I. INTRODUCTION

Heavy-ion collisions at ultrarelativistic energies produce strongly interacting matter under extreme conditions. The main goal is to create in these reactions a state in which the confinement of quarks and gluons inside hadrons is no longer effective, the so-called quark-gluon plasma. This strongly compressed matter undergoes a rapid expansion with a drop of temperature and energy density. Two-particle momentum correlations provide unique information on the size and dynamic evolution of this fireball and are therefore a widely employed observable in heavy-ion physics. Usually, correlations of identical charged pions are studied which, due to the high available statistics, allow a multidimensional study of radius parameters [1–3]. Less frequently, two-proton correlations are analyzed [4–7], although only one-dimensionally. Moreover, the large abundance of strange particles produced in heavy-ion collisions allows us to study also two-particle correlations between pairs of strange particles or pairs of strange and nonstrange particles. For example, the correlations of identical kaons were investigated at the CERN Super Proton Synchrotron (SPS) [8] as well as at the BNL Relativistic Heavy Ion Collider (RHIC) [9]. In this paper we report on the measurement of the $p$-$\Lambda$ correlation function in central Pb+Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV at the CERN SPS.
It was suggested that also the momentum correlation between $\Lambda$ and protons can be employed to measure the size of the emitting source [10]. The correlation function of $p-$$\Lambda$ pairs is only affected by the strong interaction between the particles. This distinguishes $p-$$\Lambda$ correlations from the two-proton case, for which the correlation function is dominated by the repulsive Coulomb interaction and the Fermi-Dirac statistics at low relative momenta. Both effects are absent in the $p-$$\Lambda$ correlation function, which should therefore be more sensitive to large source sizes [10]. However, the knowledge of the strong interaction between protons and $\Lambda$ is necessary to relate the strength of the correlation to the size of the emitting source. There is a substantial subset of data available on low-energy elastic $\Lambda p$ scattering [11–13], and on $K^-d \rightarrow \Lambda p\pi^-$ [14–16], as well as $pp \rightarrow pK^+\Lambda$ [17,18] reactions. Also $\Lambda$ hypernuclei provide important information on the $\Lambda$ nucleon interaction. Based on these data, many theoretical analyses have derived $p-$$\Lambda$ scattering lengths and effective interaction ranges [19–25], which can be used to calculate the $p-$$\Lambda$ correlation function.

A preliminary study by the NA49 experiment at the SPS was reported in Ref. [26]. Here we describe the final results of a new and improved analysis [27]. Similar studies of $p-$$\Lambda$ correlations in heavy-ion collisions were performed at lower [7,28] and higher [29] center-of-mass energies, allowing the investigation of the evolution of $p-$$\Lambda$ correlations with $\sqrt{s_{NN}}$.

II. DATA ANALYSIS

The data presented here were measured by the NA49 experiment at the CERN SPS. A detailed description of the experimental setup can be found in Ref. [30]. Charged particles produced by interactions of the Pb beam in a thin Pb-foil target are tracked with four large-volume time projection chambers (TPCs). Two TPCs are placed inside two superconducting dipole magnets, while the other two are situated outside of the magnetic field. Since the latter measure long pieces of the particle tracks, they allow a precise determination of the specific energy loss $dE/dx$ inside the detector gas (typical resolution of 4 %) and thus particle identification in a large region of phase space. Additional particle identification is provided around midrapidity by time-of-flight detectors. A zero degree calorimeter is used to measure the energy in the projectile fragmentation region from which the centrality of the reaction can be deduced. This analysis is based on $2.8 \times 10^6$ Pb+Pb events at $\sqrt{s_{NN}} = 17.3$ GeV recorded in the year 2000, which cover the 23.5% most central part of the total inelastic cross section, corresponding to an averaged number of wounded nucleons of $\langle N_w \rangle = 262$.

A. $\Lambda$ reconstruction

The $\Lambda$ hyperons are detected via their charged decay $\Lambda \rightarrow p\pi^-$, using the same methods as described in Refs. [31,32]. The $\Lambda$ reconstruction is done by forming pairs of positively and negatively charged tracks and extrapolating them toward the main interaction vertex. The positively (negatively) charged tracks are required to have at least 50 (30) reconstructed points. Pairs with a distance of closest approach of less than 0.5 cm anywhere between the position of the first measured point on the tracks and the target plane are considered as $V^0$ candidates. Assigning proton and pion masses to the positively and negatively charged decay particle, the invariant mass of a $\Lambda$ candidate is calculated. A significant reduction of the combinatorial background can be achieved by applying several selection criteria to the $\Lambda$ candidates. In this analysis, it is required that the secondary vertex is separated by at least 25 cm in the beam (z) direction from the target plane. Additionally, the back extrapolation of the flight path of the $\Lambda$ candidate must not deviate from the interaction vertex position in the transverse directions $x$ and $y$ by more than $|\Delta x| = 0.75$ cm and $|\Delta y| = 0.375$ cm. The signal-to-background ratio is further improved by enriching the protons in the sample of positively charged tracks by applying a momentum-dependent cut on the measured energy loss ($dE/dx$). An additional $dE/dx$ cut on the negatively charged tracks also allows the rejection of electrons from photon conversions.

An important point with respect to correlation studies is the requirement that each $\Lambda$ candidate must be unique. If it happens that a daughter track of a given $\Lambda$ candidate is also assigned to another one, a strong artificial correlation between both candidates is created which in turn affects the measured $p-$$\Lambda$ correlation function. In this analysis it is therefore ensured that any given track is used only once as a daughter track. Similarly, $\Lambda$ daughters that were not reconstructed as a single track, but as two track pieces (split tracks), will cause a distortion of the measured correlation function. To exclude these tracks it is required that the number of measured points of each accepted track is higher than 50% of the number of points that this track could maximally have according to its trajectory in the TPCs.

Figure 1 shows the distribution of invariant mass $m_{\text{inv}}$ of $\Lambda$ candidates obtained after assigning the proton ($p\pi^-$) mass to the positive (negative) daughter track for two intervals of the center-of-mass rapidity $y$ and transverse momentum $p_t$. $\Lambda$ are accepted in a mass window $m_0 - \Delta m < m < m_0 + \Delta m$ of a half-width of $\Delta m = 2$ MeV/$c^2$, where $m_0 = 1.115683$ GeV/$c^2$ is the literature value for the $\Lambda$ mass [33]. This mass window...
was chosen in order to optimize the signal-to-background ratio and reduce the corrections for the signal purity.

The ratio between signal and background inside this mass window and with it the purity of the $\Lambda$ sample vary over phase space. A $\chi^2$ fit to the invariant mass distributions in different $y$ and $p_t$ bins was performed in order to determine the relative contributions. The fit function used is the sum of a polynomial for the combinatorial background and a function for the $\Lambda$ signal. The measured shape of the $\Lambda$ signal results from a convolution of the resolutions for the single track momenta and the secondary vertex positions and is found to be well described by an asymmetric Lorentz curve. By subtracting the background function from the measured invariant mass distribution, the number of real $\Lambda$ is determined. Defining the purity $P_\Lambda$ by the ratio of the number of real $\Lambda$ to the number of accepted $\Lambda$ candidates in the chosen mass window, one obtains the result shown in Fig. 2. The phase-space averaged value of the $\Lambda$ purity is $\langle P_\Lambda \rangle = 69\%$.

### B. Proton reconstruction

Protons are identified via their energy loss $dE/dx$ as measured in the two main TPCs. A valid proton track is required to have at least 50 reconstructed points. An additional cut on the impact parameters in the target plane ($|b_x| < 5.0$ cm, $|b_y| < 2.0$ cm) reduces the contribution from secondary tracks. To assign the probability of being a proton to a given track, the energy loss spectra measured in bins of total momentum $p$ are fitted by a sum $E(x, p)$ of asymmetric Gaussians using a $\chi^2$ minimizing procedure [34]:

$$E(x, p) = \sum_{i=d, p, K, \pi, e} \frac{A_i(p)}{\sum_i n_i} \frac{1}{\sqrt{2\pi} \sigma_i(p)} \frac{n_i}{\sqrt{i}} \exp \left[ -\frac{1}{2} \frac{x - \hat{x}_i(p)}{1 \pm \delta \sigma_i(p)}^2 \right] .$$

(1)

Here, $A_i(p)$ denotes the yield for particle type $i$, $n_i$ the number of tracks in a given track length interval $l$, $\hat{x}_i(p)$ the most probable $dE/dx$ values for particle type $i$, $x$ the measured $dE/dx$ value of the track under consideration, $\sigma_i(p)$ the width of the Gaussian, and $\delta$ the asymmetry parameter.

The parameters $A_i(p)$, $\hat{x}_i(p)$, and $\sigma_i(p)$ are determined by the fitting procedure in each $p$ bin separately. The widths for the other particle types and different track length bins are derived from the parameter $\sigma_\pi(p)$ for pions: $\sigma_{i,l}(p) = \sigma_\pi(p)(\hat{x}_i/\delta\pi)^\alpha(1/\sqrt{l})$. The exponent was determined to be $\alpha = 0.625$ and the parameter $\delta$ is fixed to 0.065. Results of the fit procedure for two different total momentum bins are shown in Fig. 3. Since for low particle momenta the energy loss curves of different particle species cross each other and particle identification is thus not possible, a lower cut on the total momentum of $p > 4$ GeV/c is applied. To also exclude the region of the Fermi plateau, momenta above 50 GeV/c are discarded. Based on these fits, a momentum-dependent cut on the measured $dE/dx$ values for single tracks is defined such that the accepted tracks always have the same probability of being a proton. For the standard analysis, this probability is set to 80%, equivalent to a constant proton purity $P_p = 0.8$. As in the case of the $\Lambda$ decay daughters, it is ensured that split tracks are removed from the track sample by rejecting tracks that have less than 55% of the number of geometrically possible points.

### C. Determination of the $p-$ correlation function

The selected $\Lambda$ and proton candidates are then combined to form $p-$ pairs. To avoid trivial autocorrelations, a track that is used to reconstruct the $\Lambda$ candidate is removed from the primary proton sample. The pair distribution $S(q_{\text{inv}})$ is measured as a function of the generalized invariant relative momentum of the $p-$ pair $q_{\text{inv}}$, which is defined as the modulus of $\vec{q} = q - P(q P)/P^2$, with $q = p_p - p_\Lambda$, $P = p_p + p_\Lambda$, and $q P = m_\Lambda^2 - m^2$. Here, $p_p$ and $p_\Lambda$ are the four-momenta of the proton and the $\Lambda$. In the two-particle center-of-mass system, $\vec{q}$ reduces to $[0, 2k^*]$, with $2k^*$ being the three-momentum difference in this reference frame [35].

An event-mixing method that combines proton and $\Lambda$ candidates taken from different events is employed for the

FIG. 2. (Color online) Purity $P_\Lambda(y, p_t)$ of the selected $\Lambda$ candidates as function of rapidity $y$ and transverse momentum $p_t$.
feed-down originates from \( /Xi_1 \) for the resulting \( N \) and \( \Lambda \) decays happen long after the thermal freeze-out and will thus imply that these decay particles are not correlated, because the momentum resolution for a pair is applied for real pairs as well as for the mixed event setup using the GEANT 3.21 package \[37\]. The response of the generated particles are followed through the NA49 detector via a simulation procedure. \( \Lambda \), \( \Xi^- \), and \( \Sigma^0 \) are generated according to their measured phase-space distributions \[31\]. The measured \( \Lambda \) include the \( \Sigma^0 \) which cannot be separated experimentally. Therefore the \( \Sigma^0 \) input distribution is identical to the one of \( \Lambda \), while its yield is estimated using the \( \Sigma^0/(\Lambda + \Sigma^0) \) yield ratio from statistical model fits \[36\]. For the \( \Xi^- \), the same input distributions are assumed as for the \( \Xi^- \) scaled by the ratio \( \Xi^-/\Xi^- \) of the total multiplicities also taken from statistical model fits \[36\]. The daughter tracks of the generated particles are followed through the NA49 detector setup using the GEANT 3.21 package \[37\]. The response of the TPCs to the traversing particles is simulated with NA49 specific software. In a next step, the simulated raw signals are added to measured raw data and processed by the same reconstruction program as used for the experimental data. By applying the same cuts as in the normal analysis, the feed-down contributions to the measured \( \Lambda \) and \( \Sigma^- \) are determined. The \( y \) and \( p_t \) dependences of the feed-down fractions \( F_p(y, p_t) \) and \( F_\Lambda(y, p_t) \) are summarized in Fig. 5. The phase-space averaged values are \( F_p = 22\% \) and \( F_\Lambda = 43\% \).

The final \( p-\Lambda \) correlation function \( C_{corr}(q_{inv}) \) results from the measured \( C_{meas}(q_{inv}) \) by applying a combined correction factor \( \langle K(q_{inv}) \rangle \) for purity and feed-down. This factor is determined by averaging the product \( P_p(y, p_t) P_\Lambda(y, p_t) \) \( [1 - F_p(y, p_t)] [1 - F_\Lambda(y, p_t)] \) over all reconstructed \( p-\Lambda \) pair combinations falling into a given bin of relative momentum \( q_{inv} \). The corrected correlation function thus follows from

\[
C_{corr}(q_{inv}) = \frac{C_{meas}(q_{inv}) - 1}{\langle K(q_{inv}) \rangle} + 1. \tag{3}
\]

III. RESULTS

In total, 70,920 \( p-\Lambda \) pair candidates, corresponding to 17,520 real \( p-\Lambda \) pairs (i.e., after correcting for purities and feed-down), with \( q_{inv} < 0.2 \) GeV were measured. Dividing the signal distribution by the event-mixing background and correcting with the purities and feed-down contribution according to Eqs. (2) and (3) yields the final \( p-\Lambda \) correlation.
The necessary prerequisite is a quantitative knowledge of the emitting source \[10\], it can be used to extract its radius. It was shown by Wang and Pratt to depend on the size of the source: \[ S \]

Under the assumption of unpolarized particle production, the relative contribution of pairs in the singlet and the triplet state is \( 1:3 \). Furthermore, we use the same spherically symmetric Gaussian spatial distribution as quoted in Ref. \[29\]. By fitting it to the data, we obtain the effective radius parameter \( R_G \) as a free parameter, which reduces the resulting error. With this constraint, we obtain \( R_G = 3.02 \pm 0.20(\text{stat.}) \) fm (blue solid line in Fig. 6).

**A. Fit to theoretical calculation**

Since the shape of the momentum correlation function was shown by Wang and Pratt to depend on the size of the emitting source \[10\], it can be used to extract its radius. We obtain the effective radius parameter \( R_G \) as a free parameter, which reduces the resulting error. With this constraint, we obtain \( R_G = 3.02 \pm 0.20(\text{stat.}) \) fm (blue solid line in Fig. 6).

**B. Systematic uncertainties**

Systematic errors arise both in the extraction of the correlation function and in the theoretical model. The former uncertainties were studied by making small changes in the analysis procedure. By varying the corresponding cuts on the measured energy loss used to identify the primary protons, as well as the decay protons of the \( \Lambda \) candidates, the particle purities \( P_y(\gamma, p) \) and \( P_x(\gamma, p, \Lambda) \) can be varied to a certain extent. This changes the measured correlation function \( C_{\text{corr}}(q_{\text{inv}}) \). However, after applying the appropriate correction factor \( K(q_{\text{inv}}) \), the same corrected correlation function should be obtained. Figure 7 shows comparisons of \( C_{\text{corr}}(q_{\text{inv}}) \) for different proton [Fig. 7(a)] and \( \Lambda \) purities [Fig. 7(b)]. Even though the correction factor changes quite dramatically (\( \approx 45\% \) in the case of the proton purity), the resulting correlation functions agree quite well. The systematic error on the effective radius parameter \( R_G \) is derived by taking the maximum difference of \( R_G \) as obtained by fits to the different correlation functions. It is found that it changes between 2.91 and 3.28 fm (2.98 and 3.29 fm), if the proton (\( \Lambda \)) purity is varied between 50\% and 90\% (64\% and 72\%).

A similar study is performed by varying the feed-down contribution by changing the cuts on the impact parameters \( b_x \) and \( b_y \) (\( \Delta x \) and \( \Delta y \)) of the proton tracks [Fig. 7(c)] and \( \Lambda \) candidates [Fig. 7(d)]. One finds that \( R_G \) changes at most between 3.02 and 3.13 fm (2.92 and 3.23 fm), if the both parameters are left to vary freely, the best fit is obtained for \( R_G = 2.70 \pm 0.60(\text{stat.}) \) fm and \( \lambda = 0.77 \pm 0.38(\text{stat.}) \) (green dashed line in Fig. 6). The agreement within errors of the fitted \( \lambda \) value with unity underlines the consistency of the correction procedure. This justifies fixing \( \lambda = 1 \) and using only \( R_G \) as a free parameter, which reduces the resulting error. With this constraint, we obtain \( R_G = 3.02 \pm 0.20(\text{stat.}) \) fm (blue solid line in Fig. 6).
contributions to the protons (Λ) from feed-down is varied between 17% and 25% (39% and 46%).

The dependence of the radius parameter on the region in $q_{\text{cm}}$ that is used to determine the normalization constant $N$ [see Eq. (2)] is investigated by varying the size and position of this region. It is found that $R_G$ changes by at most ±0.11 fm.

By taking the quadratic sum of the different contributions, a total systematic error on $R_G$ of +0.44 and −0.16 fm is estimated.

Another source of systematic uncertainty of the extracted radius parameter arises from the limited precision of the knowledge of the scattering lengths and effective ranges used in the calculation of the theoretical correlation function. Therefore, the fits were repeated with $d_0^s$, $d_1^0$, $f_0^s$, and $f_0^T$ taken from Refs. [17,18,20,22,23,25,35]. The largest deviation from the $R_G$ value obtained with the standard parameter set [10] is observed when using the parameters extracted by the COSY-11 Collaboration [17]. While in all other cases the difference is smaller than ±0.1 fm, it is found to be +0.274 fm for the COSY-11 parameters, which is still close to our statistical error. Therefore we conclude that the choice of the parameters describing the $p$-Λ interaction has a negligible effect on the final result.

C. Energy dependence of the effective radius parameter

The result of this study is compared to data at lower and higher center-of-mass energies in Fig. 8. Good agreement with the effective radius parameters measured for central Au+Au collisions by the E895 Collaboration at $\sqrt{s_{NN}} = 3.83$ GeV [7] and by the STAR experiment at $\sqrt{s_{NN}} = 200$ GeV [29] is observed, indicating that there is no significant change from BNL Alternating Gradient Synchrotron energies to RHIC energies. A similar observation was made for correlations of identical charged pions [3].

![FIG. 8. (Color online) Effective radius parameter $R_G$ for $p$-Λ correlations as a function of center-of-mass energy $\sqrt{s_{NN}}$. The figure also includes data on Ar+KCl collisions by the HADES Collaboration [28] and on central Au+Au collisions by the E895 [7] and STAR [29] experiments. The systematic errors are represented by the brackets. Please note that the STAR result corresponds to a slightly higher pair $(m_i)$ than for the NA49 measurement. Assuming the $(m_i)$ dependence shown in Fig. 9, the STAR data point would move up by $\approx 6\%$, if it was measured at the same $(m_i)$.](image)

At even lower energies ($\sqrt{s_{NN}} = 2.61$ GeV), the HADES Collaboration measured a significantly smaller effective radius parameter for $p$-Λ correlations of $R_G = 2.09 ± 0.16$(stat.) fm [28]. However, the fireball volume in the case of Ar+KCl collisions is expected to be smaller than for Pb+Pb and Au+Au collisions. In fact, it was demonstrated in Ref. [28] that the measured $p$-Λ radius parameter is dominated by the reaction geometry and scales approximately as $A^{1/3}$, irrespective of center-of-mass energy. A comparable observation was previously made for two-proton correlations in the target fragmentation region [6].

D. $(m_i)$ dependence of the effective radius parameter

Figure 9 shows a comparison of $R_G$, as determined in this analysis from the $p$-Λ correlation function, to radius parameters derived from correlations of $\pi^-$ pairs [3] and charged kaon pairs [8], as well as from two-proton correlations [4], at different average transverse masses $(m_i)$. For the $\pi^-\pi^-$ and $KK$ correlations, $R_G$ was calculated from the three-dimensional radius parameter components as

$$ R_G = (R_{\text{side}} R_{\text{out}} R_{\text{long}})^{1/3}. $$

The decrease of the effective radius parameters with increasing transverse mass is generally attributed to the presence of collective flow in the fireball. The measurement of the $p$-Λ correlation allows us to extend this study to higher $(m_i)$. In fact, $R_G$ for $p$-Λ pairs is significantly smaller than the effective radius parameter extracted for pions and kaons at lower $(m_i)$ and is thus in agreement with the expected behavior. The dashed curve in Fig. 9 corresponds to a simple $\propto (m_i)^{-1/2}$ dependence. The solid line is based on the following $m_i$ dependences of the three radius components, as suggested by hydrodynamical approaches [39–41]:

$$ R_{\text{side}}^2 = R^2_{\text{geo}} / \left[ 1 + (m_i / T) \eta_f^2 \right], $$

$$ R_{\text{out}}^2 = R_{\text{side}}^2 + \beta_i^2 \Delta \tau^2, $$

$$ R_{\text{long}}^2 = \tau_0^2 (T / m_i). $$

![FIG. 9. (Color online) Effective radius parameter $R_G$ extracted from the correlation functions of $\pi^-\pi^-$ [3], $K^+K^+$ and $K^-K^-$ [8], $pp$ [4], and $p$-Λ pairs $(m_i)$ as measured by NA49 for central Pb+Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV. The systematic errors are represented by the brackets. For explanation of curves, see text.](image)
Here $R_{\text{geo}}$ is the transverse size of the particle source, $\beta_t = v_f/c$ the transverse flow velocity, $\eta_f$ the transverse flow rapidity $\eta_f = (1/2) \log((1 + v_f)/(1 - v_f))$, $T$ the kinetic freeze out temperature, $\tau_0$ the total lifetime of the source, and $\Delta \tau$ the emission duration. Under the assumption that all particle species freeze out from the same expanding source, we calculate $R_G$ from Eq. (6), using Eqs. (7)–(9). The solid curve in Fig. 9 corresponds to the parameter $\eta_f = 0.8$, $\tau_0 = 0.6$ fm/c, $\Delta \tau = 3.4$ fm/c, and $T = 90$ MeV, as extracted by fits with a blast-wave model to the pion correlations [3]. The overall normalization has been adjusted to fit the data. A reasonable description of the effective radius parameters for most particle species can thus be achieved, with the notable exception of the two-proton correlation.

IV. SUMMARY

We report on the measurement of the $p$-$\Lambda$ correlation function in momentum space for central Pb+Pb collisions at $\sqrt{s_{NN}}=17.3$ GeV. The $p$-$\Lambda$ pairs exhibit a clear positive correlation for small relative momenta. By comparison to a calculated correlation function, a one-dimensional Gaussian source size parameter of $R_G = 3.02 \pm 0.20$ (stat.)$^{+0.44}_{-0.16}$ (syst.) fm is determined. This value is in good agreement with measurements for Au+Au collisions at lower and higher center-of-mass energies. The $\langle m_3 \rangle$ dependence of the effective $p$-$\Lambda$ radius parameter follows the expectation for an expanding source as described by hydrodynamics, when compared to other two-particle correlation results.
