Bragg Scattering as a Probe of Atomic Wave Functions and Quantum Phase Transitions in Optical Lattices

Hirokazu Miyake, Georgios A. Siviloglou, Graciana Puentes, David E. Pritchard, Wolfgang Ketterle, and David M. Weld

MIT-Harvard Center for Ultracold Atoms, Research Laboratory of Electronics, and Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

(Received 26 August 2011; published 21 October 2011)

We have observed Bragg scattering of photons from quantum degenerate $^{87}$Rb atoms in a three-dimensional optical lattice. Bragg scattered light directly probes the microscopic crystal structure and atomic wave function whose position and momentum width is Heisenberg limited. The spatial coherence of the wave function leads to revivals in the Bragg scattered light due to the atomic Talbot effect. The decay of revivals across the superfluid to Mott insulator transition indicates the loss of superfluid coherence.

Ultracold atomic gases are an ideal system in which to study many-body phenomena because of the relative ease with which parameters in the model Hamiltonian can be tuned across a wide range [1,2]. Such studies have resulted in a better understanding of various phase transitions such as the Berezinskii-Kosterlitz-Thouless transition in two-dimensional systems [3], the BEC-BCS crossover of interacting fermions [4], and the superfluid to Mott insulator transition in a three-dimensional lattice [5]. One major goal of this field is to realize spin phases such as antiferromagnetic states to explore quantum magnetism and its interplay with high-temperature superconductivity [6].

Concurrently, there are numerous efforts to develop techniques to probe and understand the atomic ensemble once a new type of ordering is achieved. One recent development is the realization of single-site resolution of atoms in two-dimensional optical lattices [7,8]. An alternative method to measure in situ spatial ordering is the technique of Bragg scattering, often used in a condensed matter context to determine crystal structure [9]. In particular, Bragg scattering with neutrons led to the discovery of antiferromagnetism in the solid state [10] and with x rays led to the discovery of the double helix structure of DNA [11].

Bragg scattering relies on the interference of waves scattered coherently from an ensemble of particles. In particular, when atoms are arranged in a periodic pattern in three spatial dimensions, there are certain angles of the incoming and reflected beams where scattering is dramatically enhanced compared to other angles. This has allowed crystallographers to use x rays to determine the properties of crystals such as lattice geometry at the angstrom scale. We have applied this technique to ultracold atoms in a three-dimensional optical lattice by scattering near-infrared light where the atoms are spaced almost $10^4$ times farther apart than those in typical condensed matter samples.

Pioneering works on Bragg scattering from cold atoms in optical lattices were done by the Hänisch and Phillips groups by using laser cooled atoms [12]. These lattices were sparsely populated, and the atoms occupied several bands. In this Letter, we have used Bragg scattering to study bosonic atoms cooled to quantum degeneracy and placed in a three-dimensional cubic lattice where the atoms occupy the lowest band. In particular, we have measured directly the Heisenberg-limited width of both the position and momentum of the single ground state atomic wave function in an optical lattice. Furthermore, there is a revival of Bragg scattered light some time after releasing the atoms from the optical lattice, analogous to the optical Talbot effect. This signal gives a direct measure of the coherence of the superfluid component in the lattice.

The experimental apparatus has been described in detail elsewhere [13]. Briefly, laser cooling and evaporative cooling are used to achieve quantum degeneracy of $^{87}$Rb atoms in the $|F = 2, m_F = −2\rangle$ state which are loaded into a crossed dipole trap whose trap frequencies range between 30 and 160 Hz. Once quantum degeneracy is achieved, the optical lattices generated by a single 1064 nm fiber laser are adiabatically ramped on. The lattices are calibrated by applying a 12.5 $\mu$s pulse and measuring the Kapitza-Dirac diffraction of the atoms and comparing this to theory. The system typically contains about $10^5$ atoms, which leads to up to 5 atoms per lattice site. The Bragg reflected light is detected on a CCD camera which images along a direction which satisfies the Bragg condition.

The Bragg scattering condition for a three-dimensional cubic lattice is given by $2d\sin \theta = n\lambda_p$, where $d$ is the spacing between lattice planes, $\theta$ is the angle between the incoming beam and the lattice planes, $n$ is any positive integer, and $\lambda_p$ is the wavelength of the probe beam. For our experiment $\lambda_p$ is 780 nm and $d$ is 532 nm. With these conditions, the only allowed angle $\theta$ is $47^\circ$ where $n$ is one and corresponds to Bragg reflection off the [1 0 0] plane or any equivalent plane. A schematic of the probe beam with...
respective to the atoms is shown in the inset in Fig. 1. Since 
the full angular width of the Bragg scattered light is small 
(measured to be 4.1 ± 0.4°), a precise alignment of the 
incident beam had to be performed at the 1/ min repetition 
rate of the experiment. In contrast, in one and two di-

The probe beam at the Bragg angle had a typical power 
of 0.3 mW and beam diameter of 300 μm, large enough to 
illuminate the entire atomic cloud, and was detuned from 
the 52S1/2, F = 2 → 52P3/2, F′ = 3 cycling transition of 
87Rb by a few natural linewidths, where the natural line-

width Γ is 6 MHz. The detuning needs to be sufficient so 
that the light traverses the entire atom cloud. Although the 
absolute signal varies with the detuning, the conclusions 
reached in this Letter appear not to depend strongly on the 
amplitude or sign of the detuning. The probe beam was 
applied for a few microseconds, enough to obtain a signal 
but short enough to avoid heating effects.

As the lattice is increased, the Bragg reflected signal 
increases as expected from the crystal ordering and tighter 
localization of the atoms (Fig. 1). For these data, the lattice 
in the z direction, which is also the direction of gravity, was 
ramped to 15E_R, where E_R = h^2/(2mλ^2) is the recoil 
energy, $h$ is the Planck constant, $m$ is the mass of $^{87}$Rb, 
and $λ_2 = 1064$ nm is the lattice laser wavelength. Simultaneously, the lattices in the horizontal directions 
were ramped to various lattice depths. Note that for our 
geometry the Bragg reflected intensity is insensitive to 
the lattice depth in the $z$ direction, because Bragg scat-
tering occurs only in the horizontal $xy$ plane, as we 
discuss later.

The scattering of light by a collection of atoms can be 
modeled in the following way. In the limit of low probe 
intensity and low optical density of the cloud, the Born 
approximation can be used. Then the scattering cross 
section $dσ/dΩ$ can be written as a product of one-
dimensional Debye-Waller factors where $dσ/dΩ \approx$ 
$\prod_i \exp[-(Δr_i)^2K_i^2/2]$, where $i = x, y, z$ is the index 
for the three dimensions, $K_i$ is the magnitude of the $i$th 
component of $K$, where $K = k_{in} - k_{out}$ is the difference 
between the incoming probe beam and Bragg scattered wave 

The data can be compared to a no-free-parameter theo-
retical line, assuming noninteracting atoms. The Bragg 
scattered intensity $B(N_L)$ as a function of lattice depth 
$N_L$ is proportional to $\exp[-λ^2K^2/(8π^2\sqrt{N_L})]$. Both 
the harmonic oscillator width $Δx$, which depends on the mass 
of the rubidium atom and trap frequency, and change in 
wave vector $K$ are known. This theoretical line and the data 
are shown in Fig. 1, and we see good agreement. Thus the 
Bragg scattered light as a function of lattice depth can be 
well described by a model where the atoms are assumed to 
be noninteracting Gaussian atomic wave functions whose 
spatial width is determined by the lattice depth.

Bragg scattering can also be used to probe the moment-
width of the atomic wave functions. This is done by 
measuring Bragg reflection as a function of the expansion 
time of the atoms between a rapid lattice turn-off and 
Bragg probe. In particular, the two horizontal lattices 
were turned off from 15E_R to 0E_R in less than 1 μs, and 
the lattice in the $z$ direction was kept at 15E_R. Turning off 
the lattices allows the atomic wave packets in each indi-

wave function width. Bragg scattered intensity vs lattice depth in 
units of the recoil energy. The right axis gives the corresponding 
root-mean-square width of the wave function squared. The solid 
line is a no-free-parameter curve given by the Debye-Waller 
factor. Error bars are statistical. The inset is a schematic of the 
setup for Bragg scattering.
previously for a thermal beam [16] and for a quantum optical Talbot effect, whose atomic version was observed parameter. Furthermore, the revivals are analogous to the signals should give a measure of the superfluid order originally confined in the lattices. Therefore, these revival ing of the superfluid atomic wave functions that were als as a function of expansion time because of the rephas low lattice depths, the Bragg scattered signal shows reviv the atoms from the optical lattice in three dimensions. At be studied with Bragg scattering after a sudden release of be seen to be Heisenberg limited.

Furthermore, the atomic spatial and momentum widths are wave functions with a spatial extent of tens of nanometers. That, by releasing the atoms from a lattice, we can directly probe pulse duration of 5 μs. Error bars are statistical.

assuming Gaussian atomic wave packets. This makes use of the well-known time-dependent behavior of a Heisenberg-limited Gaussian wave packet in free space which can be written as \[ (\Delta x(t))^2 = (\Delta x)^2 + (\Delta p)^2 t^2/m^2, \] where \( \Delta x \) and \( \Delta p \) are the uncertainty of position and momentum, respectively, at the initial time and \( t \) is the expansion time [15]. In a previous paper where the atoms were not quantum degenerate, the momentum distribution was assumed to be determined by temperature [12]. The results in this Letter show that the momentum uncertainty is Heisenberg limited, meaning \( (\Delta x)^2 (\Delta p)^2 = \hbar^2/4 \), so the Bragg scattered light \( B(t) \) as a function of expansion time decays as \[ \exp\left(- (\Delta p)^2 K^2 t^2/(2m^2)\right). \] This curve is also shown in Fig. 2. The curve is broadened by taking into account the probe beam duration, which was 5 μs and shows good agreement with the data. This analysis shows that, by releasing the atoms from a lattice, we can directly probe the in situ time evolution of the ground state atomic wave functions with a spatial extent of tens of nanometers. Furthermore, the atomic spatial and momentum widths are seen to be Heisenberg limited.

Coherent many-body nonequilibrium dynamics can also be studied with Bragg scattering after a sudden release of the atoms from the optical lattice in three dimensions. At low lattice depths, the Bragg scattered signal shows revivals as a function of expansion time because of the rephasing of the superfluid atomic wave functions that were originally confined in the lattices. Therefore, these revival signals should give a measure of the superfluid order parameter. Furthermore, the revivals are analogous to the optical Talbot effect, whose atomic version was observed previously for a thermal beam [16] and for a quantum degenerate gas in the temporal domain [17]. Here we observe the atomic Talbot effect for an interacting quantum degenerate gas in a three-dimensional optical lattice. Revivals can be seen in Fig. 3 and become less pronounced as the lattice depth increases.

In particular, the characteristic revival time is deter mined by \( \tau = \hbar/[(2k)^2/(2m)] \) and is 123 μs for our parameters, where \( 2k \) corresponds to the wave vector of the matter wave. However, with Bragg scattering we expect the first revival at half that time of 61 μs, which is what we observe in Fig. 3. This can be understood by realizing that the atomic wave packets need only travel half the lattice spacing to constructively interfere with the wave packets traveling in the opposite directions from the nearest neighbor sites.

The superfluid coherence as a function of lattice depth can be studied by comparing the Bragg reflected signal when the atoms are in the optical lattice to the signal at the first revival. The revival signal as a function of lattice depth is shown in Fig. 4, where the superfluid to Mott insulator transition is expected to occur around \( 13E_R \) [5]. In a non-interacting system without any dissipation, one would expect complete revivals. The decrease in revival fraction as the lattice depth increases is consistent with the picture that, as interactions increase, phase fluctuations among neighboring lattice sites increase and, consequently, the superfluid fraction decreases. In the Mott insulating phase, revivals should completely disappear, except for a very

![FIG. 2. Bragg scattering as a probe of the momentum wave function width. Bragg scattered intensity vs the free-expansion time of the atoms after rapidly turning off the lattices from \( 15E_R \). The decay in signal indicates a melting of the crystal structure or, in other words, spreading of the atomic wave packet with a given momentum uncertainty. The gray area is a no-free-parameter curve using the Debye-Waller factor taking into account the probe beam duration, which was shown in Fig. 2. The curve is broadened by taking into account the probe pulse duration of 5 μs. Error bars are statistical.](Image 66x572 to 283x745)

![FIG. 3 (color online). Revivals of Bragg scattered light. Bragg scattered intensity vs the expansion time in three dimensions for three different initial lattice depths: \( 5E_R \) (circles), \( 8E_R \) (triangles), and \( 15E_R \) (squares). Each data set is normalized to the Bragg intensity at the initial time. Revivals at lower lattice depths indicate coherence of the atoms across multiple lattice sites. The lines are phenomenological fits to exponentially decaying sine waves. Different lattice depth data are offset for clarity, and the error bar is representative. The inset is a solution to the one-dimensional Gross-Pitaevskii equation with experimental parameters and an initial state of a chain of Gaussian wave functions, showing the revivals of the density distribution as a function of time. The white dotted line represents the revival time.](Image 337x237 to 538x390)
In this Letter, we have not focused on the effects of the occupation number on Bragg scattering. In principle, the atomic wave functions are more extended for higher occupation numbers, but this effect is small for our parameters. However, light scattering at higher occupation numbers will have an inelastic component due to colliding atoms or photoassociation [20]. The dependence of Bragg scattering on lattice depth suggests that these effects are not dominant.

After Bragg scattering has been established as a probe for Mott insulators, it can now be applied to study other types of quantum phases such as antiferromagnetic ordering in both the occupation number and spin sectors [21,22]. Although temperatures required to realize spin ordering are on the order of tens to hundreds of picokelvins, recent experimental results suggest a way forward to lower the temperature of a two-component Mott insulator [23].

In conclusion, we have observed Bragg scattering of near-resonant photons from a quantum degenerate Bose gas in a three-dimensional optical lattice. We have shown that this technique probes not only the periodic structure of the atoms but also the spatial and momentum width of the localized atomic wave functions and the superfluid coherence.

Note that Bragg scattered revivals are complementary to the observation of diffraction peaks in time-of-flight absorption images [5]. Both are based on matter-wave interference due to superfluid coherence: revivals at short expansion times and diffraction at long expansion times. Diffraction is a far-field effect possible only for finite size samples, whereas revivals are a near-field bulk effect. The order of the revival or the angular resolution of the diffraction peaks determines whether these techniques probe short-range or long-range spatial coherence. Further studies are needed to determine which technique is more sensitive to certain aspects of the superfluid to Mott insulator transition.
