in point mutations seen at 12 MPI.

In summary, we have shown that chronic H. pylori infection can cause premalignant gastric lesions and induce point mutations consistent with inflammatory processes. As our data are derived from analysis of nontranscribed DNA, it serves as an indicator of unbiased mutations reflecting genetic changes during the early stages of tumor initiation in inflamed tissues. At 12 mo, H. pylori–infected female C57BL/6 mice accumulate more inflammation-mediated point mutations compared with males as a result of a greater Th1-biased response to infection inducing earlier and more severe pathology. The sex-biased increase in premalignant gastric lesions and induction of mutations highlights the importance of taking into account sex-based effects in future studies of inflammation-driven disease.

**Materials and Methods**

**Bacteria and Animals.** H. pylori strain S51 was grown on blood agar or Brucella broth with 5% FBS as described in SI Materials and Methods. Specific pathogen-free (including Helicobacter spp.) male and female C57BL/6 gpt delta mice (24) were infected by oral gavage with H. pylori S51 or sham-dosed. At the indicated times, mice were euthanized, gastric tissue collected for histopathology and DNA and RNA extraction, and sera were collected for cytokine and Ig analysis. Gastric lesions were scored for inflammation, epithelial defects, atrophy, hyperplasia, mucous metaplasia, hyalinosis, intestinal metaplasia, and dysplasia using previously published criteria (55). The GHAI is the sum of inflammation, epithelial defects, atrophy, hyperplasia, intestinal metaplasia, and dysplasia scores. A detailed description of the husbandry, treatment, and histopathology is provided in SI Materials and Methods.

**DNA isolation and in Vitro packaging.** Genomic DNA was extracted from gastric tissue using RecoverEase DNA Isolation Kit (Stratagene) following the manufacturer’s recommendations. E. coli YG6620 expressing Cre recombinase. Infected cells were cultured on plates containing chloramphenicol (Cm) and 6-TG for 3 d until 6-TG-resistant colonies appeared. To confirm the 6-TG-resistant phenotype, colonies were restreaked on plates containing Cm and 6-TG. Confirmed 6-TG-resistant colonies were cultured, and a 739-bp DNA product containing the gpt gene was amplified by PCR. DNA sequencing of the gpt gene was performed by the Biopolymers Facility at Harvard Medical School. Sequences were aligned with the E. coli gpt gene (GenBank M13422.1) (57) using Geneious (Biomatters). Sequences were classified as transitions, transversions, deletions, insertions, or complex (multiple changes). Duplicate mutations at the same site within an individual tissue were excluded to account for clonal expansion of sibling mutations. More information on primers and methods is provided in SI Materials and Methods.

**gpt assay and Sequencing analysis.** The 6-TG selection assay was performed as previously described (24, 56). Briefly, phages rescued from murine genomic DNA were transfected into E. coli YG6620 expressing Cre recombinase. Infected cells were cultured on plates containing chloramphenicol (Cm) and 6-TG for 3 d until 6-TG-resistant colonies appeared. To confirm the 6-TG-resistant phenotype, colonies were restreaked on plates containing Cm and 6-TG. Confirmed 6-TG-resistant colonies were cultured, and a 739-bp DNA product containing the gpt gene was amplified by PCR. DNA sequencing of the gpt gene was performed by the Biopolymers Facility at Harvard Medical School (Boston, MA) with Ampicillin (Agencourt) and a 3730XL DNA Analyzer (Applied Biosystems). Sequences were aligned with the E. coli gpt gene (GenBank M13422.1) (57) using Geneious (Biomatters). Mutations were classified as transitions, transversions, deletions, insertions, or complex (multiple changes). Duplicate mutations at the same site within an individual tissue were excluded to account for clonal expansion of sibling mutations. More information on primers and methods is provided in SI Materials and Methods.

**H. pylori detection.** H. pylori levels in the gastric mucosa were quantified by real-time quantitative PCR assay of gastric DNA as described in SI Materials and Methods. A threshold of 15 copies of the H. pylori genome was set as the lower limit for a positive sample.

**Serum IgG isotype measurement.** Sera were analyzed for H. pylori-specific IgG2c and IgG1 by ELISA. Additional information on the measurements is provided in SI Materials and Methods.

**Statistical analysis.** Two-way ANOVA followed by Bonferroni posttests were used to analyze GHAI and mRNA expression values. Student two-tailed t tests were used to analyze mutant and mutation frequency data and serum IgG isotypes. Poisson distribution analysis was used to determine hotspots at a 99% confidence level (58). For some analyses, age-matched controls of both sexes were grouped when no statistical differences were detected between sexes. Analyses were done with GraphPad Prism, version 4.0, or Microsoft Excel 2002. P < 0.05 was considered significant.

**ACKNOWLEDGMENTS.** We thank Sureshkumar Muthupalani for help with the histological images and Laura J. Trudel for assistance with the manuscript and figures. This study is dedicated in loving memory of David Schauer, a mentor and a friend, for his contribution in the design and analysis of this work. This work was supported by National Institutes of Health Grants R01-AI037750 and P01-CA026731 and Massachusetts Institute of Technology Center for Environmental Health Sciences Program Project Grant P30-ES02109.
