Jet production in PbPb collisions at a nucleon-nucleon center-of-mass energy of 2.76 TeV was studied with the Compact Muon Solenoid (CMS) detector at the LHC, using a data sample corresponding to an integrated luminosity of 6.7 $\mu$b$^{-1}$. Jets are reconstructed using the energy deposited in the CMS calorimeters and studied as a function of collision centrality. With increasing collision centrality, a striking imbalance in dijet transverse momentum is observed, consistent with jet quenching. The observed effect extends from the lower cutoff used in this study ($p_T = 120$ GeV/c) up to the statistical limit of the available data sample ($p_T \approx 210$ GeV/c). Correlations of charged particle tracks with jets indicate that the momentum imbalance is accompanied by a softening of the fragmentation pattern of the second most energetic, away-side jet. The dijet momentum balance is recovered when integrating low transverse momentum particles distributed over a wide angular range relative to the direction of the away-side jet.

I. INTRODUCTION

High-energy collisions of heavy ions allow the fundamental theory of the strong interaction—quantum chromodynamics (QCD)—to be studied under extreme temperature and density conditions. A new form of matter [1–4] formed at energy densities above $\sim 1$ GeV/fm$^3$ is predicted in lattice QCD calculations [5]. This quark-gluon plasma (QGP) consists of an extended volume of deconfined and chirally symmetric quarks and gluons.

Heavy ion collisions at the Large Hadron Collider (LHC) are expected to produce matter at energy densities exceeding any previously explored in experiments conducted at particle accelerators. One of the first experimental signatures suggested for QGP studies was the suppression of high-transverse-momentum ($p_T$) hadron yields resulting from energy loss suffered by hard-scattered partons passing through the medium [6]. This parton energy loss is often referred to as “jet quenching.” The energy lost by a parton provides fundamental information on the thermodynamical and transport properties of the traversed medium, which is now believed to be strongly coupled as opposed to an ideal gas of quarks and gluons (for recent reviews, see Refs. [7,8]).

Results from nucleus-nucleus collisions at the Relativistic Heavy Ion Collider (RHIC) [9–12] have shown evidence for the quenching effect through the suppression of inclusive high-$p_T$ hadron production and the modification of high-$p_T$ dihadron angular correlations when compared to the corresponding results in much smaller systems, especially proton-proton collisions. Preliminary results for fully reconstructed jets at RHIC, measured in AuAu collisions at $\sqrt{s_{NN}} = 200$ GeV [13–16], also hint at broadened jet shapes due to medium-induced gluon radiation.

Studying the modification of jets has long been proposed as a particularly useful tool for probing the QGP properties [17,18]. Of particular interest are the dominant “dijets,” consisting of the most energetic (“leading”) and second most energetic (“subleading”) jets. At leading order (LO) and in the absence of parton energy loss, the two jets have equal $p_T$ with respect to the beam axis and are emitted very close to back to back in azimuth ($\Delta \phi_{\text{dijet}} = |\phi_{\text{jet1}} - \phi_{\text{jet2}}| \approx \pi$). However, medium-induced gluon emission can significantly alter the energy balance between the back-to-back jets and may give rise to large deviations from $\Delta \phi_{\text{dijet}} \approx \pi$ [7,19–27]. Such medium effects in nuclear interactions are expected to be much larger than those due to higher-order gluon radiation, which is also present for jet events in proton-proton (pp) collisions. The study of medium-induced modifications of dijet properties can therefore shed light on the transport properties of the QCD medium formed in heavy-ion collisions.

The dijet analysis presented in this paper was performed using the data collected in 2010 from PbPb collisions at a nucleon-nucleon center-of-mass energy of $\sqrt{s_{NN}} = 2.76$ TeV at the Compact Muon Solenoid (CMS) detector. The CMS detector has a solid angle acceptance of nearly 4$\pi$ and is designed to measure jets and energy flow, an ideal feature for studying heavy-ion collisions. A total integrated (PbPb) luminosity of 8.7 $\mu$b$^{-1}$ was collected, of which 6.7 $\mu$b$^{-1}$ has been included in this analysis. Recently, related results on a smaller data sample (1.7 $\mu$b$^{-1}$) have been reported by ATLAS [28].

Jets were reconstructed based on their energy deposits in the CMS calorimeters. In general, it is expected that the jet quenching effect on partons traversing the medium with different path lengths will lead to modifications in the observed dijet energy balance due to radiated energy which can fall outside the definition of the jet cone. Such unbalanced events are easy to detect visually even at the level of event displays, and numerous examples were in fact seen during the first days of data taking (e.g., Fig. 1).
The data provide information on the evolution of the dijet imbalance as a function of both collision centrality (i.e., the degree of overlap of the two colliding nuclei) and the energy of the leading jet. By correlating the dijets detected in the calorimeters with charged hadrons reconstructed in the high-resolution tracking system, the modification of the jet fragmentation pattern can be studied in detail, thus providing a deeper insight into the dynamics of the jet quenching phenomenon.

The paper is organized as follows: The experimental setup, event triggering, selection and characterization, and jet reconstruction are described in Sec. II. Section III presents the results and a discussion of systematic uncertainties, followed by a summary in Sec. IV.

II. EXPERIMENTAL METHOD

The CMS detector is described in detail elsewhere [29]. The calorimeters provide hermetic coverage over a large range of pseudorapidity $|\eta| < 5.2$, where $\eta = -\ln[\tan(\theta/2)]$ and $\theta$ is the polar angle relative to the particle beam. In this study, jets are identified primarily using the energy deposited in the lead-tungstate crystal electromagnetic calorimeter (ECAL) and the brass and scintillator hadron calorimeter (HCAL) covering $|\eta| < 3$. In addition, a steel and quartz-fiber Cherenkov calorimeter, called hadron forward (HF), covers the forward rapidities $3 < |\eta| < 5.2$ and is used to determine the centrality of the PbPb collision. Calorimeter cells are grouped in projective towers of granularity in pseudorapidity and azimuthal angle given by $\Delta\eta \times \Delta\phi = 0.087 \times 0.087$ at central rapidities, having a coarser segmentation approximately twice as large at forward rapidities. The central calorimeters are embedded in a solenoid with 3.8 T central magnetic field. The event display shown in Fig. 1 illustrates the projective calorimeter tower granularity over the full pseudorapidity range. The CMS tracking system, located inside the calorimeter, consists of pixel and silicon-strip layers covering $|\eta| < 2.5$, and provides track reconstruction down to $p_T \approx 100$ MeV/c, with a track momentum resolution of $\sim 1\%$ at $p_T = 100$ GeV/c. A set of scintillator tiles, the beam scintillator counters (BSC), are mounted on the inner side of the HF calorimeters for triggering and beam-halo rejection. CMS uses a right-handed coordinate system, with the origin located at the nominal collision point at the center of the detector, the $x$ axis pointing toward the center of the LHC ring, the $y$ axis pointing up (perpendicular to the LHC plane), and the $z$ axis along the counterclockwise beam direction. The detailed Monte Carlo (MC) simulation of the CMS detector response is based on GEANT4 [30].

A. Data samples and triggers

The expected cross section for hadronic inelastic PbPb collisions at $\sqrt{s_{NN}} = 2.76$ TeV is 7.65 b, corresponding to the chosen Glauber MC parameters described in Sec. II C. In addition, there is a sizable contribution from large impact parameter ultra-peripheral collisions (UPCs) that lead to the electromagnetic breakup of one or both of the Pb nuclei [31]. As described later, the few UPC events which pass the online event selection are removed in the offline analysis.

For online event selection, CMS uses a two-level trigger system: level-1 (L1) and high level trigger (HLT). The events for this analysis were selected using an inclusive single-jet trigger that required a L1 jet with $p_T > 30$ GeV/c and a HLT jet with $p_T > 50$ GeV/c, where neither $p_T$ value was corrected for the $p_T$-dependent calorimeter energy response discussed in Sec. II D. The efficiency of the jet trigger is shown in Fig. 2(a) for leading jets with $|\eta| < 2$ as a function of their corrected $p_T$. The efficiency is defined as the fraction of triggered events out of a sample of minimum bias events (described below) in bins.
OBSERVATION AND STUDIES OF JET QUENCHING IN

PHYSICAL REVIEW C

84, 024906 (2011)

Corrected leading jet $p_T$.

In addition to the jet data sample, a minimum bias event sample was collected using coincidences between the trigger signals from the $+z$ and $-z$ sides of either the BSC or the HF. This trigger has an efficiency of more than 97% for hadronic inelastic PbPb collisions. In order to suppress non-collision related noise, cosmic rays, double-firing triggers, and beam backgrounds, the minimum bias and jet triggers used in this analysis were required to fire in time with the presence of both colliding ion bunches in the interaction region. It was checked that the events selected by the jet trigger described above also satisfy all triggers and selections imposed for minimum bias events. The total hadronic collision rate varied between 1 and 210 Hz, depending on the number of colliding bunches (between $1 \times 1$ and $129 \times 129$) and on the bunch intensity.

B. Event selection

In order to select a pure sample of inelastic hadronic collisions for analysis, a number of offline selections were applied to the triggered event sample, removing contaminations from UPC events and non-collision beam backgrounds (e.g., beam gas). Table I shows the number of events remaining after the various selection criteria are applied. First, beam-halo events were vetoed based on the timing of the $+z$ and $-z$ BSC signals. Then, to veto UPC and beam-gas events, an offline HF coincidence of at least three towers on each side of the interaction point was required, with a total deposited energy of at least 3 GeV. Next, a reconstructed vertex was required with at least two tracks of $p_T > 75$ MeV/c, consistent with the transverse beam spot position and the expected collision region along the $z$ axis. Finally, to further reject beam-gas and beam-scraping events, the length of pixel clusters along the beam direction were required to be compatible with particles originating from the primary vertex. This last selection is identical to the one used for the study of charged hadron pseudorapidity density and $p_T$ spectrum in 7 TeV pp collisions [32]. Figure 2(b) shows the correlation between the total energy deposited in the HF calorimeters and the number of hits in the first layer of the silicon pixel barrel detector after these event selections. A tight correlation between the two detectors is observed, with very few of the events showing HF energy deposits that deviate significantly (at any given number of pixel hits) from the expectations for hadronic PbPb collisions. This correlation is important to verify the selection

of a pure collision event sample, and also to validate the HF energy sum as a measure of event centrality (Sec. II C).

Starting from inelastic hadron collisions based on the selections described above, the basic offline selection of events for the analysis is the presence of a leading calorimeter jet in the pseudorapidity range of $|\eta| < 2$ with a corrected jet $p_T > 120 \text{ GeV}/c$ (corrected for the $p_T$-dependent calorimeter energy response). By selecting these leading jets we avoid possible biases due to inefficiencies close to the trigger threshold. Furthermore, the selection of a rather large leading jet momentum expands the range of jet momentum imbalances that can be observed between the leading and subleading jets, as the subleading jets need a minimum momentum of $p_T > 35–50 \text{ GeV}/c$ to be reliably detected above the high-multiplicity underlying event in PbPb collisions (Sec. II D). In order to ensure high-quality dijet selection, kinematic selection cuts were applied. The azimuthal angle between the leading and subleading jet was required to be at least $2\pi/3$. Also, we require a minimum $p_T$ of $p_{T,1} > 120 \text{ GeV}/c$ for leading jets and of $p_{T,2} > 50 \text{ GeV}/c$ for subleading jets. No explicit requirement is made either on the presence or absence of a third jet in the event. Prior to jet finding on the selected events, a small contamination of noise events from ECAL and HCAL was removed using signal timing, energy distribution, and pulse-shape information [33,34]. As a result, $\sim 2.4\%$ of the events were removed from the sample.

### C. Centrality determination

For the analysis of PbPb events, it is important to know the “centrality” of the collision, i.e., whether the overlap of the two colliding nuclei is large or small. In this analysis, the observable used to determine centrality is the total energy from both HF calorimeters. The distribution of the HF signal used in this analysis is shown in Fig. 3(a). The shape of the energy distribution is characteristic of all observables related to (soft) particle production in heavy-ion collisions. The more frequent peripheral events with a large impact parameter produce very few particles, while the central ones with a small impact parameter produce many more particles because of the increased number of nucleon-nucleon interactions.

The distribution of this total energy was used to divide the event sample into 40 centrality bins, each representing $2.5\%$ of the total nucleus-nucleus interaction cross section. Because of inefficiencies in the minimum bias trigger and event selection, the measured multiplicity distribution does not represent the full interaction cross section. MC simulations were used to estimate the distribution in the regions where events are lost. Comparing the simulated distribution to the measured distribution, it is estimated that the minimum bias trigger and event selection efficiency is $97 \pm 3\%$.

For the jet analysis, these fine-grained bins were combined into five larger bins corresponding to the most central $10\%$ of the events (i.e., smallest impact parameter), the next most central $10\%$ of the events (denoted $10\%–20\%$), and further bins corresponding to the $20\%–30\%$, $30\%–50\%$, and $50\%–100\%$ selections of the total hadronic cross section.

Simulations can be used to correlate centrality, as quantified using the fraction of the total interaction cross section, with more detailed properties of the collision. The two most commonly used physical quantities are the total number of nucleons in the two lead ($^{208}\text{Pb}$) nuclei which experienced at least one inelastic collision, denoted $N_{\text{part}}$, and the total number of binary nucleon-nucleon collisions $N_{\text{coll}}$.

The centrality bins can be correlated to the impact parameter $b$ and to average values and variances of $N_{\text{part}}$ and $N_{\text{coll}}$ using a calculation based on a Glauber model in which the nucleons are assumed to follow straight-line trajectories as the nuclei collide (for a review, see Ref. [35]). The bin-to-bin smearing of the results of these calculations due to the finite resolution and fluctuations in the HF energy measurement was obtained from fully simulated and reconstructed MC events generated with the AMPT event generator [36]. Standard parameters of the Woods-Saxon function used to model the distribution of nucleons in the Pb nuclei were used [37]. The nucleon-nucleon inelastic cross section, which is used to determine how close

the nucleon trajectories need to be in order for an interaction to occur, was taken to be $64 \pm 5$ mb, based on a fit of the existing data for total and elastic cross sections in proton-proton and proton-antiproton collisions [38]. The uncertainties in the parameters involved in these calculations contribute to the systematic uncertainty in $N_{\text{part}}$ and $N_{\text{coll}}$ for a given bin. The other source of uncertainty in the centrality parameters comes from the determination of the event selection efficiency.

Using the procedure outlined above, the mean and spread (RMS) values of the impact parameter $N_{\text{part}}$ and $N_{\text{coll}}$ for the five bins used in this analysis, and their systematic uncertainties, were extracted and are listed in Table II. The rms values for the centrality parameters are due to their correlation with the percentage cross section and the width of the chosen centrality bins.

It is important to note that the selection of rare processes, such as the production of high-$p_T$ jets, leads to a strong bias in the centrality distribution of the underlying events toward more central collisions, for which $N_{\text{coll}}$ is very large. This can be seen in Fig. 3(a), where the HF energy distribution for events selected by the jet trigger is shown in comparison to that for minimum bias events. The bias can be seen more clearly in Fig. 3(b), where the distribution of minimum bias and jet-triggered events in the 40 centrality bins is shown.

D. Jet reconstruction in PbPb collisions

1. Jet algorithm

The baseline jet reconstruction for heavy-ion collisions in CMS is performed with an iterative cone algorithm modified to subtract the soft underlying event on an event-by-event basis [39]. Each cone is selected with a radius $\Delta R = \sqrt{\Delta \phi^2 + \Delta \eta^2} = 0.5$ around a tower cell with the highest-energy deposition with a minimum transverse energy of 1 GeV. The underlying event subtraction algorithm is a variant of an iterative “noise and pedestal subtraction” technique [40]. Initially, the mean value $\langle E_{\text{cell}} \rangle$ and dispersion $\sigma(E_{\text{cell}})$ of the energies recorded in the calorimeter cells are calculated for all rings of cells that have at least 0.3 GeV transverse energy deposit at constant pseudorapidity. The algorithm subtracts $\langle E_{\text{cell}} \rangle + \sigma(E_{\text{cell}})$ from each cell. If a cell energy is negative after subtraction, the value is set to zero. Subtracting the mean plus the dispersion, as opposed to simply the mean, compensates for the bias caused by the “zeroing” of negative-energy cells. Jets are then reconstructed, using a standard iterative cone algorithm [41,42], from the remaining cells with nonzero energy. In a second iteration, the pedestal function is recalculated using only calorimeter cells outside the area covered by reconstructed high-$p_T$ jets ($p_T > 10$ GeV/c). The threshold of 10 GeV/c was chosen in studies optimizing the final extracted jet $p_T$ resolution. The cell energies are updated with the new pedestal function (again subtracting mean plus dispersion) and the jets are reconstructed again, using the updated calorimeter cells. The performance of this algorithm is documented in Ref. [39]. Jet corrections for the calorimeter response have been applied, as determined in studies for pp collisions [43]. When applying the algorithm to PbPb data, the subtracted background energy for $R = 0.5$ jet cones ranges from 6 to 13 GeV for peripheral events (centrality bins 50%–100%) to 90–130 GeV for central collisions (0%–10%), before applying jet energy scale corrections.

To perform a cross check of the main results, the anti-$k_T$ algorithm [44] with a resolution parameter of 0.5 was used to reconstruct jets, as was done for the pp reference measurements presented here. The energy attributed to the underlying event was estimated and subtracted using the “average energy per jet area” procedure provided by the FASTJET package [45,46]. In order to eliminate biases in the underlying event estimation, an $\eta$ strip of total width $\Delta \eta = 1.6$ centered on the jet position was used, with the two highest-energy jets in each event excluded [47]. In addition, the anti-$k_T$ jets were reconstructed based on particle flow objects [48,49] instead of calorimeter-only information. A good agreement was found with the calorimeter-based, iterative cone algorithm results.

2. Simulated data samples

For the analysis of dijet properties in PbPb events, it is crucial to understand how the jet reconstruction is modified in the presence of the high multiplicity of particles produced in the PbPb underlying event. The jet-finding performance was studied using dijets in pp collisions simulated with the PYTHIA event generator (version 6.423, tune D6T) [50], modified for the isospin content of the colliding nuclei [51]. In order to enhance the number of Pythia dijets in the momentum range studied, a minimum $p_T$ selection of 80 GeV/c was used. Lower $p_T$ selections, as discussed in Ref. [52], were also investigated and found to agree with the $p_T = 80$ GeV/c results within uncertainties. The PYTHIA dijet events were processed with the full detector simulation and analysis chain. Additional samples were produced in which the PYTHIA dijet events were embedded into a minimum bias selection of PbPb events at the raw data level [53]. For this embedding procedure, both real PbPb data events (PYTHIA + DATA), and PbPb events simulated with the HYDJET event generator [51].
The PYTHIA + HYDJET parameters were tuned to reproduce the total particle multiplicities at all centralities and to approximate the underlying event fluctuations seen in data. The HYDJET events included the simulation of hard-scattering processes for which radiative parton energy loss was simulated, but collisional energy loss was turned off [51]. Both embedded samples were propagated through the standard reconstruction and analysis chain.

The PYTHIA + DATA sample was used in several ways for studies of calorimeter jets. First, by matching the same PYTHIA dijet event reconstructed with and without the PbPb underlying event, the degradation of the jet $p_T$ and position resolution, the jet $p_T$ scale, and the jet-finding efficiency were determined as a function of collision centrality and jet $p_T$ (Sec. II D3). In addition, PYTHIA + DATA events were compared to nonembedded PYTHIA for dijet observables such as azimuthal correlations and momentum balance distributions. Finally, to separate effects due to the medium itself from effects simply due to reconstructing jets in the complicated environment of the underlying PbPb event, a direct comparison of results for PYTHIA + DATA and actual data events was made (Sec. III A).

The PYTHIA + HYDJET sample was used for studies of track momentum balance and track-jet correlations (Secs. III B and III C), where access to the full MC particle level (truth) information for charged tracks is important for systematic studies.

3. Jet-finding performance

A detailed characterization of the CMS calorimeter jet-finding performance in pp collisions can be found in Ref. [54]. The dependence of the jet energy scale and of the jet energy resolution on centrality was determined using the PYTHIA + DATA sample (Fig. 4, standard pp jet energy corrections are applied [43]). In this study, reconstructed jets were matched to the closest generator-level jet in $\eta$-$\phi$ within a cone of $\Delta R = 0.3$. The residual jet energy scale dependence and the relative jet energy resolution are derived from the mean and standard deviation of the Gaussian distributions of the ratio of the reconstructed calorimeter jet transverse momentum $p_T^{\text{CaloJet}}$ and the transverse momentum of jets reconstructed based on event generator level final state particles $p_T^{\text{GenJet}}$. For peripheral events in the 50%–100% centrality selection, the jet energies are undercorrected by 5% after applying the standard pp jet energy corrections. The difference between corrected jets reconstructed in PbPb compared to generator jets is the residual jet energy correction, which is not applied, but included in the systematic uncertainty. For the most central events, the large transverse energy per unit area of the underlying event leads to an overcorrection of low-$p_T$ jet energies by up to 10% and a degradation of the relative resolution by $\sim$30% to $\sigma(p_T^{\text{CaloJet}}/p_T^{\text{GenJet}}) = 0.16$ at $p_T = 100$ GeV/c. The jet energy resolution is found to be $\sim$15% worse in central PbPb events than in pp collisions, where the % is with respect to the energy of the generator jet. The effect of the underlying event on the jet angular resolution was also studied. Integrated over jet $p_T > 50$ GeV/c, the angular resolution in $\phi$ worsens from 0.03 for peripheral events (50%–100%) to 0.04 for central events (0%–10%), while the resolution in $\eta$ changes from 0.02 to 0.03 over the same centrality range. With the embedding of PYTHIA into minimum bias PbPb data and comparison of reconstructed jets to generator level jets, the effect of the soft
The jet reconstruction efficiency as a function of generator level jet $p_T$ for the leading jet (filled circles) and subleading jet (open squares). From left to right three centrality bins are shown: 30%–100%, 10%–30%, 0%–10%. The vertical bars denote the statistical uncertainty.

The goal of this analysis is to characterize possible modifications of dijet properties as a function of centrality in PbPb collisions. In addition to the standard event selection of inelastic hadronic collisions and the requirement of a leading jet with $p_{T,1} > 120 \text{ GeV/c}$ (Sec. II B), most of the subsequent analysis required the subleading jet in the event to have $p_{T,2} > 50 \text{ GeV/c}$, and the azimuthal angle between the leading and subleading jet ($\Delta \phi_{12}$) to be larger than $2\pi/3$. Only jets within $|\eta| < 2$ were considered for the analysis of calorimeter jets in Sec. III A. For a data set of 149k jet events, this selection yields 3514 jet pairs. For studies of correlations of calorimeter jets with charged particles (Secs. III B and III C), a more restrictive pseudorapidity selection was applied. The analysis was performed mostly in five bins of collision centrality: 0%–10%, 10%–20%, 20%–30%, 30%–50%, and 50%–100%.

Thus far, no pp reference data exist at the PbPb collision energy of $\sqrt{s_{NN}} = 2.76 \text{ TeV}$. Throughout the paper, the results obtained from PbPb data will be compared to references based on the PYTHIA and PYTHIA + DATA samples described in Sec. II D2.

For most results, the PYTHIA + DATA events will be used for direct comparisons. To calibrate the performance of PYTHIA for the observables used in this analysis, the dijet analysis was also performed using the anti-$k_T$ algorithm on 35 pb$^{-1}$ of pp data at $\sqrt{s} = 7 \text{ TeV}$, collected by CMS prior to the heavy-ion data taking and compared to PYTHIA simulations for the same collision system and energy. The same jet selection criteria used for the 2.76 TeV PbPb data were applied to both pp data and PYTHIA.

A. Dijet properties in pp and PbPb data

The correlation between the transverse momentum of the reconstructed leading and subleading jets in the calorimeters is plotted in Fig. 6. The top row contains PbPb data for peripheral, midcentral, and central events, the second row shows pp jets simulated by PYTHIA and embedded into PbPb data, and the bottom panel shows pp jets from PYTHIA without embedding. One can already observe a downward shift in the subleading jet $p_T$ for the more central PbPb events. In the following discussion, a more quantitative and detailed assessment of this phenomenon will be presented.
FIG. 6. (Color online) Subleading jet $p_T$ vs leading jet $p_T$ distributions with $\Delta \phi_{12} > 2\pi/3$. The top two rows show results for centrality 30%–100% (left-hand column), 10%–30% (middle column) and 0%–10% (right-hand column), for PbPb data (top row) and reconstructed PYTHIA jets embedded into PbPb data events (middle row). The panel in the bottom row shows the distribution for reconstructed jets from PYTHIA alone.

1. Leading jet spectra

Figure 7(a) shows the leading jet $p_T$ distributions for 7 TeV pp data and corresponding PYTHIA simulations. The distribution of leading jet $p_T$ for PbPb is shown in Figs. 7(b)–7(f) for five different centrality bins. The spectra obtained for PbPb data are shown as solid markers, whereas the hatched histograms show the leading jet spectrum reconstructed from PYTHIA + DATA dijet events. All spectra have been normalized to an integral of unity. The detector-level leading jet spectra in PbPb data and the corresponding results for PYTHIA + DATA samples show good quantitative agreement in all centrality bins over the $p_T$ range studied.

It is important to note that the jet momentum spectra at detector level presented here have not been corrected for smearing due to detector resolution, fluctuations in and out of the jet cone, or underlying event fluctuations. Therefore, a direct comparison of these spectra to analytical calculations or particle-level generator results is not possible. For the jet asymmetry and dijet $\Delta \phi$ distributions discussed below, the effect of the finite jet energy resolution is estimated using the PYTHIA + DATA events.

2. Dijet azimuthal correlations

One possible medium effect on the dijet properties is a change of the back-to-back alignment of the two partons. This can be studied using the event-normalized differential dijet distribution $(1/N)(dN/d\Delta \phi_{12})$ vs $\Delta \phi_{12}$. Figure 8 shows distributions of $\Delta \phi_{12}$ between leading and subleading jets which pass the respective $p_T$ selections. In Fig. 8(a), the dijet $\Delta \phi_{12}$ distributions are plotted for 7 TeV pp data in comparison...
FIG. 7. (Color online) Leading jet $p_T$ distribution for dijet events with subleading jets of $p_{T,2} > 50$ GeV/c and $\Delta\phi_{1,2} > 2\pi/3$ for 7 TeV pp collisions (a) and 2.76 TeV PbPb collisions in several centrality bins: (b) 50%–100%, (c) 30%–50%, (d) 20%–30%, (e) 10%–20%, and (f) 0%–10%. Data are shown as black points, while the histograms show (a) PYTHIA events and (b)–(f) PYTHIA events embedded into PbPb data. The error bars show the statistical uncertainties.

to the corresponding PYTHIA simulations using the anti-$k_T$ algorithm for jets based on calorimeter information. PYTHIA provides a good description of the experimental data, with slightly larger tails seen in the PYTHIA simulations. A recent study of azimuthal correlations in pp collisions at 7 TeV can be found in Ref. [55]. For the PYTHIA comparison to

FIG. 8. (Color online) $\Delta\phi_{1,2}$ distributions for leading jets of $p_{T,1} > 120$ GeV/c with subleading jets of $p_{T,2} > 50$ GeV/c for 7 TeV pp collisions (a) and 2.76 TeV PbPb collisions in several centrality bins: (b) 50%–100%, (c) 30%–50%, (d) 20%–30%, (e) 10%–20%, and (f) 0%–10%. Data are shown as black points, while the histograms show (a) PYTHIA events and (b)–(f) PYTHIA events embedded into PbPb data. The error bars show the statistical uncertainties.
S. CHATRCHYAN et al.

FIG. 9. (Color online) Fraction of events with Δφ12 > 3.026 as a function of Npart, among events with pt,1 > 120 GeV/c and pt,2 > 50 GeV/c. The result for reconstructed PYTHIA dijet events (blue filled star) is plotted at Npart = 2. The other points (from left to right) correspond to centrality bins of 50%–100%, 30%–50%, 20%–30%, 10%–20%, and 0%–10%. The red squares are for reconstruction of PYTHIA + DATA events and the filled circles are for the PbPb data, with statistical (vertical bars) and systematic (brackets) uncertainties.

PbPb results at √sNN = 2.76 TeV, this discrepancy seen in the higher-energy pp comparison is included in the systematic uncertainty estimation. It is important to note that the PYTHIA simulations include events with more than two jets, which provide the main contribution to events with large momentum imbalance or Δφ12 far from π.

Figures 8(b)–8(f) show the dijet Δφ12 distributions for PbPb data in five centrality bins, compared to PYTHIA + DATA simulations. The distributions for the four more peripheral bins are in good agreement with the PYTHIA + DATA reference, especially for Δφ12 ≳ 2. The three centrality bins spanning 0%–30% show an excess of events with azimuthally misaligned dijets (Δφ12 < 2), compared with more peripheral events. A similar trend is seen for the PYTHIA + DATA simulations, although the fraction of events with azimuthally misaligned dijets is smaller in the simulation. The centrality dependence of the azimuthal correlation in PYTHIA + DATA can be understood as the result of the increasing fake-jet rate and the drop in jet reconstruction efficiency near the 50 GeV/c threshold from 95% for peripheral events to 88% for the most central events. In PbPb data, this effect is magnified since low-pT away-side jets can undergo a sufficiently large energy loss to fall below the 50 GeV/c selection criteria.

Furthermore, a reduction of the fraction of back-to-back jets above Δφ12 ≳ 3 is observed for the most central bin. This modification of the Δφ12 distribution as a function of centrality can be quantified using the fraction Rr of dijets with Δφ12 > 3.026, as plotted in Fig. 9, for pt,1 > 120 GeV/c and pt,2 > 50 GeV/c. The threshold of 3.026 corresponds to the median of the Δφ12 distribution for PYTHIA (without embedding). The results for both the PbPb data and PYTHIA + DATA dijets are shown as a function of the reaction centrality, given by the number of participating nucleons Npart, as described in Sec. II C. This observable is not sensitive to the shape of the tail at Δφ12 < 2 seen in Fig. 8, but can be used to measure small changes in the back-to-back correlation between dijets. A decrease in the fraction of back-to-back jets

FIG. 10. (Color online) Dijet asymmetry ratio AJ for leading jets of pt,1 > 120 GeV/c, subleading jets of pt,2 > 50 GeV/c, and Δφ12 > 2π/3 for 7 TeV pp collisions (a) and 2.76 TeV PbPb collisions in several centrality bins: (b) 50%–100%, (c) 30%–50%, (d) 20%–30%, (e) 10%–20%, and (f) 0%–10%. Data are shown as black points, while the histograms show (a) PYTHIA events and (b)–(f) PYTHIA events embedded into PbPb data. The error bars show the statistical uncertainties.
in PbPb data is seen compared to the pure PYTHIA simulations. Part of the observed change in \( R_B(\Delta \phi) \) with centrality is explained by the decrease in jet azimuthal angle resolution from \( \sigma_\phi = 0.03 \) in peripheral events to \( \sigma_\phi = 0.04 \) in central events, due to the impact of fluctuations in the PbPb underlying event. This effect is demonstrated by the comparison of PYTHIA and PYTHIA + DATA results. The difference between the pp and PYTHIA + DATA resolutions was used for the uncertainty estimate, giving the dominant contribution to the systematic uncertainties, shown as brackets in Fig. 9.

3. Dijet momentum balance

To characterize the dijet momentum balance (or imbalance) quantitatively, we use the asymmetry ratio

\[
A_J = \frac{p_{T,1} - p_{T,2}}{p_{T,1} + p_{T,2}}
\]

where the subscript 1 always refers to the leading jet, so that \( A_J \) is positive by construction. The use of \( A_J \) removes uncertainties due to possible constant shifts of the jet energy scale. It is important to note that the subleading jet \( p_{T,2} > 50 \text{ GeV/c} \) selection imposes a \( p_{T,1} \)-dependent limit on the magnitude of \( A_J \). For example, for the most frequent leading jets near the 120 GeV/c threshold, this limit is \( A_J < 0.41 \), while the largest possible \( A_J \) for the present dataset is 0.7 for 300 GeV/c leading jets. Dijets in which the subleading jet is lost below the 50 GeV/c threshold are not included in the \( A_J \) calculation. Dijets are selected with \( \Delta \phi_12 > 2\pi/3 \).

In Fig. 10(a), the \( A_J \) dijet asymmetry observable calculated by PYTHIA is compared to pp data at \( \sqrt{s} = 7 \text{ TeV} \). Again, the data and event generator are found to be in agreement [56]. This observation, as well as the good agreement between PYTHIA + DATA and the most peripheral PbPb data shown in Fig. 10(b), suggest that PYTHIA at \( \sqrt{s} = 2.76 \text{ TeV} \) can serve as a good reference for the dijet imbalance analysis in PbPb collisions.

The centrality dependence of \( A_J \) for PbPb collisions can be seen in Figs. 10(b)–10(f), in comparison to PYTHIA + DATA simulations. Whereas the dijet angular correlations show only a small dependence on collision centrality, the dijet momentum balance exhibits a dramatic change in shape for the most central collisions. In contrast, the PYTHIA simulations only exhibit a modest broadening, even when embedded in the highest multiplicity PbPb events.

Central PbPb events show a significant deficit of events in which the momenta of leading and subleading jets are balanced and a significant excess of unbalanced pairs. The large excess of unbalanced compared to balanced dijets explains why this effect was apparent even when simply scanning event displays (see Fig. 1). The striking momentum imbalance is also confirmed when studying high-\( p_T \) tracks associated with leading and subleading jets, as will be shown in Sec. III B. This observation is consistent with the expected degradation of the parton energy, or jet quenching, in the medium produced in central PbPb collisions [17].

The evolution of the dijet momentum balance illustrated in Fig. 10 can be explored more quantitatively by studying the fraction of balanced jets in the PbPb events. The balanced fraction \( R_B(A_J < 0.15) \) is plotted as a function of collision centrality (again in terms of \( N_{\text{part}} \)) in Fig. 11. It is defined as the fraction of all events with a leading jet having \( p_{T,1} > 120 \text{ GeV/c} \) for which a subleading partner with \( A_J < 0.15 \) and \( \Delta \phi_12 > 2\pi/3 \) is found. Since \( R_B(A_J < 0.15) \) is calculated as the fraction of all events with \( p_{T,1} > 120 \text{ GeV/c} \), it takes into account the rate of apparent “monojet” events, where the subleading partner is removed by the \( p_T \) or \( \Delta \phi \) selection.

The \( A_J \) threshold of 0.15 corresponds to the median of the \( A_J \) distribution for pure PYTHIA dijet events passing the criteria used for Fig. 10. By definition, the fraction \( R_B(A_J < 0.15) \) of balanced jets in PbPb is therefore 50%, which is plotted as a dashed line in Fig. 11. As will be discussed in Sec. III C, a third jet having a significant impact on the dijet imbalance is present in most of the large-\( A_J \) events in PYTHIA.

The change in jet-finding performance from high to low \( p_T \), discussed in Sec. II D3, leads to only a small decrease in the fraction of balanced jets, of less than 5% for central PYTHIA + DATA dijets. In contrast, the PbPb data show a rapid decrease in the fraction of balanced jets with collision centrality. While the most peripheral selection shows a fraction of balanced jets of close to 45%, this fraction drops by close to a factor of 2 for the most central collisions. This again suggests that the passage of hard-scattered partons through the environment created in PbPb collisions has a significant impact on their fragmentation into final-state jets.

The observed change in the fraction of balanced jets as a function of centrality, shown in Fig. 11, is far bigger than the estimated systematic uncertainties, shown as brackets. The main contributions to the systematic uncertainties include the uncertainties on jet energy scale and resolution, jet reconstruction efficiency, and the effects of underlying event subtraction. The uncertainty in the subtraction procedure is estimated based on the difference between pure PYTHIA and
for PYTHIA are shown with blue stars, and PYTHIA + DATA with red squares. The dotted-dashed line to guide the eye is drawn at the value for pure PYTHIA for the lowest $p_T$ bin.

PYTHIA + DATA simulations. For central events, the subtraction procedure contributes the biggest uncertainty to $R_0(A_J)$, of close to 8%. The uncertainty on the residual jet energy scale was estimated based on the results shown in the top row of Fig. 4. The full difference between the observed residual correction and unity, added in quadrature with the systematic uncertainty obtained for pp [43], was used as the systematic uncertainty on the jet $p_T$ and propagated to $R_0(A_J)$. For the jet $p_T$ resolution uncertainty, the full difference of the PYTHIA + DATA result to the pp resolution, as shown in Fig. 4 (bottom), was used as an uncertainty estimate for the PbPb jet $p_T$ resolution. The uncertainties in jet energy scale and jet resolution contribute 5% and 6%, respectively, to the 11% total systematic uncertainty in central events. For peripheral events, the total uncertainty drops to 9%, mostly due to the smaller uncertainty related to the PbPb background fluctuations for lower multiplicity events.

4. Leading jet $p_T$ dependence of dijet momentum imbalance

The dependence of the jet modification on the leading jet momentum can be studied using the fractional imbalance $(p_{T,1} - p_{T,2})/p_{T,1}$, where $p_{T,1}$ and $p_{T,2}$ are the uncertainties in the $p_T$-dependent residual energy scale (based on results shown in the top row of Fig. 4), and the centrality-dependent difference observed between PYTHIA and PYTHIA + DATA seen in Fig. 12. As before, the uncertainty on the residual jet energy scale was estimated using the full difference between the observed residual correction and unity, and also assuming that within these limits the low-$p_T$ and high-$p_T$ response could vary independently.

B. Track-jet correlations

The studies of calorimeter jets show a strong change of the jet momentum balance as a function of collision centrality. This implies a corresponding modification in the distribution of jet fragmentation products, with energy being either transported out of the cone area used to define the jets, or to low-momentum particles which are not measured in the calorimeter jets. The CMS calorimeter is less sensitive to these low momentum particles which are not measured in the calorimeter jets. The main contributions to the systematic uncertainty in $(p_{T,1} - p_{T,2})/p_{T,1}$ are the uncertainties in the $p_T$-dependent residual energy scale and the $p_T$-dependent difference observed between PYTHIA and PYTHIA + DATA seen in Fig. 12. As before, the uncertainty on the residual jet energy scale was estimated using the full difference between the observed residual correction and unity, and also assuming that within these limits the low-$p_T$ and high-$p_T$ response could vary independently.

The dependence of the dijet momentum imbalance on the leading jet $p_T$ can be studied using the fractional imbalance $(p_{T,1} - p_{T,2})/p_{T,1}$ for three bins of collision centrality. The mean value of this fraction is presented as a function of $p_{T,1}$ in Fig. 12 for three bins of collision centrality, 30%–100%, 10%–30%, and 0%–10%. PYTHIA is shown as stars, PYTHIA + DATA simulations are shown as squares, while the data are shown as circles. Statistical and systematic uncertainties are plotted as error bars and brackets, respectively. The dominant contribution to the systematic uncertainty comes from the observed $p_T$ dependence of the residual jet energy correction in PbPb events (6% out of a total systematic uncertainty of 8%). The jet energy resolution and underlying event subtraction uncertainties contribute ~4% each.

The fractional imbalance exhibits several important features: The imbalance seen in PbPb data grows with collision centrality and reaches a much larger value than in PYTHIA or PYTHIA + DATA. In addition, the effect is clearly visible even for the highest-$p_T$ jets observed in the data set, demonstrating that the observed dijet imbalance is not restricted to the threshold region in our leading jet selection. Within the present uncertainties, the $p_T$ dependence of the excess imbalance above the PYTHIA prediction is compatible with either a constant difference or a constant fraction of $p_{T,1}$.
FIG. 13. (Color online) Distribution of the transverse momentum sum of tracks for three $p_T$ ranges, as a function of the distance $\Delta R$ to the leading and subleading jet axes. Results for the 0%–30% centrality selection are shown for PYTHIA + HYDJET (upper row) and PbPb data (lower row). For each figure, the requirements on the dijet asymmetry $A_J$ are given. Note that events with $A_J > 0.22$ are much rarer in the PYTHIA+HYDJET sample than in the data. Vertical bars are statistical and systematic uncertainties, combined in quadrature, the systematic contributions being 20%, independent of the bin.

The summed $p_T$ spectra from the underlying event regions were then subtracted from the jet regions, yielding the momentum distribution of charged tracks associated with the jets as a function of $\Delta R$.

The resulting distributions of associated track momentum as a function of track $p_T$ and $\Delta R$ are presented in Fig. 13 for four selections in dijet asymmetry, from $A_J < 0.11$ (left-hand side) to $A_J > 0.33$ (right-hand side). For both data and PYTHIA + HYDJET results, the jet selections and $A_J$ values are based on the reconstructed calorimeter jet momenta (Sec. II D) in order to have consistent event selections for comparison. The middle bin boundary ($A_J = 0.22$) corresponds to the median of the $A_J$ distribution for the 0%–30% central PbPb events shown here. The top row shows the results for PYTHIA + HYDJET simulations. The track results shown for the PYTHIA + HYDJET simulations were found using the known (“truth”) values of the track momenta from the embedded PYTHIA events. The track results for PbPb were corrected for tracking efficiency and fake rates using corrections that were derived from PYTHIA + HYDJET simulations and from the reconstruction of single tracks embedded in data. In each panel, the area of each colored region in $p_T$ and $\Delta R$ corresponds to the total transverse momentum per event carried by tracks in this region.

For the balanced-jet selection $A_J < 0.11$, one sees qualitative agreement in the leading and subleading jet momentum distributions between PYTHIA+HYDJET (top) and data (bottom). In data and simulation, most of the leading and subleading jet momentum is carried by tracks with $p_T > 8$ GeV/$c$, with the data tracks having a slightly narrower $\Delta R$ distribution. A slightly larger fraction of the momentum for the subleading jets is carried by tracks at low $p_T$ and $\Delta R > 0.16$ (i.e., beyond the second bin) in the data.

Moving toward larger dijet imbalance, the major fraction of the leading jet momentum continues to be carried by high-$p_T$ tracks in data and simulation. For the $A_J > 0.33$ selection, it is important to recall that less than 10% of all PYTHIA dijet events that do are overwhelmingly 3-jet events.

While the overall change found in the leading jet shapes as a function of $A_J$ is small, a strong modification of
the track momentum composition of the subleading jets is seen, confirming the calorimeter determination of the dijet imbalance. The biggest difference between data and simulation is found for tracks with $p_T < 4$ GeV/c. For PYTHIA, the momentum in the subleading jet carried by these tracks is small and their radial distribution is nearly unchanged with $A_J$. However, for data, the relative contribution of low-$p_T$ tracks grows with $A_J$, and an increasing fraction of those tracks is observed at large distances to the jet axis, extending out to $\Delta R = 0.8$ (the largest angular distance to the jet in this study).

The major systematic uncertainties for the track-jet correlation measurement come from the $p_T$-dependent uncertainty in the track reconstruction efficiency. The algorithmic track reconstruction efficiency, which averages 70% over the $p_T > 0.5$ GeV/c and $|\eta| < 2.4$ range included in this study, was determined from an independent PYTHIA + HYDJET sample, and from simulated tracks embedded in data. Additional uncertainties are introduced by the underlying event subtraction procedure. The latter was studied by comparing the track-jet correlations seen in pure PYTHIA dijet events for generated particles with those seen in PYTHIA + HYDJET events after reconstruction and background subtraction. The size of the background subtraction systematic uncertainty was further cross checked in data by repeating the procedure for random ring-like regions in 0%-30% central minimum bias events. In the end, an overall systematic uncertainty of 20% per bin was assigned. This uncertainty is included in the combined statistical and systematic uncertainties shown in Fig. 13.

C. Overall momentum balance of dijet events

The requirements of the background subtraction procedure limit the track-jet correlation study to tracks with $p_T > 1.0$ GeV/c and $\Delta R < 0.8$. Complementary information about the overall momentum balance in the dijet events can be obtained using the projection of missing $p_T$ of reconstructed charged tracks onto the leading jet axis. For each event, this projection was calculated as

$$p_T^\parallel = \sum_i p_T^i \cos (\phi_i - \phi_{\text{Leading jet}}),$$

where the sum is over all tracks with $p_T > 0.5$ GeV/c and $|\eta| < 2.4$. The results were then averaged over events to obtain $\langle p_T^\parallel \rangle$. No background subtraction was applied, which allows this study to include the $|\eta|_{ij} < 0.8$ and $0.5 < p_T^{\text{track}} < 1.0$ GeV/c regions not accessible for the study in Sec. III B. The leading and subleading jets were again required to have $|\eta| < 1.6$.

In Fig. 14, $\langle p_T^\parallel \rangle$ is shown as a function of $A_J$ for two centrality bins, 30%-100% (left-hand side) and 0%-30% (right-hand side). Results for PYTHIA + HYDJET are presented in the top row, while the bottom row shows the results for PbPb data. Using tracks with $|\eta| < 2.4$ and $p_T > 0.5$ GeV/c, one

![Fig. 14. (Color online) Average missing transverse momentum $\langle p_T^\parallel \rangle$ for tracks with $p_T > 0.5$ GeV/c, projected onto the leading jet axis (solid circles). The $\langle p_T^\parallel \rangle$ values are shown as a function of dijet asymmetry $A_J$ for 30%-100% centrality (left-hand side) and 0%-30% centrality (right-hand side). For the solid circles, vertical bars and brackets represent the statistical and systematic uncertainties, respectively. Colored bands show the contribution to $\langle p_T^\parallel \rangle$ for five ranges of track $p_T$. The top and bottom rows show results for PYTHIA + HYDJET and PbPb data, respectively. For the individual $p_T$ ranges, the statistical uncertainties are shown as vertical bars.](024906-14)
sees that indeed the momentum balance of the events, shown as solid circles, is recovered within uncertainties, for both centrality ranges and even for events with large observed dijet asymmetry, in both data and simulation. This shows that the dijet momentum imbalance is not related to undetected activity in the event due to instrumental (e.g., gaps or inefficiencies in the calorimeter) or physics (e.g., neutrino production) effects.

The figure also shows the contributions to $\langle p_T^i \rangle$ for five transverse momentum ranges from 0.5–1 GeV/c to $p_T > 8$ GeV/c. The vertical bars for each range denote statistical uncertainties. For data and simulation, a large negative contribution to $\langle p_T^i \rangle$ (i.e., in the direction of the leading jet) by the $p_T > 8$ GeV/c range is balanced by the combined contributions from the 0.5–8 GeV/c regions. Looking at the $p_T < 8$ GeV/c region in detail, important differences between data and simulation emerge. For PYTHIA + HYDJET both centrality ranges show a large balancing contribution from the intermediate $p_T$ region of 4–8 GeV/c, while the contribution from the two regions spanning 0.5–2 GeV/c is very small. In peripheral PbPb data, the contribution of 0.5–2 GeV/c tracks relative to that from 4–8 GeV/c tracks is somewhat enhanced compared to the simulation. In central PbPb events, the relative contribution of low and intermediate-$p_T$ tracks is actually the opposite of that seen in PYTHIA + HYDJET. In data, the 4–8 GeV/c region makes almost no contribution to the overall momentum balance, while a large fraction of the negative imbalance from high $p_T$ is recovered in low-momentum tracks.

The dominant systematic uncertainty for the $p_T$ balance measurement comes from the $p_T$-dependent uncertainty in the track reconstruction efficiency and fake rate described in Sec. III B. A 20% uncertainty was assigned to the final result, stemming from the residual difference between the PYTHIA generator level and the reconstructed PYTHIA + HYDJET tracks at high $p_T$. This is combined with an absolute 3 GeV/c uncertainty that comes from the imperfect cancellation of the background tracks. The background effect was cross checked in data from a random cone study in 0%–30% central events similar to the study described in Sec. III B. The overall systematic uncertainty is shown as brackets in Figs. 14 and 15.

Further insight into the radial dependence of the momentum balance can be gained by studying $\langle p_T^i \rangle$ separately for tracks inside cones of size $\Delta R = 0.8$ around the leading and subleading jet axes, and for tracks outside of these cones. The results of this study for central events are shown in Fig. 15 for the in-cone balance and out-of-cone balance for MC and data. As the underlying PbPb event in both data and MC is not $\phi$ symmetric on an event-by-event basis, the back-to-back requirement was tightened to $\Delta \phi_{12} > 5\pi/6$ for this study.

One observes that for both data and MC an in-cone imbalance of $\langle p_T^i \rangle \approx -20$ GeV/c is found for the $A_J > 0.33$ selection. In both cases this is balanced by a corresponding out-of-cone imbalance of $\langle p_T^i \rangle \approx 20$ GeV/c. However, in the PbPb data the out-of-cone contribution is carried almost entirely by tracks with $0.5 < p_T < 4$ GeV/c, whereas in MC

![FIG. 15. (Color online) Average missing transverse momentum $\langle p_T^i \rangle$ for tracks with $p_T > 0.5$ GeV/c, projected onto the leading jet axis (solid circles). The $\langle p_T^i \rangle$ values are shown as a function of dijet asymmetry $A_J$ for 0%–30% centrality, inside ($\Delta R < 0.8$) one of the leading or subleading jet cones (left-hand side) and outside ($\Delta R > 0.8$) the leading and subleading jet cones (right-hand side). For the solid circles, vertical bars and brackets represent the statistical and systematic uncertainties, respectively. For the individual $p_T$ ranges, the statistical uncertainties are shown as vertical bars.](image.png)
more than 50% of the balance is carried by tracks with $p_T > 4\text{ GeV/c}$, with a negligible contribution from $p_T < 1\text{ GeV/c}$.

The PYTHIA + HYDJET results are indicative of semi-hard initial- or final-state radiation as the underlying cause for large $A_J$ events in the MC study. This has been confirmed by further studies which showed that in PYTHIA the momentum balance in the transverse plane for events with large $A_J$ can be restored if a third jet with $p_T > 20\text{ GeV/c}$, which is present in more than 90% of these events, is included. This is in contrast to the results for large-$A_J$ PbPb data, which show that a large part of the momentum balance is carried by soft particles ($p_T < 2\text{ GeV/c}$) and radiated at large angles to the jet axes ($\Delta R > 0.8$) in the direction of the subleading jet.

### IV. SUMMARY

The CMS detector has been used to study jet production in PbPb collisions at $\sqrt{s_{NN}} = 2.76\text{ TeV}$. Jets were reconstructed using primarily the calorimeter information in a data sample corresponding to an integrated luminosity of $L_{int} = 6.7\mu b^{-1}$. Events having a leading jet with $p_T > 120\text{ GeV/c}$ and $|\eta| < 2$ were selected. As a function of centrality, dijet events with a subleading jet of $p_T > 50\text{ GeV/c}$ and $|\eta| < 2$ were found to have an increasing momentum imbalance. Data were compared to PYTHIA dijet simulations for pp collisions at the same energy which were embedded into real heavy ion events. The momentum imbalances observed in the data were significantly larger than those predicted by the simulations. While the relative imbalance between the leading and subleading jets increased with increasing collision centrality, it was found to be largely independent of the leading jet $p_T$, up to the highest $p_T$ region studied ($\approx 210\text{ GeV/c}$).

The angular distribution of jet fragmentation products has been explored by associating charged tracks with the dijets observed in the calorimeters. The calorimeter-based momentum imbalance is reflected in the associated track distributions, which show a softening and widening of the subleading jet fragmentation pattern for increasing dijet asymmetry, while the high-$p_T$ components of the leading jet remain nearly unchanged.

Studies of the missing transverse momentum projected on the jet axis have shown that the overall momentum balance can be recovered if tracks at low $p_T$ are included. In the PbPb data, but not in the simulations, a large fraction of the balancing momentum is carried by tracks having $p_T < 2\text{ GeV/c}$. Comparing the momentum balance inside and outside of cones of $\Delta R = 0.8$ around the leading and subleading jet axes demonstrates that a large contribution to the momentum balance in data arises from soft particles radiated at $\Delta R > 0.8$ to the jets, a feature which is also not reproduced in PYTHIA calculations.

In conclusion, a strong increase in the fraction of highly unbalanced jets has been seen in central PbPb collisions compared with peripheral collisions and model calculations, consistent with a high degree of jet quenching in the produced matter. A large fraction of the momentum balance of these unbalanced jets is carried by low-$p_T$ particles at large radial distance, in contrast to PYTHIA simulations embedded into heavy-ion events. The results provide qualitative constraints on the nature of the jet modification in PbPb collisions and quantitative input to models of the transport properties of the medium created in these collisions.

### ACKNOWLEDGMENTS

We wish to congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC machine. We thank the technical and administrative staff at CERN and other CMS institutes. This work was supported by the Austrian Federal Ministry of Science and Research; the Belgium Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport; the Research Promotion Foundation, Cyprus; the Estonian Academy of Sciences and NICPB; the Academy of Finland, Finnish Ministry of Education, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules/CNRS, and Commissariat à l’Energie Atomique et aux Énergies Alternatives/CEA, France; the Bundesministerium für Bildung und Forschung, Deutsche Forschungsgemeinschaft, and Helmholtz-Gemeinschaft Deutscher Forschungszentren, Germany; the General Secretariat for Research and Technology, Greece; the National Scientific Research Foundation, and National Office for Research and Technology, Hungary; the Department of Atomic Energy, and Department of Science and Technology, India; the Institute for Studies in Theoretical Physics and Mathematics, Iran; the Science Foundation, Ireland; the Istituto Nazionale di Fisica Nucleare, Italy; the Korean Ministry of Education, Science and Technology and the World Class University program of NRF, Korea; the Lithuanian Academy of Sciences; the Mexican Funding Agencies (CINVESTAV, CONACYT, SEP, and UASLP-FAI); the Pakistan Atomic Energy Commission; the State Commission for Scientific Research, Poland; the Fundação para a Ciência e a Tecnologia, Portugal; JINR (Armenia, Belarus, Georgia, Ukraine, Uzbekistan); the Ministry of Science and Technologies of the Russian Federation, and Russian Ministry of Atomic Energy; the Ministry of Science and Technological Development of Serbia; the Ministerio de Ciencia e Innovación, and Programa Consolider-Ingenio 2010, Spain; the Swiss Funding Agencies (ETH Board, ETH Zurich, PSI, SNF, UnizH, Canton Zurich, and SER); the National Science Council, Taipei; the Scientific and Technical Research Council of Turkey, and Turkish Atomic Energy Authority; the Science and Technology Facilities Council, UK; the US Department of Energy, and the US National Science Foundation.
