Heterogeneity in mouse spasmolytic polypeptide-expressing metaplasia lineages identifies markers of metaplastic progression

Victoria G Weis,1 Josane F Sousa,1 Bonnie J LaFleur,2 Ki Taek Nam,1 Jared A Weis,3 Paul E Finke,4 Nadia A Ameen,5 James G Fox,6 James R Goldenring1

ABSTRACT

Objectives Spasmolytic polypeptide-expressing metaplasia (SPEM) develops as a preneoplastic lesion in the stomachs of mice and humans after parietal cell loss. To identify the commonalities and differences between phenotypic SPEM lineages, SPEM were studied from three different mouse models of parietal cell loss: with chronic inflammation with Helicobacter felis infection; with acute inflammation with L635 treatment; and without inflammation following DMP-777 treatment.

Design RNA transcripts from laser capture microdissected normal chief cells and SPEM lineages were compared using gene microarray. Alterations in transcripts were validated by quantitative real-time PCR. Clusterin and cystic fibrosis transmembrane conductance regulator (CFTR) were selected for immunohistochemical analysis in all mouse models as well as in human SPEM, intestinal metaplasia and gastric cancer.

Results Transcript expression patterns demonstrated differences among the phenotypic SPEM models. Clusterin expression was significantly upregulated in all three mouse SPEM models as well as in human SPEM. The highest clusterin expression in human gastric cancers correlated with poor survival. Conversely, CFTR expression was upregulated only in SPEM with inflammation in mice. In humans, intestinal metaplasia, but not SPEM, expressed CFTR.

Conclusions While markers such as clusterin are expressed in all phenotypic SPEM lineages, distinct patterns of upregulated genes including CFTR are present in murine metaplasia associated with inflammation, indicative of progression of metaplasia towards a more intestinalised metaplastic phenotype.

INTRODUCTION

Helicobacter pylori infection is the major predisposing factor for human gastric cancer.1 In humans, H pylori infection causes a disruption in the gastric homeostasis by inducing chronic inflammation and loss of parietal cells. The loss of parietal cells leads to two distinct types of mucous cell metaplasia: intestinal metaplasia and spasmolytic polypeptide-expressing metaplasia (SPEM). Increasing evidence in humans and rodent models suggests that intestinal metaplasia develops in the presence of pre-existing SPEM, supporting the concept that SPEM is a neoplastic precursor in the carcinogenesis cascade.2–4

Chronic Helicobacter felis infection in mice is a critical model for H pylori infection in humans. After 6 months of H felis infection, significant parietal cell loss accompanied by inflammation leads to the emergence of a proliferative SPEM lineage derived almost completely from transdifferentiated chief cells (figure 1A). SPEM progresses to dysplasia after 1 year of infection without developing phenotypic intestinal metaplasia.5 7 All present evidence thus indicates that SPEM is the direct precursor to...
dysplasia in *H. felis*-infected mice. A mouse model of acute oxyntic atrophy using the parietal cell-specific protonophore, DMP-777, allows for the separation of the roles of parietal cell loss and inflammation in the initiation of SPEM (figure 1A).8,9 Oral gavage administration of DMP-777 for 14 days induces SPEM as a direct result of parietal cell loss. However, DMP-777 also inhibits any inflammatory response because of its ability to inhibit neutrophil elastase potently resulting in SPEM, which is less proliferative.8,9 Moreover, DMP-777-induced SPEM contains two distinct component lineages: transdifferentiated chief cells at the gland bases and mucous neck cell hyperplasia in the neck region.5 Even after a year of DMP-777 administration, SPEM fails to progress to dysplasia.8 The DMP-777 model thus shows that parietal cell loss is sufficient for SPEM initiation, but inflammation is necessary for the progression of SPEM to dysplasia. In contrast, acute administration of L635, a protonophore analogue of DMP-777 that lacks elastase inhibition results in a prominent inflammatory response and induces a SPEM lineage phenotypically similar to *H. felis* infection (figure 1A).5 Analysis of the progression to dysplasia with chronic administration of L635 is not currently feasible due to limited supplies of the drug. These results have led to the concept that transdifferentiation of chief cells to SPEM is common to all SPEM lineages, but inflammatory cells drive the evolution of metaplasia towards a more proliferative lineage and later to dysplasia. However, no studies have investigated differences in expression among phenotypic SPEM lineages.

METHODS

Gene microarray analysis

DMP-777 or L635 was administered by oral gavage to groups of six 7-month-old C57BL/6 male mice. Another group of six mice...
(two males and four females) were *H. felis* infected for 6–12 months. Untreated C57BL/6 male mice were used as controls. Chief cells from control mice or SPEM lineages at the base of glands from treated mice were laser capture microdissected from frozen sections of fundic stomach. Total RNA was isolated from microdissected cells with the PicoPure RNA isolation kit (Arcturus, Mountain View, California, USA). The Nugen WT Pico kit (San Carlos, California, USA) was used to reverse transcribe and amplify 25 ng of total RNA for each sample. Fragmented and labelled samples were hybridised to Affymetrix mouse gene 1.0ST arrays (Santa Clara, California, USA) using standard Affymetrix protocols. Statistical analysis is described in the supplementary material (available online only). The pan-SPEM and acute SPEM categories focus on the microdissected cells were measured with Affymetrix gene online only). The pan-SPEM and acute SPEM categories focus on the microdissected cells were measured with Affymetrix gene slides. Tissue arrays were analysed using the Ariol SL-50 automated slide scanner (Genetix, San Jose, California, USA). Tissue arrays were analysed using the Ariol SL-50 automated slide scanner (Genetix, San Jose, California, USA). Sections were analysed with an Olympus FV1000 confocal microscope (Olympus, Tokyo, Japan) or an esity digital imaging system (Zeiss, Jena GmBH, Germany) or an Olympus FV1000 confocal microscope (Olympus, Tokyo, Japan) and tissue arrays were analysed using the Ariol SL-50 automated slide scanner (Genetix, San Jose, California, USA).

### RESULTS

**Gene microarray analysis of phenotypic SPEM lineages with and without inflammation**

To compare the expression profiles of SPEM lineages arising in different milieu, we used laser capture microdissection to isolate chief cells from control untreated mice and SPEM cells at the bases of glands from mice treated with DMP-777, L635, or *H. felis* infection. These SPEM models were selected based on their distinct characteristics such as length of treatment (acute vs chronic) and progression to dysplasia (presence vs absence of inflammation; figure 1A), so that the commonalities and differences among the different phenotypic SPEM lineages could be analysed. Levels of isolated messenger RNA transcripts from the microdissected cells were measured with Affymetrix gene microarrays. Five comparison categories were established based on the SPEM model characteristics (as mentioned above) to analyse upregulated transcripts associated with either the emergence or progression of SPEM (listed in table 1 with heat maps of each group shown in supplementary figure 1, available online only). The pan-SPEM and acute SPEM categories focus on transcripts upregulated with the induction of SPEM. Transcripts upregulated in all SPEM lineages compared with chief cells are markers indicative of the initiation of SPEM (pan-SPEM). Eight transcripts were upregulated in pan-SPEM including the secreted glycoprotein, Clu, and the previously reported SPEM marker, whey acidic protein 4 disulphide core domain 2 (Wac2d, also known as HE4). In the previous study, we identified HE4 as a marker of SPEM and intestinal metaplasia that was not found in the normal stomach. The acute SPEM comparison, consisting of transcripts increased in acute SPEM lineages (DMP-777 and L635-induced SPEM) versus chief cells, revealed transcripts that initially increase in SPEM induction, but decrease in chronic SPEM lineages. Acute SPEM identified five additional transcripts upregulated in the initiation of SPEM (table 1), which included fidgetin-like 1 (Fgnl1), a transcript previously reported as upregulated in gastrin-deficient mice treated with DMP-777.

Because previous studies have indicated that SPEM cannot progress to dysplasia in the absence of inflammation, transcripts putatively involved in the progression of SPEM were identified with comparisons focusing on SPEM accompanied by

Normal chief cells and spasmolytic polypeptide-expressing metaplasia (SPEM) lineages from three SPEM models were compared by gene microarray (six mice per group). Five comparison categories were established: pan-SPEM (I), acute SPEM (II), acute SPEM with inflammation (III), specific to SPEM with inflammation (IV) and SPEM with chronic inflammation (V). The linear fold change in each sample group is listed compared with the column marked with a bullet point (•). In categories I, II and III fold changes are upregulated compared with chief cells. Category IV changes are compared with DMP-777.

In category V listed transcripts are upregulated in *H. felis* compared with each of the other groups; thus fold changes are shown as relative downregulation in the respective groups. *Transcripts previously found upregulated in human metaplasias of the stomach.*

Transcripts previously found upregulated in human metaplasias of the stomach.

---

inflammation (L655 and *H. felis*-induced SPEM). Transcripts increased in L655 and *H. felis*-induced SPEM versus chief cells are listed as ‘SPEM with inflammation’, whereas the comparison of inflammatory SPEM with non-inflammatory SPEM (DMP-777-induced SPEM) identified ‘specific to SPEM with inflammation’ transcripts. The ‘SPEM with chronic inflammation’ category compares *H. felis*-induced SPEM with acute SPEM models (with and without inflammation) and chief cells. Ten transcripts were upregulated in the specific to SPEM with inflammation comparison. The SPEM with inflammation and SPEM with chronic inflammation categories yielded numerous upregulated transcripts (43 and 151, respectively; selected transcripts are listed in table 1). Pathway analysis of the comparison categories only identified an increase in interferon γ-associated genes in SPEM with chronic inflammation (supplementary figure 2, available online only). As a whole, these gene microarray studies demonstrated that phenotypic SPEM lineages did indeed demonstrate distinct differences in transcript expression.

To narrow the lists for further investigation, we compared the upregulated transcripts with transcripts previously reported as upregulated in microdissected human metaplasias of the stomach (SPEM or intestinal metaplasia) by gene microarray (table 1). Nine transcripts from SPEM with inflammation, including the chloride transporter, CFTR homologue, were also upregulated in human metaplasia, while 17 common transcripts were found for SPEM with chronic inflammation. Only three other transcripts from the other comparison categories, topoisomerase (DNA) I1x (Top2α), cyclin B2 and centromere protein K, were also upregulated in the human metaplasia microarrays. We thus found considerable overlap in transcripts associated with SPEM with inflammation in mice and those associated with metaplasias in humans.

### Quantitative PCR analysis of upregulated transcripts

Quantitative real-time PCR (qRT–PCR) was used to evaluate further selected upregulated transcripts from each of the comparison categories (figure 2 and supplementary figures 2–7, available online only). *H. felis*-induced SPEM was divided into two time points (6 and 12 months) to distinguish between the earlier stages of SPEM and chronic SPEM. In these studies, regions of whole gastric fundus were used for qRT–PCR, rather than microdissected samples. While this approach failed to validate all transcripts from the categories, it allowed for analysis of and insight into upregulation on a more global scale. The poorly understood gene, schafelin 9 (Sfln9), from the pan-SPEM category was significantly upregulated in all SPEM models versus normal gastric mucosa (figure 2A). H4E expression showed an increasing trend in all SPEM models, but failed to reach statistical significance in all individual comparisons. Clusterin was significantly upregulated in acute SPEM models, and there was a trend towards upregulation in 12-month *H. felis* infection-induced SPEM (figure 2A). All five acute SPEM transcripts were significantly increased in DMP-777 and L655-induced SPEM versus normal mucosa (figure 2B and supplementary figure 4, available online only). The six transcripts in SPEM with inflammation that were upregulated in human metaplasias of the stomach were tested along with a selected transcript, ets variant gene 5 (ETV5), which was the only transcription factor found in the category (figure 2C and supplementary figure 5, available online only). Many of the transcripts, including CFTR and ETV5, were validated as significantly upregulated in SPEM with inflammation compared with normal mucosa. CFTR expression increased over 100-fold in 12-month *H. felis* infection-induced SPEM. Notably, ETV5 was significantly upregulated in L655 and 6-month *H. felis* infection-induced SPEM, but decreased to near normal levels after 12 months of *H. felis* infection. Similar to pan-SPEM transcripts, not all of the specific to SPEM with inflammation transcripts followed the trend found in the microarray data with statistical significance (figure 2D and supplementary figure 6, available online only). Expression of carinoembryonic antigen-related cell adhesion molecule 10 (Ceacam10) and TYRO protein tyrosine kinase binding protein (Tyrobp) expression was significantly increased in inflammatory SPEM models compared with the non-inflammatory SPEM model. While others such as glioma pathogenesis-related 1 (Glipr1) and the two members of the membrane-spanning 4-domains subfamily A, member 6B and member 6C (Ms4a6b and Ms4a6c), followed the trend, but did not achieve statistical significance. Five transcripts from SPEM with chronic inflammation that were also upregulated in human metaplasias of the stomach (table 1) were selected for qRT–PCR analysis (figure 2E and supplementary figure 7, available online only). Four of these transcripts, including villin 1 (Vil1), were significantly upregulated in the 12-month *H. felis* infection-induced SPEM model compared with the other sample groups (acute SPEM models and control). Together, these results provide a consistent profile of the alterations in the expression of the transcripts in each comparison category, and thus classify gene expression characteristics of SPEM with and without inflammatory influence.

### Clusterin expression is increased in all SPEM lineages

Based on antibody availability, we selected Clu from the Pan-SPEM category to investigate protein expression profiles of the induction of SPEM. Clusterin is a ubiquitously expressed secreted glycoprotein thought to be involved in a variety of cellular processes such as tissue remodelling, differentiation, cytoprotection and anti-apoptosis.19–20 In untreated mice, Clu staining was observed at low levels only in cells in the isthmus of the oxyntic glands (figure 3). Some Clu-positive cells co-labelled with the first few TFF2-expressing mucous neck cells. In all SPEM models, Clu was strongly expressed throughout the SPEM lineages (figure 3). Differences in the upregulation of Clu mRNA versus detectable protein suggest that Clu mRNA is processed differently between the SPEM lineages. Together, these results demonstrate that Clu protein expression is a marker of SPEM regardless of the causation or surrounding milieu of chief cell transdifferentiation to SPEM.

### Upregulation of CFTR expression is observed only in SPEM with inflammation

To investigate possible markers for the progression of SPEM lineages, we examined the expression of CFTR, the most upregulated transcript in SPEM with inflammation as detected by qRT–PCR. CFTR is an ATP-gated chloride channel, which is found on the apical membrane of epithelial cells including intestinal crypt cells.19 CFTR was not detected in the normal gastric fundus (figure 4) confirming previous investigations.20 Although CFTR mRNA was increased in all SPEM lineages, DMP-777-induced SPEM lineages lacked detectable CFTR protein expression. However, expression of CFTR protein was observed in the apical membranes of the inflammatory SPEM lineages induced by either L655 administration or *H. felis* infection, which both have large increases in CFTR mRNA expression (figure 4). These results show that CFTR is a marker of advanced proliferative SPEM.

### Clusterin and CFTR expression in human metaplasias of the stomach and gastric cancer

Based on the murine data, we examined the expression of Clu and CFTR in human gastric tissues. In normal human gastric

---

Gastric cancer

4 of 10

mucosa, Clu was detected in the isthmus region of fundic glands (figure 5A). Some dual-labelling with TFF2 was observed in cells near the upper neck region of oxyntic glands, similar to our observations in mice. In metaplasias of the stomach, Clu had a granular pattern throughout SPEM glands, but was limited to a few cells at the bases of glands when detected in intestinal metaplasia (figure 5B). These Clu-positive intestinal metaplasia cells did not express TFF2. In a tissue array of metaplasias from the human gastric fundus, 90% of cores with SPEM and 46% with intestinal metaplasia (18/20 and 5/11, respectively) were positive for the respective Clu staining patterns. In a small cohort of gastric adenocarcinomas collected at Vanderbilt, Clu was expressed in 56.5% of cancers (9/16 intestinal type and 4/7 diffuse type). A second cohort of 450 Korean patient samples, predominantly early stage cancers, was used to assess Clu as a prognostic biomarker. Clusterin staining was quantified by calculating the percentage of keratin-staining epithelial cells in each sample that were Clu positive (figure 5C and supplementary figure 8, available online only). There was a statistically significant association between the percentage of Clu-positive epithelial cells and stage. In particular, there were pairwise differences between all comparisons except stage 1 versus 3, and stage 3 versus 4 (figure 5D). Both positive Clu staining and stage were associated with survival (p values of 0.0232 and <0.0001, respectively). Clusterin was modelled using a restricted cubic spline with four knots. While the second knot (consisting of 23–43% Clu-positive epithelial staining) correlated with longer survival time, the 43–95% staining group was associated with shorter survival time (figure 5E). Furthermore, the model including both stage and percentage of Clu staining had a

Figure 2  Quantitative real-time PCR (qRT–PCR) assay of selected upregulated transcripts from each comparison category. Expression of selected upregulated transcripts from each category was assessed by qRT–PCR in RNA isolated from the whole fundic stomach (three mice per group). Pan-spasmolytic polypeptide-expressing metaplasia (SPEM) (A) and acute SPEM (B) transcripts were associated with the emergence of SPEM, while SPEM with inflammation (C), specific to SPEM with inflammation (D), and SPEM with chronic inflammation (E) relate to the progression of SPEM lineages. Results are shown as fold change compared with the mean value of the control group (labelled WT). Single asterisks in A, B and C signify significant upregulation compared with wild type (WT). Double asterisks in D are significant compared with DMP-777-induced SPEM. Significance in E (+) is noted compared with 12-month \textit{H. pylori} infection. All values are shown as means ± SE of the mean, SE (p < 0.05 by Mann-Whitney U test). This figure is produced in colour in the online journal—please visit the website to view the colour figure.
c-index of 0.86, which is equivalent to an area under the receiver operating characteristic curve (demonstrating good prediction). CFTR expression was also investigated to understand the correlation between murine and human gastric metaplasias. Similar to murine expression patterns, CFTR was undetectable in normal gastric mucosa (figure 6). Conversely, CFTR was not observed in human SPEM even though it was accompanied by prominent inflammation. Nevertheless, intestinal metaplasia showed strong CFTR expression in the apical membranes throughout the glands. An analysis of CFTR expression in adenocarcinomas using tissue arrays was not possible because all available antibody reagents only perform well in frozen sections.

Nevertheless, taken together with the murine tissue data, these results suggest a correlation between SPEM with inflammation in mice and intestinal metaplasia in humans, supporting the hypothesis that murine SPEM with inflammation is more advanced and acquires intestinal characteristics.

**DISCUSSION**

Chronic *H pylori* infection in humans results in the loss of parietal cells accompanied by prominent inflammation. Our previous data have shown that parietal cell loss without inflammation (DMP-777 treatment) results in the transdifferentiation of chief cells into SPEM, possibly as a transient and local injury response.
mechanism. However, when SPEM becomes chronic, under the continuing influence of chronic inflammation as in the setting of H pylori infection, SPEM progresses to dysplasia. Although SPEM alone is not sufficient for progression to dysplasia, it is necessary for the initiation of carcinogenesis. Therefore, metaplastic cell lineages such as SPEM and intestinal metaplasia are considered neoplastic precursors. Intestinal metaplasia arises in the presence of pre-existing SPEM\(^2\) suggesting a progression from SPEM to intestinal metaplasia and then to neoplasia. A number of investigators have utilised chronic H felis infection in mice as a model for the development of metaplasia and dysplasia in the stomach.\(^5\)\(^-\)\(^7\)\(^21\)\(^-\)\(^23\) H felis-infected mice do not develop phenotypic intestinal metaplasia, but instead SPEM progresses directly to dysplasia.\(^6\)\(^-\)\(^7\) The present investigation indicates that, while phenotypic intestinal metaplasia may not develop from SPEM in H felis-infected mice, over time the SPEM lineages do begin to

Figure 5  Clusterin expression in human normal gastric mucosa, metaplasia of the stomach and gastric cancer. (A) In normal glands, clusterin (green) was detected in the isthmus and in a few cells dual-labelled with TFF2 (red) as seen in the inset (arrowheads in top right panel). The sample shown was taken from the University of Tokyo metaplasia array. (B) Clusterin was prominently expressed throughout spasmolytic polypeptide-expressing metaplasia (SPEM) glands as marked by TFF2 in red. In intestinal metaplasia (IM), clusterin was limited to a few cells at the base of glands (designated by arrowheads in bottom right panel). These staining patterns were found in 90% of SPEM samples and 45% of intestinal metaplasia samples on the University of Tokyo metaplasia tissue array. Left panel scale bar=100 μm. Inset panel scale bar=50 μm. (C) Representative images from a human gastric cancer tissue microarray show clusterin (green) expression in gastric cancer cells in each stage. Pan-cytokeratin staining (red) marks epithelial cells. Clusterin expression was present in all stages of cancer (I–IV) with averages of 27.75%, 21.82%, 31.32% and 37.94% clusterin-positive epithelial cells, respectively. 4',6-diamidino-2-phenylindole (blue). Bar=100 μm. (D) The percentage of clusterin-positive epithelial cells was statistically significantly related to tumour stage by analysis of variance (p=0.05). There were significant differences in clusterin staining between stage 1 compared with stages 2 and 4 (labelled with *) and stage 2 versus stages 3 and 4 (labelled with +). (E) Estimated survival curves of clusterin by staining percentage categorised into four quartiles. The highest staining quartile (43–95% clusterin-positive epithelial cells) correlated with the worst survival outcome. express intestinal transcripts, including CFTR and villin. Therefore, while these lineages may not display all of the characteristics of goblet cells and absorptive cells as in human intestinal metaplasia, they do represent further alterations towards more intestinal characteristics that correlate with susceptibility to the development of dysplasia (figure 1).

Studies using DMP-777 and L635 have shown that parietal cell loss is sufficient to induce SPEM, but the presence of inflammation is necessary for the progression of SPEM to a more proliferative metaplasia as well as to gastritis cystica profunda/dysplasia. In this study, we analysed the transcriptional expression of three SPEM models, establishing expression profiles for each lineage model. Specific comparisons of these profiles identified commonalities and differences among the SPEM lineages arising in different milieus. Thirteen transcripts were upregulated in two comparison categories (pan-SPEM and acute SPEM) indicative of SPEM initiation. Two of these, the secreted glycoprotein Wfdc2/HE4 and the poorly characterised ATPase Fignl1, were previously reported as upregulated in SPEM from gastrin null mice after only 1 day of DMP-777 treatment. Other secreted glycoprotein, Clu, was also upregulated in SPEM. Similar to HE4, Clu was expressed in all SPEM lineages. A recent study has shown that Clu upregulation may be induced by gastrin, which is elevated in our mouse models of SPEM. However, Clu is also upregulated in SPEM from DMP-777-treated gastrin null mice (data not shown), indicating that gastrin-independent pathways exist for Clu upregulation.

Although the mechanisms for Clu upregulation are unclear, Clu represents a specific marker of SPEM induction in the gastric oxyntic mucosa.

Comparisons of expression profiles of the inflammatory SPEM models identified putative markers of advanced SPEM. In particular, prominent upregulation of CFTR was observed in both inflammatory SPEM models, but was undetectable in normal glands and in the non-inflammatory DMP-777-induced SPEM lineages. This represents the first definite expression difference among phenotypic SPEM lineages. Along with the other changes in intestinal transcripts such as villin, these findings suggest that inflammation elicits upregulation of genes, such as CFTR, which are more characteristic of the duodenum. As inflammation is required for progression of metaplasia to dysplasia, it follows that SPEM accompanied by prominent inflammation acquires intestinal markers. Moreover, Varon et al. have suggested Helicobacter-induced metaplasia advances after 75 weeks to express Muc2, an intestinal metaplasia marker, in the upper portions of glands. The comparisons in the present study represent expression profiles that can be used to distinguish more advanced SPEM with intestinal characteristics (SPEM-IC), which is susceptible to progression to dysplasia. It remains unclear at this time whether proteins such as Clu and CFTR represent markers of the metaplastic process or whether they directly contribute to the progression of disease. Direct analysis of these questions remains problematical because there are no in-vitro models of normal chief cells and metaplastic

---

**Figure 6**

Cystic fibrosis transmembrane conductance regulator (CFTR) expression in human normal gastric mucosa and in metaplasia of the human stomach. Frozen sections of human stomach were immunostained with an antibody against CFTR (bottom panels). Top panels are H&E staining of sections for orientation and morphology. CFTR was absent from normal mucosa (bottom left) and spasmolytic polypeptide-expressing metaplasia (SPEM) lineages (designated by arrowheads in right panels). The diffuse cytoplasmic immunoreactivity seen in surface cells is non-specific as CFTR is localised to apical membranes. However, expression was observed in intestinal metaplasia (bottom right). Due to limitations of the CFTR antibody and the lack of availability of frozen adenocarcinoma samples, CFTR expression was not evaluated in cancers. Bar = 100 µm. This figure is produced in colour in the online journal—please visit the website to view the colour figure.
lineages (SPEM and intestinal metaplasia). Nevertheless, we anticipate that the rapid induction of metaplasia following L65S treatment will aid future examination of candidate protein influences using mouse strains with targeted gene disruption. 

Taken together, the identification of differences among the expression profiles of phenotypic SPEM lineages illustrates the need to characterise in greater detail SPEM lineages found in the various models of metaplasia of the stomach and gastric cancer. Although SPEM was initially underappreciated as a preneoplastic lesion, recent investigations have illustrated the high prevalence of SPEM in numerous mouse models of gastric homeostasis and gastric cancer.25–30 The loss of Klf4 in glandular tissues results in the development of a SPEM phenotype in the absence of inflammation.25 Similar to DMP-777-induced SPEM, SPEM in Klf4-deficient mice does not acquire intestinal characteristics (such as Muc2 or villin expression) nor does it progress to dysplasia. Keeley and Samuelson25 and Jain et al27 reported that the loss of Hipp1 in parietal cells resulted in apoptotic loss of parietal cells and chief cells. A SPEM lineage accompanied by inflammatory infiltrates emerged at 5 weeks of age.25–27 Expression of intestinal features such as Muc2 and villin is unknown in this SPEM model; however, this model is of interest for comparison with L65S-induced SPEM (an acute SPEM model with inflammation). K19-C2mE transgenic mice, which over-express COX-2 and microsomal prostaglandin E synthase-1 (mPGES-1), develop SPEM at 12 weeks of age and then progress to tumours at 48 weeks.28 The addition of Wnt1 expression (K19-Wnt1/C2mE or Gαn mice) resulted in SPEM at 5 weeks of age progressing to dysplastic tumours at 20 weeks.29 In these models, the development of mucosal lesions was associated with prominent macrophage infiltrates similar to H. felis-induced SPEM. In contrast to all SPEM models utilised in this study, mice deficient for Runx3 develop a SPEM phenotype without prominent inflammation and without the loss of parietal cells. Although there is no inflammatory infiltrate, cells at the base of some SPEM glands expressed intestinal markers, Muc2 and CDX2,30 which are not seen in our metaplasia models. This model is of interest for comparison because of the progression of SPEM to acquire intestinal characteristics without the presence of inflammation or loss of parietal cells. The markers identified in our present investigations should provide reference points for analysis of the metaplastic lineages that arise in these other mouse models.

By establishing commonalities and differences in the expression patterns in our three murine SPEM models, we were able to find novel potential biomarkers of metaplasia in the human stomach. While all SPEM lineages in mice expressed Clu, we found that 90% of SPEM and 46% of intestinal metaplasia in humans expressed Clu. In human intestinal metaplasia, Clu localised to a few cells at the base of the intestinal metaplasia, which is the region suggested as a transitional and proliferative area of intestinal metaplasia arising from SPEM.4 Clusterin may be acting in an anti-apoptotic or cytoprotective manner to help maintain this transitional niche. Clusterin upregulation was maintained in the majority of intestinal-type and diffuse-type cancers. Correlation between Clu expression and stage was U-shaped, suggesting Clu functions differently in the different stages of cancer, a pattern previously observed in other types of cancers.31 Adverse patient outcome was associated with the highest percentage of Clu expression, which was more frequently seen in late-stage cancers. This study supports the recent findings that high Clu expression in late-stage gastric cancers correlated with a poor outcome.32 Therefore, Clu is a useful biomarker for SPEM and an adverse prognostic marker for adenocarcinomas. Conversely, CFTR expression was absent in human SPEM, but was upregulated in intestinal metaplasia. These findings show that expression profiles in murine SPEM with inflammation (SPEM–IC) overlap with human intestinal metaplasia, suggesting that SPEM–IC is a more advanced SPEM lineage (figure 1). Further investigation of murine SPEM lineages will provide greater insight into the heterogeneity of SPEM as well as the progression of early stage SPEM to SPEM–IC in mouse and, by analogy, to the progression of SPEM to intestinal metaplasia in humans.

In summary, we have established distinct expression profiles of SPEM with or without inflammation that illustrate similarities among all SPEM lineages and differences in SPEM lineages with the potential for progression to dysplasia in mice. From these profiles, Clu upregulation was verified as a biomarker of SPEM and poor patient outcome. In addition, CFTR was identified as a biomarker of SPEM with inflammation in mice and intestinal metaplasia in humans. The expression profiles of SPEM lineages with inflammation, especially H. felis infection-induced SPEM, identified a more advanced SPEM lineage in mice that has adopted some intestinal characteristics. These studies support a model of metaplastic progression in mice that begins with the induction of SPEM and advances to SPEM–IC that may have dysplastic potential. The studies also indicate that the mouse model of chronic H. felis infection does mimic the analogous human condition of H. pylori infection, suggesting a progression of parietal cell loss to the initiation of SPEM to further metaplastic progression towards intestinalising metaplasia in the presence of inflammatory influences.

Contributors VGW performed experiments, analysed data, prepared figures and wrote the manuscript. JFS performed experiments, analysed data and edited the manuscript. BJL performed statistical analysis and edited the manuscript. KTN performed experiments and edited the manuscript. JAW developed a new system for analysis of array staining. PEF synthesised L65S and edited the manuscript. NAA developed CFTR antibodies and analysed data. JGF supervised Helicobacter infections studies, developed experimental design and edited the manuscript. JRG developed experimental design, analysed data and edited the manuscript.

Funding These studies were supported by grants from a Department of Veterans Affairs merit review award, NIH grant R01 DK071950, and an ARRA supplement (DK071950-S1) (to JRG); NIH grants R01 AI037750 and P30 ES02109 (to JGF); R01 DK 077065 (to NAA); P50 CA85063 (to BJL). This work was supported by core resources of the Vanderbilt Digestive Disease Center (P30 DK058404) and the Vanderbilt—Ingram Cancer Center, and imaging was supported by both the Vanderbilt combined imaging shared resource and the shared imaging resource of the Vanderbilt Epithelial Biology Center.

Competing interests None.

Ethics approval Ethics approval was provided by Vanderbilt institutional review board.

Provenance and peer review Not commissioned; externally peer reviewed.
