(Received 25 June 2012; published 27 August 2012)

Spin-orbit coupling is responsible for a variety of phenomena, from the fine structure of atomic spectra to the spin Hall effect, topological edge states, and, in the presence of interactions, the predicted phenomenon of topological superconductivity [1,2]. In electronic systems, spin-orbit coupling arises from the relativistic transformation of electric fields into magnetic fields in a moving reference frame. In the reference frame of an electron moving with wave vector \( \mathbf{k} \) in an electric field, the motional magnetic field couples to the electron spin through the magnetic dipole interaction. In a two-dimensional semiconductor heterostructure, the electric field can arise from structure or bulk inversion asymmetry [3], leading to magnetic fields of the form \( \mathbf{B}^{(R)} = \alpha(-k_y, k_x, 0) \) or \( \mathbf{B}^{(D)} = \beta(k_y, k_x, 0) \), respectively known as the Rashba [4] and Dresselhaus [5] contributions. Including a possible momentum-independent Zeeman field \( \mathbf{B}^{(Z)} = (0, B_y^{(Z)}, B_z^{(Z)}) \), the Hamiltonian of the electron takes the form

\[
\mathcal{H} = \frac{\hbar^2 k^2}{2m} - \frac{g \mu_B}{\hbar} \mathbf{S} \cdot \left( \mathbf{B}^{(D)} + \mathbf{B}^{(R)} + \mathbf{B}^{(Z)} \right),
\]

(1)

where \( g \) is the electron \( g \) factor, \( \mu_B \) is the Bohr magneton, and \( \mathbf{S} \) is the electron spin.

The energy-momentum dispersion and the associated spin texture of the Hamiltonian in Eq. (1) are shown in Fig. 1(a) for \( B_z^{(Z)} = 0 \) and \( \alpha = \beta \). In the absence of a perpendicular Zeeman field \( B_z^{(Z)} \), the spectrum consists of the parabolic free particle dispersions for the two spin states that are shifted relative to each other in \( k \) space owing to the spin-orbit interaction. For a nonzero field \( B_z^{(Z)} \), a gap opens in the spectrum. This gap, known as the spin-orbit gap, has been recently observed in one-dimensional quantum wires [6,7]. The two energy bands are spinful in the sense that the spin of an atom is locked to its momentum.

In this work, we engineer the Hamiltonian in Eq. (1) with equal Rashba and Dresselhaus strengths in an optically trapped, degenerate gas of fermionic lithium atoms via Raman dressing of atomic hyperfine states [8,9]. Raman fields have previously been used to generate spin-orbit coupling and gauge fields in pioneering work on Bose-Einstein condensates [10–12] and, recently, spin-orbit coupling in Fermi gases [13]. Here, we directly measure the spinful band structure of Eq. (1), as well as the rich band structure of a spin-orbit coupled lattice. For this, we introduce spin-injection spectroscopy, which is capable of completely characterizing the quantum states of spin-orbit coupled fermions, including the energy-momentum dispersion and the associated spin texture. By tracing the evolution of quantum states in the Brillouin zone, this method can be extended to directly measure topological invariants, such as the Chern number in a two-dimensional system [1,2,14].

Spin-orbit coupling is generated by using a pair of laser beams that connects the second and third lowest hyperfine levels in \( ^6\text{Li} \), labeled \( |\downarrow\rangle \) and \( |\uparrow\rangle \), via a two-photon Raman transition, as shown in Figs. 1(b) and 1(c). The Raman process imparts momentum \( h\mathbf{Q} \) to an atom while changing its spin from \( |\downarrow\rangle \) to \( |\uparrow\rangle \) and momentum \( -h\mathbf{Q} \) while changing the spin from \( |\uparrow\rangle \) to \( |\downarrow\rangle \). Defining a quasimomentum \( q = k_x + \frac{\mathbf{Q}}{2} \) for spin \( |\downarrow\rangle \) and \( q = k_x - \frac{\mathbf{Q}}{2} \) for spin \( |\uparrow\rangle \), one obtains the Hamiltonian of the form given in Eq. (1) [10]. In this mapping, \( B_z^{(Z)} = h\Omega_\mathbf{Q}/g\mu_B \), where \( \Omega_\mathbf{Q} \) is the two-photon Rabi frequency, \( B_y^{(Z)} = h\delta/g\mu_B \), where \( \delta \) is the two-photon detuning, and \( \alpha = \beta = \frac{\mathbf{Q}^2}{2m\mu_B} \). In addition to providing spin-orbit coupling, the Raman beams lead to spontaneous photon scattering. For our experimental setup, the spontaneous scattering rate is \( \sim 240 \) times smaller than \( \Omega_\mathbf{Q} \), slow enough to permit accurate spin-injection spectroscopy (see Supplemental Material [15]).
We sympathetically cool $^6$Li atoms with $^{23}$Na in a magnetic trap down to a temperature of $T < 0.1 T_F$, where $T_F$ is the Fermi temperature [16]. After removal of Na atoms, the Li atoms are transferred into an optical dipole trap formed by two orthogonal 1064 nm beams. To separate the atomic hyperfine levels, we apply a magnetic field trap formed by two orthogonal 1064 nm beams. To separate the atoms, the Li atoms are transferred into an optical dipole trap in the $z$ direction providing the quantization axis. (c) Energy level diagram of states coupled by the Raman fields: $\hbar \delta$ is the two-photon detuning. The hyperfine interaction splits $|\uparrow\rangle$ and $|\downarrow\rangle$ by $\hbar \omega_{0\gamma}$, and the relevant polarization components are $\pi$ and $\sigma_z$. (d) Momentum-dependent Rabi oscillations for $\hbar \Omega_R = 0.71(2) \hbar \omega$ and $\hbar \delta = -0.25(1) \hbar \omega$, Atoms are prepared in $|\downarrow\rangle$ (red) and are subsequently projected into a superposition of eigenstates as the Raman field is pulsed on. (e) A $\pi$ pulse for the resonant momentum class is applied at different $\delta \hbar$ for $\hbar \Omega_R = 0.035(5) \hbar \omega$. (f),(g) Adiabatic loading and unloading of atoms into the upper (lower) band with $\hbar \Omega_R = 0.53(5) \hbar \omega$. The Raman beams are turned on with $\delta = \mp 8.5 \hbar \omega$, which is then swept linearly to $\delta = 0$ and back at a rate of $|\delta| = 0.27(5) \hbar \omega$. 

As a function of pulse duration, we observe oscillations of the spin polarization with momentum-dependent frequencies, as shown in Fig. 1(d). Since our Fermi gas occupies a large range of momentum states with near-unity occupation, each image at a given pulse duration $\tau$ contains information for a large range of momenta $q$. The observation of momentum-dependent oscillations demonstrates the presence of a spin-orbit gap and shows that the atomic system is coherent over many cycles. To highlight the momentum selectivity of this process, we prepare an equal mixture of atoms in states $|\uparrow\rangle$ and $|\downarrow\rangle$ and pulse on the Raman fields for a time $t = \pi/\hbar \Omega_R$ for different two-photon detunings $\delta$. This inverts the spins for atoms with momentum $q$ where $\Delta(q)$ is minimal and equals $\hbar \Omega_R$. The resonant momentum class depends linearly on $\delta$ due to the Doppler shift $\sim k_x Q$, as shown in Fig. 1(e).

Instead of pulsing on the Raman field and projecting the initial state into a superposition of states in the two bands, one can introduce the spin-orbit gap adiabatically with respect to band populations. This is achieved by starting with a spin-polarized Fermi gas and sweeping the two-photon detuning $\delta$ from an initial value $\delta_i$ to a final detuning $\delta_f$. The magnitude of the initial detuning $|\delta_i|$ is much larger than the two-photon recoil energy $E_R = \hbar^2 Q^2/2m$, so that the effective Zeeman field is almost entirely parallel with the spins. Depending on the direction of the sweep, this loads atoms into either the upper or the lower dressed band. We interrupt the sweep at various times and image the spin-momentum distribution. This reveals that the spin texture follows the effective Zeeman field. We verify that the process is reversible by sweeping the detuning back to $\delta_i$ and observing that full spin polarization is restored, as shown in Figs. 1(f) and 1(g).

Having demonstrated the ability to engineer spin-orbit coupling in a Fermi gas, we introduce a general approach to measure the eigenstates and energies of fermions at each quasimomentum $q$ and thus resolve the band structure and the spin texture of spin-orbit coupled atomic systems. Our approach yields similar information to spin and angle-resolved photoemission spectroscopy (spin-ARPES), a powerful technique recently developed in condensed matter physics [17]. Spin-ARPES is particularly useful for studying magnetic and quantum spin Hall materials; it has been used, for example, to directly measure topological quantum numbers in the Bi$_{1-x}$Sb$_x$ series, revealing the presence of topological order and chiral properties [18].

Our spectroscopic technique uses radio frequency (rf) spin injection of atoms from a free Fermi gas into an empty spin-orbit coupled system using photons of a known energy, as shown in Fig. 2(a). After injection, the momentum and spin of the injected atoms are analyzed by using time of flight [19] combined with spin-resolved detection. Atoms are initially loaded into one of two free "reservoir" atomic states $|\uparrow\rangle_K$ and $|\downarrow\rangle_K$, for which we use the first and fourth lowest hyperfine states of $^6$Li. State $|\downarrow\rangle_K$ can be
The topological characteristics of the bands, which are encoded in the eigenstates, can be extracted from the spin and momentum composition. For our spin-orbit system with $\delta = 0$, the spin of the eigenstates is confined to the $y$-$z$ plane on the Bloch sphere, because the effective magnetic field has no $\hat{x}$ component. More general couplings may not restrict the spin to a great circle on the Bloch sphere, in which case at least two spin components must be measured for a complete characterization of the bands. This can be achieved by rotating the different spin components onto the measurement basis with an rf pulse.

Applying spin-injection spectroscopy, we have measured the band structure of the equal-part Rashba-Dresselhaus Hamiltonian at $\delta = 0$ for several $\Omega_R$. Figures 2(b)–2(e) show spin- and momentum-resolved spin-injection spectra obtained with atoms starting in the $|\uparrow\rangle_R$ reservoir (top row) and starting in the $|\downarrow\rangle_R$ reservoir (bottom row), for the case $h\Omega_R = 0.43(5)E_R$ and $\delta = 0$. The $(q, |\uparrow\rangle) \leftrightarrow (-q, |\downarrow\rangle)$ symmetry of the system can be seen in the spectra in Fig. 2. The energy at each quasimomentum is found by adding the energy injected into the system by the rf pulse to the initial kinetic energy of the free particle in the reservoir. Figures 2(f)–2(h) show the dispersion and spin texture of the bands obtained from the data. As $\Omega_R$ is increased, we observe the opening of a spin-orbit gap at $q = 0$. The spin composition of the bands evolves from purely $|\uparrow\rangle$ or $|\downarrow\rangle$ away from the spin-orbit gap to a mixture of the two spin states in the vicinity of the spin-orbit gap, where the spin states are resonantly coupled.

A Fermi gas with the above dispersion has a spinful semimetallic behavior when the Fermi energy lies within the spin-orbit gap. When the Fermi energy is outside the spin-orbit gap, there is a fourfold degeneracy of states at the Fermi surface. Inside the gap, however, the degeneracy is halved. Furthermore, propagation of spin up particles at the Fermi energy can occur only in the positive $q$ direction, while spin down fermions can propagate only in the opposite direction. For energies within the gap, the system thus acts as a spin-current diode.

An even richer band structure involving multiple spinful bands separated by fully insulating gaps can arise in the presence of a periodic lattice potential. This has been realized for Bose-Einstein condensates by adding rf coupling between the Raman-coupled states $|\uparrow\rangle$ and $|\downarrow\rangle$ [20]. Using a similar method, we create a spinful lattice for ultracold fermions and use spin-injection spectroscopy to probe the resulting spinful band structure. The combined Raman-rf coupling scheme is shown in Fig. 3(a). The Raman field couples the states $|\downarrow, k_x = q\rangle$ and $|\uparrow, k_x = q + Q\rangle$ with strength $\Omega_R$, whereas the rf field couples the states $|\downarrow, k_x = 0\rangle$ and $|\uparrow, k_x = Q\rangle$ with strength $\Omega_{RF}$. As a result, the set of coupled states for a given quasimomentum $q$, shown in the repeated Brillouin scheme in Fig. 3(b), is $|\sigma, k_x = q + nQ\rangle$ for integer $n$ and $\sigma = \uparrow, \downarrow$. The lowest four bands are degenerate at the band center $q = 0$ when $\Omega_R = \Omega_{RF} = 0$. The Raman field splits the degeneracy between the first and fourth bands, leaving the other two degenerate. The remaining degeneracy, which is a Dirac point, is removed with the addition of the rf field. Thus,
FIG. 3 (color online). Creating and probing a spin-orbit coupled lattice. (a) The addition of a radio frequency field allows momentum transfer of any multiple of $Q$, producing a spinful lattice band structure. (b) The band structure of the Raman-rf system in the repeated zone scheme. Band structures from top to bottom correspond to $\hbar \Omega_{RF} = 0$ and $\hbar \Omega_R = 0.25E_R$, $\hbar \Omega_R = 0.5E_R$ and $\hbar \Omega_{RF} = 0$, and $\hbar \Omega_R = 0.5E_R$ and $\hbar \Omega_{RF} = 0.25E_R$. In the bottommost band, all degeneracies are lifted. (c) Spin injection from free particle bands to spinful lattice bands, starting from $|\downarrow\rangle$. Transitions near zero rf detuning ($\hbar \Delta \nu \sim 0$) that give rise to dominant spectral features are identified. (d) Experimental spectrum of the Raman-rf system with $\hbar \Omega_R = 0.40(5)E_R$ and $\hbar \Omega_{RF} = 0.28(2)E_R$ in the spin $|\downarrow\rangle$ channel after injection from reservoir $|\downarrow\rangle$. (e) The theoretical spectra corresponding to (d). Features corresponding to the gaps and transitions identified in (c) are labeled.

when the system is filled up to the top of the second band, it is an insulator. Furthermore, when $\Omega_{RF}$ is large enough, a band gap also opens between the first and second bands.

Figure 3(d) shows the $|\downarrow\rangle$ channel of the spin-injection spectra, measured with fermions initially in reservoir state $|\downarrow\rangle$. Spectra with injection from $|\downarrow\rangle$ is sufficient to reconstruct the full band structure given the $(q,\downarrow) \leftrightarrow (-q,\downarrow)$ symmetry of the Hamiltonian. The transitions between the reservoir and the spin-orbit coupled bands for $\hbar \Omega_R = 0.40(5)E_R$ and $\hbar \Omega_{RF} = 0.28(2)E_R$ are shown in Fig. 3(c). The experimental spectrum in Fig. 3(d) is compared to the theoretically calculated spectrum, shown in Fig. 3(e). The spectrum exhibits four prominent features separated by three energy gaps, labeled $\Delta_1$, $\Delta_2$, and $\Delta_3$ in Fig. 3(e). The gaps giving rise to these features are shown on the band structure in Fig. 3(c). The gap $\Delta_1$ is opened by the spin-orbit coupling, while $\Delta_2$ is opened by a direct rf coupling, and $\Delta_3$ is opened by a second-order process that involves both the rf and Raman fields, explaining its smallness. We have explored the Raman-rf system for a range of coupling strengths as shown in the spectra in Figs. 4(a) and 4(b). With a careful choice of the Raman-rf coupling strengths, spinful flat bands can be realized (see Supplemental Material, Fig. S3 [15]), where interactions should play a dominant role [21].

To illustrate how the energy bands along with the corresponding eigenstates can be extracted, we reconstruct the energy bands along with the spin texture for $\hbar \Omega_R = 0.93(7)E_R$ and $\hbar \Omega_{RF} = 0.28(2)E_R$, as shown in Fig. 4(c). The energies of the bands are obtained from the resonant frequencies in the spin-injection spectra, while the spin composition $S_{y,z}$ is extracted from the relative weights of the signal in the two spin channels (see Supplemental Material [15]). In Figs. 4(d)–4(f), we show the extracted value of $S_y(k_x)$ and $|S_z(k_x)|$ for the bottommost band when $\hbar \Omega_R = 0.93(7)E_R$ and $\hbar \Omega_{RF} = 0.28(2)E_R$. For more general spin-orbit Hamiltonians involving $\sigma_z$, one can extract the phase between all three components of $S(k_x)$ with additional rf pulses and fully characterize the eigenstate for the corresponding quasimomentum $q$. The topology of the band, encoded in the evolution of its eigenstates across the Brillouin zone, can thus be measured.

In summary, we have created and directly probed a spin-orbit gap in a Fermi gas of ultracold atoms and realized a fully gapped band structure allowing for spinful flat bands. We introduced spin-injection spectroscopy to characterize the spin-textured energy-momentum dispersion. We further show that spin-injection spectroscopy allows reconstruction of eigenstates in a spinful lattice system. Extensions of this method can reveal the nontrivial topology of bands in more general spin-orbit coupled systems [22], opening a path to probing topological insulators with ultracold atoms. Similar spectroscopic techniques should
allow the demonstration of effective $p$-wave interactions in a single component spin-orbit coupled Fermi gas, either near an $s$-wave Feshbach resonance or for flat bands as realized here. In these systems, interactions may lead to BCS pairing in a $p$-wave channel and, in a two-dimensional Fermi gas with pure Rashba coupling, to $p_x + ip_y$ pairing and chiral superfluidity [23,24].
