Engineering Encodable Lanthanide-Binding Tags

(LBTs) into Loop Regions of Proteins

Coordinates of the IL1β-S1 and IL1β-L3 structure have been deposited in the Protein Data Bank as
entry 3LTQ and XXX, respectively.
Lanthanide-binding-tags (LBTs) are valuable tools for investigation of protein structure, function and dynamics by NMR spectroscopy, X-ray crystallography and luminescence studies. We have inserted LBTs into three different loop positions (denoted L, R, and S) of the model protein interleukin-1β and varied the length of the spacer between the LBT and the protein (denoted 1-3). Luminescence studies demonstrate that all nine constructs bind Tb$^{3+}$ tightly in the low nanomolar range. No significant change in the fusion protein occurs from insertion of the LBT, as shown by the X-ray crystallographic structure of the IL1β-S1 construct and for the remaining constructs by comparing $^1$H-$^1$H-HSQC NMR spectra with wild-type IL1β. Additionally, binding of LBT-loop IL1β proteins to their native binding partner in vitro remains unaltered. X-ray crystallographic phasing was successful using only the signal from the bound lanthanide. Large residual dipolar couplings (RDCs) could be determined by NMR spectroscopy for all LBT-loop-constructs revealing that the LBT-2 series were rigidly incorporated into the interleukin-1β structure. The paramagnetic NMR spectra of loop-LBT mutant IL1β-R2 were assigned and the $\Delta\chi$ tensor components were calculated based on RDCs and pseudocontact shifts (PCSs). A model structure of IL1β-R2 was calculated using the paramagnetic restraints. The current data provide support that encodable LBTs serve as versatile biophysical tags when inserted into loop regions of proteins of known structure or predicted via homology modelling.

KEYWORDS

Lanthanide-binding-tag, LBT, loop-LBT, peptide fusion tag, encodable lanthanide-binding tag, paramagnetic tag, X-ray crystallography, NMR spectroscopy, luminescence, pseudocontact shift, residual dipolar coupling
Introduction

Peptide-based tags find widespread application in molecular, cellular, and structural biology.\textsuperscript{1,2} The recently introduced lanthanide-binding tags (LBTs) represent a versatile class of such tags given their potential utility in luminescence-based measurements\textsuperscript{3}, NMR spectroscopy\textsuperscript{4} and X-ray-crystallography\textsuperscript{5}. The spectral characteristics of LBTs arise from the photophysical properties of the selected trivalent lanthanide ions. In particular, Tb\textsuperscript{3+} and Eu\textsuperscript{3+} ions\textsuperscript{6} are luminescent upon sensitization by organic fluorophores and exhibit distinct and long-lived\textsuperscript{7} emission profiles allowing cellular localization and binding interaction studies of LBT-tagged proteins.\textsuperscript{8} These attributes make lanthanide ions useful probes for imaging and resonance energy transfer experiments.\textsuperscript{9,10} The indole side chain of tryptophan residue serves as a sensitizer to induce luminescence of the bound Tb\textsuperscript{3+} in LBTs.\textsuperscript{11} In X-ray crystallography, lanthanides are used as heavy atoms and provide high phasing power due to their strong anomalous scattering that can be used for single- or multi-wavelength anomalous phasing.\textsuperscript{12-15} In NMR-spectroscopy, the paramagnetic properties of lanthanide ions can be exploited to weakly align biomolecules along the magnetic field leading to structural and dynamic restraints such as residual dipolar couplings (RDCs), pseudo-contact shifts (PCSs), paramagnetic relaxation enhancement (PRE) or Curie cross-correlated relaxation (CCR).\textsuperscript{16-24} These parameters have been shown to be sufficient to determine the overall fold of the protein even in the absence of NOE information. Compared to short-range distance restraints such as NOEs (< 5 Å) and scalar couplings, RDCs provide long-range orientation information.\textsuperscript{25} Additionally, PCSs can be used to determine structures of protein-protein and protein-ligand complexes.\textsuperscript{26-29} Paramagnetic centers therefore augment the repertoire of methods which include liquid crystals,\textsuperscript{30} polyacrylamide gels\textsuperscript{31} and phages\textsuperscript{32} to induce partial alignment. The use of paramagnetic centers overcomes the problem of external alignment interactions of the target protein with the media. In addition, the determination of relative domain motion in multidomain proteins or RNA strictly requires internal alignment to provide an independent frame of reference.\textsuperscript{33,34}

The first biomolecular applications of paramagnetic alignment in NMR spectroscopy were introduced
utilizing naturally-occurring metal ion binding sites substituted with paramagnetic lanthanide ions or a heme-cofactor as the paramagnetic center bound to myoglobin. Similarities between the ionic radii of the divalent metal ions Ca\(^{2+}\), Mg\(^{2+}\), and Zn\(^{2+}\) and the trivalent lanthanide ions led to applications in which either one or two of these metal ions were replaced with paramagnetic lanthanide ions. This approach was then extended to diamagnetic proteins lacking native metal binding sites by fusion with entire paramagnetic protein domains such as zinc finger proteins, EF hand motifs, or calmodulin-binding peptides loaded with paramagnetic lanthanide ions for alignment. However, use of such domains results in a considerable increase in molecular weight, which may cause a subsequent loss of signal intensity and also compromise the function of the protein. Furthermore, the high mobility of the tags relative to the protein frame reduces the extent of alignment and therefore may result in a low number of measureable structural restraints.

Other strategies exploited small organic metal-binding chelators based on DTPA, EDTA or DOTA attached to the protein via cysteine modification chemistry. Although such chemical tags have been shown to induce alignment, they result in highly overlapping spectra due to peak doubling caused by the diastereomeric nature of the tag. This limitation could be overcome by a two point tag attached via cysteine disulfide bridges (CLaNP-5). Similar, the smallest known lanthanide binding tag, DPA, chelates the lanthanide ion using proximal carboxyl groups of the protein. These tags need to be positioned carefully taking into account a suitable distance between the thiol group and nearest carboxyl group. Additionally, free cysteine thiols need to be available in the protein of interest or need to be engineered by site-directed mutagenesis.

Exploiting the strategy of paramagnetic protein fusion domains for alignment, a family of closely related single-LBTs (sLBTs) were designed by optimizing naturally occurring calcium-binding loops to avidly bind Ln ions. These tags are short peptide sequences comprising up to 23 amino acids, which enable incorporation via standard molecular biology strategies. Design and engineering studies have resulted in tags that bind lanthanide ions tightly with low nanomolar K\(_D\)s and which are selective...
for lanthanides over other common metal ions.\textsuperscript{53-56} Attached to either the N- or C-terminus, sLBTs were successfully introduced for NMR structure determination of proteins.\textsuperscript{18,57} Based on previous investigations, the alignment induced by paramagnetic lanthanide ions was found to depend on the mobility of the tag relative to the protein frame.\textsuperscript{25} Rigidification and site-specific tagging was achieved by linking an sLBT to a single cysteine via a disulfide bridge within the protein.\textsuperscript{58,59} Two-point anchoring has been shown to further reduce the mobility of the tag compared to single-point anchoring.\textsuperscript{60} However, this approach necessitates appropriate placement of a cysteine residue close to the N-terminus. The strategy using an encodable multi-functional peptide-based tag at the protein terminus was further improved by the design of a double LBT (dLBT) with two lanthanide binding motifs. An increase in luminescence output, X-ray phasing power\textsuperscript{5} and alignment for NMR spectroscopy was shown for the dLBT-tagged ubiquitin fusion protein.\textsuperscript{61}

Use of LBTs as protein co-expression tags combines all of the aforementioned benefits of paramagnetic lanthanide complexes for NMR spectroscopy, X-ray crystallography, fluorescence microscopy, and LRET. In this report, we systematically investigate the possibility of further rigidifying LBTs with respect to the protein by incorporating a sLBT into defined loop regions. This design approach is based on our previous structure determination of Ln-bound LBTs. From these structural studies, we conclude that integration of the LBT unit into proteins should be feasible with minimal disruption of the loop structures of the target protein. In this report, we systematically investigate the loop position and the length of the linker between the protein and the tag. We use interleukin-1\(\beta\) (IL1\(\beta\)), a protein comprising three loops and a \(\beta\)-sheet core as a model system. In the case of IL1\(\beta\), the incorporation of the lanthanide binding tag into any of three different protein loops does not impact the overall fold of the protein, the \textit{in vitro} affinity for native binding partner, or the binding affinity of Ln\textsuperscript{3+} to the LBT. The present report demonstrates a new and potentially general application of encoded lanthanide-binding tags.
Results and Discussion

Design of IL1β-LBT. In order to utilize lanthanide-binding coexpression tags in NMR spectroscopy and in phasing for X-ray crystallography in macromolecular structure determination, the lanthanide tag must be well ordered with respect to the protein. Indeed, initial attempts to use sLBTs for phasing failed in our laboratories, presumably because the tag was too mobile with respect to the protein when attached to the N- or C-terminus. X-ray structure determination was accomplished successfully utilizing an N-terminal dLBT, wherein two Tb\(^{3+}\)-binding modules were concatenated in a single 32-residue peptide.\(^5\) The X-ray studies and NMR-spectroscopic analysis of the subnanosecond dynamics of the tag\(^6\) demonstrated that the increased tag size results in a less mobile tag that is sufficiently ordered with respect to the fusion protein ubiquitin.

A survey of structures deposited in the protein data bank reveals that in over 50% of the structures submitted to the PDB, the N-terminal and/or C-terminal residues are disordered (E. Peisach, unpublished results). These statistical studies suggest that without significant interaction between the LBT and fusion protein or other means of decreasing domain-domain dynamics, the LBT might be ordered, but adopt several different orientations relative to the core of the protein of interest, therefore limiting its utility.

One method to reduce the conformational dynamics is to restrain both termini of the LBT to decrease interdomain motion. By inserting the LBT integral to the proteins sequence, one might obtain a protein bearing the LBT in a stable conformation. Although such placement requires some knowledge of either the secondary or tertiary structure of the protein, secondary structure prediction and homology modelling programs now allow for considerable accuracy in the prediction of β-turns from amino-acid sequences. Therefore it may be possible to predict appropriate placement of LBTs in structures based upon analyses of protein structures directly from the protein sequence.\(^62,63\) As a model system, the LBT was placed into three different loops (denoted L, R, and S) of IL1β differing in spacer length (denoted
LBT-1-3) between the LBT and IL1β resulting in nine different loop-LBT constructs (Table 1). The choice of the LBT sequence GYIDTNNDGWIEGDELY was based upon inspection of the crystal structure of ubiquitin with the dLBT tag.\textsuperscript{5} Specifically, the termini of one terbium-binding loop were chosen so that they could insert into a pre-existing protein loop allowing overlap of the two short β-strands of the dLBT with the native β-turn of the protein. It was envisioned that the metal-binding residues would remain appropriately positioned to bind the lanthanide without disrupting the protein fold. Based on published crystal and NMR structures of IL1β, three loops were identified as well suited for LBT insertion (Figure 1).\textsuperscript{64,65} Previously, the S loop has been replaced in a similar, but not identical position, (residues 50-53 versus those replaced herein 52-55) with the result that the protein was well folded, as assessed by NMR structure determination and the loop insertion (alpha 1-antitrypsin inhibitor) retained biological activity.\textsuperscript{66} In this case, the construct did not have the same number of residues removed on either side of the loop and yet still folded robustly. This provides evidence that precise pre-knowledge of loop structure is not an absolute requirement for the success of insert design.

![Figure 1](image_url)

**Figure 1.** NMR structure of interleukin-1β (IL1β).\textsuperscript{65} sLBTs have been incorporated into three different loops shown here in purple for the L-loop (residues 74 to 77), in green for the S-loop (residues 52 to 55) and in cyan for the R-loop (residues 138 to 141).

**Table 1.** Summary of IL1β-LBT constructs, LBT sequences, $K_D$ and q values.
Three constructs of each S-, L- and R-series were generated such that in the LBT-1 series (IL1β-S1/L1/R1), the LBT was inserted between the middle loop residues. In the LBT-2 series (IL1β-S2/L2/R2), the flanking residues were removed and the LBT was inserted in their place. In the LBT-3 series (IL1β-S3/L3/R3), all four protein loop residues were removed and replaced by LBT. Dissociation constants (K_D) were determined by luminescence titration of LBTs by Tb^{3+}, in 100 mM NaCl and 10 mM HEPES buffer at pH 7.0. All values are the average of at least three titrations. The number of bound water molecules, q, was determined by luminescence decay experiments (see Materials and Methods).

An additional goal for incorporation of the tag was to retain binding affinity for the native IL1β receptor, s-IL-1R1. For the S-series proteins, it is known from the literature that modification of this loop does not impair receptor binding, and binding is not related to the size of the inserted loop. The second loop (L-series) targeted for LBT insertion is a β-turn. A previous co-crystal structure of IL1β with the IL1 receptor showed that this second loop is not involved in receptor recognition, and from computational studies it was predicted that it is also not involved in binding of an accessory protein. Because residues 138-141 were also shown not to be involved in binding to the receptor, this loop was chosen for the third (R) series. It is also known that derivatization of a IL1β-K138C mutant with iodoactamidofluorescein does not alter receptor recognition, and that fusion with a large (275 kDa) protein did not significantly affect receptor binding. Thus, inserting the relatively small LBT at this position may result in a construct retaining its ability to bind the receptor.

**Preparation of IL1β-LBT.** For luminescence measurements, NMR spectroscopy and receptor binding assays, full-length IL1β-S1 – S3, IL1β-R1 – R3 and IL1β-L1 – L3 were obtained via heterologous expression in *Escherichia coli* using a glutathione S-transferase (GST) fusion strategy for purification. For luminescence measurements and NMR spectroscopy, the expressed GST-IL1β-LBT

proteins were cleaved with TEV protease at the inserted TEV site between the GST and IL1β and purified by size-exclusion chromatography to yield the desired LBT-tagged IL1β products.

For all NMR spectroscopic applications, 15N-labeled proteins were expressed in P-5052 minimal-auto-induction media. Expression of the R- and S-series resulted in very good yields of the fusion protein of 40-100 mg/L. Proteins of the L-series expressed in inclusion bodies in 15N-minimal media. Therefore, the temperature was lowered to 16°C and proteins of the L-series expressed in yields of 20 mg/L (see Supplementary Information Figure S1). Constructs of the S-series used for crystallization were expressed in inclusion bodies without the use of a GST-tag and subsequently refolded (see Materials and Methods).

Receptor-binding assays. The IL1s including IL1α and IL1β are proinflammatory cytokines, which participate in the regulation of numerous immunological and inflammatory processes. To control biological activity of IL-1, initiation of signal transduction occurs upon binding of agonist ligands (IL1α or IL1β) to a specific membrane receptor, the transmembrane glycoprotein of the immunoglobulin superfamily IL-1R1.

Receptor binding studies were performed using a pull-down assay, in which GST-tagged IL1β-LBT bound to glutathione sepharose beads served as bait for the soluble receptor s-IL-1R1. As confirmed by SDS-PAGE and Western blot analysis (see Supplementary Information, Figure 2 and 3) the incorporation of the LBT does not impair the receptor binding capability of the engineered loop-LBT IL1β mutants. Representative data for the IL1β-S-series are shown in Figure 2 (lanes 4, 7 and 10).
Figure 2. Receptor-binding assay results, with representative 12% SDS-PAGE gel (left) and anti-sIL-1R\textsubscript{1} Western blot (right) shown for GST-IL1\textbeta-S1, -S2 and -S3. All experiments were performed in 10 mM HEPES, 100 mM NaCl, pH 7.0 with 0.1% BSA. 1 mg of each protein was preloaded with 1 equivalent of Tb\textsuperscript{3+}.

**Photophysical characterization.** We assessed the photophysical properties of the newly incorporated tags via determination of the luminescence properties including the number of Tb\textsuperscript{3+}-bound water molecules. Luminescence titration studies revealed that the LBTs in all three insert sites bind Tb\textsuperscript{3+} tightly, with binding constants in the low nanomolar range (Figure 3 and Table 1). The binding affinity of Tb\textsuperscript{3+} to the loop-LBTs is similar to those found for the first binding event of Tb\textsuperscript{3+} binding to the dLBT.\textsuperscript{18,61} While IL1\textbeta-L2 shows a slightly higher dissociation constant than the others, we note that two positively charged lysine residues flank the LBT incorporation site in this construct. It is possible that the positively charged side chains surrounding the LBT slightly impede binding of Tb\textsuperscript{3+}. From these results, it can be concluded that covalently linking the LBT into protein loops does not compromise binding affinity for Tb\textsuperscript{3+}.
Figure 3. Tb³⁺ titration data and fit, shown for IL1β-R1. Data points represent the average of three independent measurements.

LBTs were originally developed to exclude H₂O from the lanthanide coordination sphere, since coordinated water molecules cause excited Tb³⁺ to undergo rapid, non-radiative energy transfer to the vibrational states of the water O-H bonds leading to a decrease in luminescence intensity and lifetime. The number of bound water molecules was thus evaluated for six of the nine IL1β-LBT proteins (see Table 1 and Supplementary Information Figure S4) using standard methods. It was confirmed that there are no water molecules bound to the metal center in any of the loop-LBT proteins as shown by near-zero \( q \) values (Table 1). These findings are consistent with data reported previously for sLBTs and dLBTs.

**Characterization of loop-LBT by NMR spectroscopy.**

In solution, dipolar couplings are averaged to zero due to molecular tumbling. Lanthanides with an anisotropic magnetic susceptibility tensor \( \Delta \chi \) induce partial alignment within the magnetic field leading to residual dipolar couplings (RDCs). The RDC between two heteronuclear nuclei A and B, \( D_{AB} \), is described by
\[ D_{AB}(\theta, \phi) = -\frac{\gamma_A \gamma_B \mu_0 S h}{8\pi^2 r_{AB}^3} \left[ A_a \left(3 \cos^2 \theta - 1\right) + \frac{3}{2} A_r \sin^2 \theta \cos 2\phi \right] \] (1)

where \( \theta \) and \( \phi \) describe the orientation of the internuclear vector in the principal axes system of the alignment tensor, \( A_a \) and \( A_r \) are the axial and rhombic components of the alignment tensor, \( r_{AB} \) is the internuclear distance, \( S \) is the generalized order parameter, \( \gamma_A \) and \( \gamma_B \) are the gyromagnetic ratios of nuclei A and B, \( \hbar \) is Planck's constant divided by \( 2\pi \) and \( \mu_0 \) is the magnetic permeability of vacuum.\(^{25,59}\)

Furthermore, pseudocontact shifts (PCSs, \( \Delta \))\(^{75}\) induced by the anisotropic magnetic susceptibility of paramagnetic centers correspond to a change in the observed chemical shifts between paramagnetic and diamagnetic samples that depend on distance and position relative to the paramagnetic center and are described by

\[ \Delta \Delta = \frac{1}{12\pi r^3} \left[ \Delta \chi_{ax} \left(3 \cos^2 \theta - 1\right) + \frac{3}{2} \Delta \chi_{rh} \sin^2 \theta \cos 2\phi \right] \] (2)

where \( \Delta \chi_{ax} \) and \( \Delta \chi_{rh} \) are the axial and rhombic components of the anisotropic magnetic susceptibility tensor describing the magnetic moment of the paramagnetic center and \( r, \theta, \) and \( \phi \) are the spherical coordinates of the nucleus in the frame of the \( \Delta \chi \) tensor.\(^{76}\)

The alignment tensor is proportional to the \( \Delta \chi \) tensor:

\[ A_{a,r} = \frac{B_0^2}{15 \mu_0 k_B T} \Delta \chi_{a,r}, \] (3)

where \( B_0 \) is the external magnetic field, \( k_B \) is the Boltzmann constant, \( T \) is the temperature in Kelvin, and \( \Delta \chi_{a,r} \) are the axial and rhombic components of the anisotropic magnetic susceptibility tensor. The observed RDC depend on the magnetic field strength \( B_0^2 \), and the \( \Delta \chi_{ax} \) and \( \Delta \chi_{rh} \) for the different lanthanides.\(^{59,77}\)

These paramagnetic properties differ between lanthanides.\(^{75}\) Therefore, the extent of alignment and observed RDC and PCS can be fine tuned by the choice of the paramagnetic ion. The peptide-based
LBTs bind Tb$^{3+}$, Tm$^{3+}$, Er$^{3+}$, Lu$^{3+}$, La$^{3+}$, Dy$^{3+}$, Y$^{3+}$, Ho$^{3+}$ and NMR studies were performed for the described lanthanide ions.$^{18,57-61}$ The possibility of measuring RDCs for LBTs as fusion tags was first shown for sLBTs and dLBTs attached to the N-terminus of ubiquitin using Tm$^{3+}$ as the paramagnetic ion. Compared to the sLBT, an additional $\beta$-sheet was formed in the structure of the dLBT peptide chain which resulted in decreased tag flexibility and improved alignment. For the sLBT, RDC values between -2 to 6 Hz could be measured on a spectrometer with a $^1$H frequency of 800 MHz. The size of the RDC was increased for the dLBT by a factor of three with RDCs in the range of -18 Hz to 12 Hz due to the decreased mobility of the tag relative to the protein as inferred from analysis of order parameters from $^{15}$N relaxation data. For the sLBT complexed with Tb$^{3+}$, RDCs were observed between -7.6 and 5.5 Hz.

Previous studies have shown that fusion to the highly flexible N- and C- termini limits the possible attachment sites and does not confer maximum rigidity of the tag. Attaching the sLBT sequence via a disulfide linkage to a cysteine residue yielded RDC values from -12 to 21 Hz for Tm$^{3+}$ at 800 MHz. Recently, increased rigidification could also be achieved by linking the sLBT via two anchoring points providing RDC values in the range of -12 to +11 Hz for Tb$^{3+}$ at 600 MHz.$^{60}$ The present study was conducted to improve the rigid attachment of the sLBT. NMR analyses were performed for all nine IL1$\beta$-LBT constructs in the IL1$\beta$-R, -S and L series. We titrated $^{15}$N-labeled protein with a 1.1-fold excess of paramagnetic Tb$^{3+}$ and Tm$^{3+}$ ions or Lu$^{3+}$ ions as a diamagnetic reference. Paramagnetic shifts and signal broadening could be observed in the $^1$H-$^{15}$N-HSQC spectra of the paramagnetic protein complexes demonstrating the utility of loop-LBTs for the measurement of paramagnetic effects.

**Magnitude of observed RDCs.** RDC values for the amide $^1$H-$^{15}$N backbone amide spin pairs ($^1$D$_{HN}$) were obtained by subtracting the scalar coupling ($^1$J$_{HN}$) in the presence of diamagnetic Lu$^{3+}$ from the sum of scalar and dipolar coupling in the presence of paramagnetic Tb$^{3+}$, both measured in $^1$H-$^{15}$N-IPAP-HSQC spectra. Large RDC values could be observed for the IL1$\beta$-S-series in the range of -14 to 18 Hz for Tb$^{3+}$, for the IL1$\beta$-R-series of about -12 to 12 Hz and for IL1$\beta$-L-series of -16 Hz to 18 Hz at 600
MHz. Additionally, RDCs were measured for the loop mutant IL1β-R2 using Tm$^{3+}$ as a second paramagnetic lanthanide ion. RDCs with values from -12 to 10 Hz were observed (see Supplementary Information, Figure S6). Compared to RDC values of sLBT, the loop-LBTs provide a more than three-fold improvement demonstrating that the LBT is rigidly attached within the protein frame. Furthermore, the RDC values depend on the linker length, where the LBT-2 series was found to be optimal (Figure 4).

**Figure 4.** (a) RDC histogram for IL1β-S1, -S2 and -S3. (b) RDC histogram for IL1β-R1, -R2 and -R3. (c) RDC histogram for IL1β-L1, -L2 and –L3. (d) Estimated values of $D_a^{NH}$ and $R$ are obtained by nonlinear least-squares optimization of equations $D_{zz}^{NH} = 2D_a^{NH}$, $D_{yy}^{NH} = -D_a^{NH}(1+1.5R)$,
\[ D_{xx}^{NH} = -D_{a}^{NH} (1 - 1.5R) \] and \[ R = \frac{D_{yy}^{NH}}{D_{a}^{NH}}. \] The values of \( D_{zz} \), \( D_{yy} \) and \( D_{xx} \) were measured from the histograms of the RDCs for IL1\( \beta \)-LBT by taking the extreme high and low values such that \[ |D_{zz}^{NH}| > |D_{yy}^{NH}| \geq |D_{xx}^{NH}|. \] \( D_{xx} \) corresponds to the most populated value in the histogram of the RDCs.\(^{78,79}\)

In order to make use of RDCs for structure refinement, the magnitude of the axial component of the molecular alignment tensor and the rhombicity must be known. A generalized expression for the RDC can be described by

\[ D_{AB} (\theta, \phi) = D_{a}^{AB} \left[ \left( 3 \cos^2 \theta - 1 \right) + \frac{3}{2} R \sin^2 \theta \cos 2\phi \right], \quad (4) \]

where \( D_{a} \) is the magnitude of the residual dipolar coupling tensor with

\[ D_{a}^{AB} = -(B_0^2 h/60kT\pi^2) S_{\gamma_A \gamma_B} \left\langle r_{AB}^{-3} \right\rangle \chi_A \] and \( R \) the rhombicity.\(^{78,80}\) The histogram of the ensemble of RDCs approximates a powder pattern from which \( D_{a}^{NH} \) and \( R \) are readily extracted in the absence of any prior structural information for all IL1\( \beta \)-LBT loop constructs.\(^{78,80,81}\) The histograms for the IL1\( \beta \)-S, -R and -L series suggest asymmetric shapes of the molecules with calculated values for the rhombicity greater than zero \((R > 0)\) (Figure 4).

**Diamagnetic assignment of the loop-LBT construct IL1\( \beta \)-R2.** To assign the \(^{1}H-{^{15}}N\)-HSQC cross-peaks of the diamagnetic spectra of IL1\( \beta \)-R2, a 3D-\(^{1}H-{^{15}}N\)-NOESY-HSQC was recorded and assigned utilizing the known assignments of wt-IL1\( \beta \).\(^{82}\) The similarity of the \(^{1}H-{^{15}}N\)-HSQC spectra of wt-IL1\( \beta \) and the LBT insertion mutants shows the minimal structural perturbation induced by the LBTs onto the protein structure (see Supplementary Information Figure S5). Additional peaks for the LBT sequence could be detected by comparing the diamagnetic spectra with a reference sample missing the lanthanide ion. In this sample, 89\% of the backbone amide signals of diamagnetic spectra could be assigned. Figure 5 shows the paramagnetic and diamagnetic \(^{1}H-{^{15}}N\) HSQC spectra of IL1\( \beta \)-R2. The effects of the paramagnetic lanthanide ion are shown in representative one-dimensional traces for residues N119,
I104, and M44 because residues in close proximity to the lanthanide ion experience larger paramagnetic effects than those more distant to the paramagnetic center.

**Figure 5.** $^1$H-$^{15}$N-HSQC spectrum showing the assigned backbone amide resonances of the sLBT-tagged interleukin-1β-R2 in the presence of 1.1 equivalents of diamagnetic Lu$^{3+}$ (blue) and paramagnetic Tb$^{3+}$ (pink) and Tm$^{3+}$ (green). PCS vectors are indicated as black lines between corresponding diamagnetic and paramagnetic peaks. 1D spectra from the diamagnetic (blue) and paramagnetic (pink, Tb$^{3+}$) experiments are shown for representative resonances indicating paramagnetic shift and signal broadening. Additional peaks resulting from the LBT sequence are annotated in orange.

**Paramagnetic assignment of the loop-LBT construct IL1β-R2.** The $^1$H-$^{15}$N HSQC cross peaks of the paramagnetic spectra were assigned using the diamagnetic assignment. Based on the similarity of the PCS values of the bonded $^1$H and $^{15}$N spins are the resonances in the $^1$H-$^{15}$N-HSQC spectra for Tb$^{3+}$, Tm$^{3+}$ and the diamagnetic sample with Lu$^{3+}$ displaced on diagonal lines by what most of the signals could be assigned.$^{83}$ Signals that remained unassigned were assigned using a bootstrapping procedure. The initial experimental PCS values were used to predict a first position of the lanthanide ion based on
the wild type crystal structure (PDB entry 9ILB) using the program Numbat\textsuperscript{84}. Prediction of the unassigned PCSs onto the wild type crystal structure was achieved using the program Echidna\textsuperscript{83} where the initial lanthanide position, the diamagnetic assignment, and the peak table of the paramagnetic \textsuperscript{1}H-\textsuperscript{15}N-HSQC including some of the reliable and unambiguously assigned paramagnetic peaks were used as input data.\textsuperscript{84} The iterative procedure resulted in the assignment of 102 out of 140 of the backbone amide cross-peaks peaks for the spectrum with Tb\textsuperscript{3+} and 99 cross-peaks for that with Tm\textsuperscript{3+}. PCS of up to 1 and 0.6 ppm could be detected for Tb\textsuperscript{3+} and Tm\textsuperscript{3+}, respectively (see Supplementary information, Table 2).

A cross-validation of the experimental RDCs showed a correlation of 0.93 with the three-dimensional crystal structure of native IL1\textbeta (PDB entry 9ILB) using the program PALES.\textsuperscript{79} A structure minimization was performed using the crystal structure of native IL1\textbeta and the previously optimized alignment tensor parameters for Tb\textsuperscript{3+} showing only small changes (see Supplementary Information Figure S6). Cross-validation of the final experimental RDCs and PCS showed an excellent fit with the refined crystal structure of wt-IL1\textbeta (Figure 6a). \Delta\chi tensor values were than calculated based on the PCS values and the refined wild type crystal structure. These values are, however, smaller than those reported in the literature, the reason for which remains unclear.\textsuperscript{85} The data were proven to be robust when performing a Monte-Carlo error analysis where 30\% of the experimental PCS were randomly deleted. The Monte-Carlo error analysis and the principal tensor axis orientations are shown in Sanson-Flamsteed-projections. Additionally, using the assigned PCS, perfect metal positions located adjacent to the R-loop were calculated with an optimal distance of 10\AA with respect to the loop residues. Alignment tensors for IL1\textbeta-R2 with Tb\textsuperscript{3+} were calculated based on the RDC values and the refined crystal structure of wt-IL1\textbeta using PALES.\textsuperscript{79} To compare the RDC and PCS datasets the alignment tensor was converted to the \Delta\chi tensor using equation 2. The result shows a \Delta\chi_{\text{RDC}} tensor scaled by 20\% - 30\% in comparison with \Delta\chi_{\text{PCS}}. The RDCs seem to be more sensitive to the mobility of the lanthanide ion than the PCS,
such observations have been previously discussed (Figure 6). Figure 6. (a) Scatter plot showing the correlation between observed $^1$D$_{\text{HN}}$ dipolar shifts [Hz] for loop-LBT mutant IL1$\beta$-R2 and those back-calculated using the program PALES based on the refined crystal structure of IL1$\beta$ (PDB entry 9ILB). Cross-validation of the final experimental PCSs using Numbat. Orientations of the $\Delta \chi$ tensor axis components of Tb$^{3+}$ in complex with IL1$\beta$-R2 are visualized in Sanson-Flamsteed projections with the z-, y- and x- axis in blue, green and red respectively. 500 sets of plots represent the result of the Monte Carlo error analysis in which 30% of the data was randomly deleted. (b) The position of the lanthanide ion with respect to the protein is indicated as a black sphere for Tb$^{3+}$ and as an orange sphere for Tm$^{3+}$. (c) The calculated axial and rhombic components of the anisotropic magnetic susceptibility ($\Delta \chi$) tensor and the alignment tensor based on the refined crystal structure of IL1$\beta$ (PDB entry 9ILB).

Model of the loop-LBT construct IL1$\beta$-R2. In an effort to invert the iterative assignment procedure, we modeled the structure of the loop from experimental RDCs, Diffusion Anisotropy and PCSs using CNS. The X-ray crystal structure of IL1$\beta$ (PDB entry 9ILB) was used as starting structure. Distance
information calculated for the lanthanide position from PCSs using Numbat and the experimental RDCs were used as restraints. Calculation of the loop-LBT-IL1β-R2 model structure was performed keeping the stable secondary structure core parts of the molecule by fixing the heavy atom coordinate positions and addition of hydrogen bond restraints. Based on the X-ray crystal structure of IL1β-S1 (vide infra), heavy atom distance restraints were added for the LBT and the lanthanide ion to keep the structure of the tag intact. The linker region of the tag was fully unrestrained. Figure 7 shows the final calculated model of the loop-LBT-construct IL1β-R2. Following the calculation, a cross-validation of the model was performed using the paramagnetic restraints in Numbat. The back-calculated PCS for the backbone amide protons are in excellent agreement with the model. In addition, the overlay of the lanthanide position resulting from the model and from the Numbat back-calculated position is in excellent agreement and gives further support for the calculated model of IL1β-R2 and to the applicability of loop-LBTs for protein structure determination.

![Graph](image)

**Figure 8.** Generalized order parameters \(S^2\) for the \(^1\text{H}-^{15}\text{N}\) amide bond vector shown for loop-LBT IL1\(\beta\)-R2. Analysis was performed using the programme TENSOR2. An overall \(\tau_c\) of 11.49 ns and a axially symmetric diffusion tensor was determined with an asymmetry of 1.37.

Spin-lattice \(^{15}\text{N}-R_1\) and spin-spin \(^{15}\text{N}-R_2\) relaxation rates as well as the heteronuclear \({}^1\text{H}\}^{15}\text{N}\) nuclear Overhauser effect were measured for most backbone amide groups of loop-LBT IL1\(\beta\)-R2 and used to calculate the general order parameter \(S^2\), characterizing the amplitude of internal amide bond vector motion on time scales faster than the overall correlation time \(\tau_c\), by a Lipari-Szabo analysis\textsuperscript{88,89} with the program TENSOR2\textsuperscript{90} using an anisotropic diffusion tensor (Figure 8).

Mean order parameters for loop-LBT IL1\(\beta\)-R2 show lower values for the loop-LBT residues than those of the remainder protein indicating some mobility of the loop residues (G1-Y17) compared to the \(\beta\)-sheet core structure of IL1\(\beta\). However, these values are of the same order than those for the dLBT.
sequence. The increased dynamics in the loop-LBT residues might account for the measured Δχ tensor values resulting in averaged tensor values.

Characterization of IL1β-S1 by X-ray crystallography

Comparison to native IL1β and known LBT structures. The structure of IL1β-S1 complexed with Tb³⁺ (Figure 9) determined by X-ray crystallography comprises an IL1β with the LBT domain inserted at the end of a pair of anti-parallel β-sheets. The structure of IL1β is essentially unchanged. Notably, initial phasing was accomplished utilizing only the anomalous scattering from the bound Tb³⁺. Comparison of the structure of IL1β-S1 to that of the known 1.5 Å IL1β structure (PDB accession code 2NVH) shows an RMSD of 0.918 Å for 152 of 153 residues. The largest deviations are found in residues 32-34, 105-109 (both surface turns) and in 49-53. The 49-53 stretch leads up to the insertion with a Cα displacement of 1.6 to 3.3 Å. Notably, after the insertion point and the first atom of residue 54 the displacement is only 0.2-0.6 Å. Thus, no significant change in the fusion protein occurs from insertion of the LBT, as shown by the X-ray crystallographic structure. Only some minor, local deviations are apparent at the insertion site itself. The generality of the finding that the LBT does not affect the scaffold protein structure is also supported by the X-ray crystallographic structure determination of IL1β-L3 to 1.7 Å resolution (Supplementary Information Table S4). The LBT loop in this structure showed disorder (7 of the 17 LBT residues could not be modelled and the lanthanide could not be built into the electron density). However, the overall protein fold does not differ from that of wild-type IL1β with RMSD = 0.87Å. The observed disorder in the LBT electron density in IL1β-L3 is also consistent with the conclusion from NMR that the mobility of the LBT is dependent on the insertion topology.
Figure 9. (a) Crystal structure of IL1β-S1 colored from N-terminus (red) to C-terminus (blue). (b) Overlay of the IL1β-S1 model (green) on the reference 2NVH (red) (c) IL1β-S1 structure colored by temperature factor (blue, low to red, high). The LBT (inserted in the S-loop) is marked by the Tb³⁺ depicted as a sphere.

The LBT inserted in the IL1β-S1 construct was designed based on the structure of the double LBT domain from the dLBT-ubiquitin structure. The RMSD of the 20 matching atoms of the IL1-S1-LBT and the dLBT is 0.682 Å. Therefore, the structure of the LBT is essentially unchanged in the environment of the insertion site in the protein (Figure 10).

Figure 10. Overlay of the LBT portion of IL1β-S1 (red) with the dLBT portion of the ubiquitin structure (green) showing how the dLBT forms a pair of anti-parallel beta strands which fit into the beta sheet of IL1β.

B-factor analysis. In a typical globular protein, the temperature factors of atoms in the model are
lower in the core of the protein and increase radially from the center, reflecting the mobility inherent in
the protein. Such is the case with the reference IL1β (PDB entry 2NVH). However, in the IL1β-S1
model, the relatively low B-factors in the core are shared by those residues in the LBT. The atoms of the
LBT domain have temperature factors of 11-17 Å² compared to the overall average B-factor of 31 Å² for
the entire structure. The lower values are for atoms chelating the Tb³⁺ and the tryptophan which makes a
crystal contact. This is consistent with the LBT domain acting like a “core”. The stability of the LBT
domain allows for the scattering from Tb³⁺ to be used for phasing. Additional stability is afforded by
crystal packing interactions between IL1β molecules.

**Crystal Packing.** With any X-ray crystal structure, one must be cognizant of the role that crystal
packing may have on the target molecule. In this structure, as in the dLBT-ubquitin model, the
tryptophan of the LBT fits into a groove of a hydrophobic pocket created by the symmetry related
molecule, thereby stabilizing and immobilizing the LBT. The pocket is formed on the face of the
symmetry related 105-109 region which also showed a 1.0-3.9 Å displacement relative to the reference
model 2NVH. Although the relative mobility of the LBT is restricted in this design by the insertion into
a β-turn, a potential additional source of stability is the formation of this crystal contact. However, the
results from NMR presented herein reflect the solution mobility of the LBT domain in these fusion
proteins and rule out crystal contacts as the primary source of inter-domain stability.

**Conclusions**

Overall, this study provides a comprehensive analysis of the effect of inserting LBTs into protein
loops, using the model protein IL1β. Analysis of the loop position shows that a canonical β-turn or loop
motif provides a suitable insertion site. Luminescence studies demonstrate that the binding affinity is
not correlated to loop mobility (determined by NMR) and is fairly insensitive to flanking sequence or to
length of spacer between LBT and protein. However, effects correlated with motion as assessed by
NMR show that the LBT-2 series (IL1β-S2, -R2 and –L2) is superior in terms of conferring a low
relative mobility of the LBT with respect to the fusion partner.

Through a systematic analysis, we show that LBTs are versatile tools for the exploitation of the photophysical, paramagnetic and diffractive properties of lanthanides in NMR and crystallographic structure determination and luminescence applications. LBTs can be attached to proteins via the N-terminus and/or C-terminus, attached to 1 or 2 cysteine side chains or, as shown here, incorporated into loop regions of proteins, relying on well-established molecular biology protocols. For IL1β, incorporation of the LBT neither impairs the overall fold of the protein nor the binding affinity of Ln$^{3+}$ to the LBT. As such, the insertion of and LBT can be used for phasing via X-ray crystallography. Furthermore, the loop insertion does not impair binding of IL1β to the soluble receptor. Incorporation of LBTs into loop regions of proteins provides a broadly applicable strategy for protein research. Such an improved toolkit is of importance to future applications in phase determination in X-ray crystallography and for the structure determination of large protein complexes by NMR where the LBT can be fused into one NMR-silent binding partner without increased mobility in a similar manner.

Materials and Methods

Preparation of IL1β-LBT. Starting from a plasmid encoding human IL1β obtained from ATCC (S595) the cloning of IL1β–S2, IL1β-L2 and -R2 was accomplished via a two-step PCR procedure. First, the two halves of IL1β were separately amplified by PCR, with primers that included overhangs encoding the desired LBT. (GYIDTNNDGWIEGDELY). The two PCR fragments contained complementary sequences at their termini that could be annealed to each other. Extension via PCR then yielded a product encoding full-length IL1β-S2, -L2 or -R2 respectively, with the LBT at the desired position. This insert was then inserted into the vector pGEX-4T-2. A TEV (Tobacco Etch Virus) protease cleavage site (ENLYFQM) was included to facilitate removal of the N-terminal GST (glutathione-S-transferase) fusion protein. The final construct expresses GST-ENLYFQM-IL1β(LBT).

To generate IL1β-S1 and IL1β-S3, site-directed mutagenesis was used to insert or remove codons
corresponding to the appropriate amino acids (see Table 1). IL1β-R1 and –R3 were similarly generated from IL1β-R2, and IL1β-L1 and –L3 were similarly generated from IL1β-L2.

Initially, proteins were expressed using IPTG induction with excellent protein yields of ~25-50 mg/L, identified by SDS-PAGE, and purified using glutathione sepharose. The temperature for IPTG-induced protein expression was lowered to 16°C since expression at higher temperatures led to truncation products. Improved yields could be obtained using the Studier autoinduction method for protein expression.\(^{70}\) The proteins were expressed in BL21-CodonPlus(DE3)-RIL using ZYM-5052 complex autoinducing media with excellent yields of about 40–200 mg/L. Protein expression was conducted overnight at 37°C, resulting in no significant truncation products. Following purification on glutathione sepharose, the GST-IL1β-LBT proteins were cleaved with TEV protease and purified by size-exclusion chromatography to yield the desired LBT-tagged IL1β products. For protein expression of the L-series the temperature was lowered to 16°C to avoid expression in inclusion bodies.

For crystallization experiments, constructs of the S-series were cloned starting from IL1-AT(4) which was kindly provided by Prof. T. Pochapsky, Brandeis University. The gene encoding IL1β was modified to remove the chymotrypsin recognition site, insert the LBT domain, and transfer the gene to a pET3a vector with a T7 promoter for IPTG inducible expression. Standard molecular biology tools were used via a QuickChange protocol to insert the LBT using an “inchworm technique”, adding approximately a third of the LBT with each round of modification. Plasmids were sequenced at the Tufts University Core Facility.

**Luminescence Titrations.** Titrations were recorded on a Fluoromax-3 spectrometer (Jobin Yvon Horiba) in a 1 cm path length quartz cuvette. Tryptophan-sensitized Tb\(^{3+}\) emission spectra were collected by exciting the sample at 280 nm and recording emission at 544 nm. A 315 nm longpass filter was used to avoid interference from harmonic doubling. Slit widths of 5 nm were used with one second integration times. Luminescence spectra were recorded at room temperature and were corrected for
intensity using the manufacturer-supplied correction factors. For all titrations the buffer was 10 nM HEPES and 100 mM NaCl. Titrations were performed in 3 mL of buffer by adding aliquots of the appropriate lanthanide to 50 nM solutions of the appropriate protein to obtain a titration curve. The protein concentration of the stock solutions used in photophysical experiments was determined by UV absorption at 280 nm in a 6 M guanidinium hydrochloride solution using the known extinction coefficient of Trp. After recording a background data point, five 1 µL aliquots of 40 µM Tb$^{3+}$ were added, followed by five aliquots of 100 µM Tb$^{3+}$ and 3 aliquots of 200 µM Tb$^{3+}$. After each addition, the solution was mixed and a data point taken. All data points represent the average values from three independent titrations. The data was fit using SPECFIT/32, using a 1:1 binding model, which determines log $\beta$ values where $\beta$ is the binding constant. Errors reported for the $K_D$ measurements represent the standard deviation of the results from three independent titrations.

**Determination of Tb$^{3+}$-Bound Water Molecules.** Luminescence lifetimes were measured for all proteins in buffered solutions in a Fluoromax-3 (Jobin Yvon Horiba) spectrometer, equipped with a Spex 1934D3 phosphorimeter. The intensity at 544 nm (Tb$^{3+}$) was monitored at 60 µsec increments for 12 ms after an initial delay of 50µsec, following a lamp pulse at 280 nm from a Xenon flash lamp. Reported data is the average of 3 runs. Using Kaleidagraph, the curves were fit to a monoexponential \[ I(t) = I(0) * e^{-t/\tau} \] where $I(t)$ is the luminescence intensity at time $t$ after the excitation pulse, $I(0)$ is the initial intensity at $t = 0$, and $\tau$ is the lifetime. The number of bound water molecules $q$ can be determined by measuring the rate constant of luminescence decay $\tau^{-1}$ in pure H$_2$O and pure D$_2$O. The value of $\tau^{-1}$ for D$_2$O is determined by measuring the lifetime in varying concentrations of D$_2$O and H$_2$O. The value of $q$ can than be calculated using the equation \[ q = A \left[ (\tau_{H_2O})^{-1} - (\tau_{D_2O})^{-1} - 0.06ms \right] \] where $A$ is the sensitivity of lanthanide to vibronic quenching, $\tau$ is the lifetime in the specified solvent and 0.06 ms is the correction factor for outer-sphere water molecules.$^{74}$

**NMR Experiments.** NMR experiments were performed in buffer containing 10 mM HEPES, 100
mM NaCl, 5 mM β-ME, 10 µM DSS and 9/1 (v/v) H2O/D2O. Samples were prepared by carefully titration of a protein solution below 0.1 mM with 10 times 0.11 equivalents of Lanthanide either Tb3+ or Lu3+. The final sample with 1.1 equivalents of Lanthanide was concentrated to 0.5 mM using Amicon Centriprep/Centricon centrifugal concentrator devices. All spectra were recorded at 293K on a Bruker Avance 600 MHz spectrometer equipped with a 5 mm TXI CryoProbe H-C/N-D with single-axis. 1H-15N-HSQC were recorded using 2304 x 512 data points in t2 and t1, respectively, spectral widths of 14 x 40 ppm in ω2 and ω1 and 16 scans per t1 increment with a Z-gradient.

RDCs were obtained by subtraction of the scalar 1J (HN,N) coupling of the superposition of scalar and dipolar coupling, both measured in 1H-15N-IPAP-HSQC. They were recorded using 2304 x 1024 data points in t2 and t1, respectively, spectral widths of 14 x 40 ppm in ω2 and ω1 and 32 scans per t1 increment with a Z-gradient at 293K. Scalar couplings were measured using diamagnetic lutetium (Lu3+), were as paramagnetic terbium (Tb3+) was used for RDC measurements. Deconvolution of the picked peaks was performed in Topspin2.1 using dcon2d.

The 3D-1H-15N-NOESY-HSQC experiment was recorded on a Bruker AV600 NMR spectrometer. The mixing time was 150 ms and the ω3, ω2 and ω1 sweep widths were 8417.5, 1762.9 and 7498.5 Hz (corresponding to 29 ppm in the 15N dimension), respectively.

The bootstrapping procedure was performed using Echidna83 to assign paramagnetic peaks and the back-calculation of the experimental PCS as well as the estimated lanthanide position, Δχα,τ tensors components and distances of the backbone amide protons to the metal center were determined using the program Numbat84.

Back-calculated RDC values and alignment tensors were determined using the program PALES79, assuming an order parameter S = 1.

15N longitudinal relaxation rates (T1) were obtained using relaxation delays of 100, 200, 400, 600, 800, 1200, 1600, 2000, and 2800 ms. For measurement of 15N transversal relaxation rates (T2), delays of 0,
17.6, 35.2, 52.8, 70.4, 105.6, 140.8, 176.0, and 281.6 ms were used. The spectra were recorded at 298 K using $2048 \times 160$ data points in $t2$ and $t1$, respectively, spectral widths of $13.3 \times 28$ ppm in $\omega_2$ and $\omega_1$, and 24 scans per $t1$ increment on Bruker DRX600 spectrometers equipped with a 5 mm TXI RT $1H\{^{13}C/^{15}N\}$ with Z-gradient. The $\{^1H\}^{15}N$ HetNOE was measured interleaved, using $2048 \times (2 \times 128)$ data points, spectral widths of $13.3 \times 21.7$ ppm, and 64 scans per $t1$ increment on Bruker DRX600 spectrometers with a 5 mm TXI CryoProbe $^1H\{^{13}C/^{15}N\}$ with Z-gradient.

**Crystallization and Data Collection of IL1β-S1.** For crystallization, proteins were loaded with TbCl$_3$ following a previously established protocol$^5$. Briefly, protein was diluted to 1 mg/mL in storage buffer, sodium acetate was added to 10 mM (f.c.) and terbium chloride (in 1 mM HCl) was added in 10 equal aliquots to a final molar ratio of Tb$^{3+}$: protein of 1.1:1. Protein was concentrated to 30mg/ml in preparation for crystallization. Initial screening used the Hampton index screen. IL1β-S1 crystallized readily from 100mM sodium acetate trihydrate pH 4.5, 3.0 M NaCl and the conditions did not require further optimization. Crystals were not obtained for IL1β -S2 and IL1β -S3.

Data were collected at beamline X12C at the National Synchrotron Light Source. IL1β-S1 crystals were cryoprotected by soaking the crystals in 15% glucose in mother liquid and then transferred to 30% glucose solution plus mother liquor. Crystals were flash frozen in the gaseous cryogenic N$_2$ stream. Data were collected at a wavelength of 0.95 Å and processed with DENZO/SCALEPACK$^{91}$. Crystals diffracted to 2.1 Å and belong to space group P6(3)22. Data collection statistics are presented in Table 2.

**X-ray crystal structure solution.** The space group assignment was confirmed by systematic absences and presence of a 20 sigma peak on the Harker section of the anomalous Patterson map calculated to 2.1 Å. At the wavelength of data collection \( f' \sim -0.45e^- \) and \( f'' \sim 6.8e^- \); phases were determined by the program Phenix\(^{92}\) (FOM 0.49) followed by phase improvement and automatic building (final FOM 0.70) resulting in 83.6% of the backbone being built in an automated fashion including most of the LBT. Protein rebuilding was in COOT\(^{93}\) and refinement was carried out in Phenix\(^{92}\) using phase recombination with the starting phases determined from Tb. The final model contains the entire IL1β
molecule including LBT domain with Tb\(^{3+}\), 2 acetate molecules and 131 waters. Only the first two residues of the construct and the C-terminal residue could not be observed in the electron density map.

**Acknowledgment.** H.S. is member of the DFG-funded Cluster of Excellence: Macromolecular Complexes. This work was supported by NSF MCB 0744415 to KNA and BI. A.M.R. acknowledges the NIH for a Ruth L. Kirschstein National Research Service Award. The work was further supported by EU-funded SPINE2 project. Data for this study were measured at Beamline X12C of the National Synchrotron Light Source. Financial support comes principally from the Offices of Biological and Environmental Research and of Basic Energy Sciences of the US Department of Energy, and from the National Center for Research Resources of the National Institutes of Health. NMR data were obtained at the Center for Biomolecular Magnetic Resonance (BMRZ) supported by the state of Hesse.

**Supporting Information Available:** Protocols for protein expression and purification, protease cleavage, PAGE analysis, Receptor-binding assay, Number of bound water molecules in the coordination sphere of terbium, NMR spectra, PCSs, RDC analysis, Relaxation data, Complete ref. 63 and 92.
