(CDF Collaboration)
We report on a search for the standard model Higgs boson produced in association with a vector boson in the full data set of proton-antiproton collisions at $\sqrt{s} = 1.96$ TeV recorded by the CDF II detector at the Tevatron, corresponding to an integrated luminosity of 9.45 fb$^{-1}$. We consider events having no identified charged lepton, a transverse energy imbalance, and two or three jets, of which at least one is consistent with originating from the decay of a $b$ quark. We place 95% credibility level upper limits on the production cross section times standard model branching fraction for several mass hypotheses between 90 and 150 GeV/c$^2$. For a Higgs boson mass of 125 GeV/c$^2$, the observed (expected) limit is 6.7 (3.6) times the standard model prediction.

In the standard model (SM) [1], the mechanism responsible for spontaneous electroweak symmetry breaking gives mass to the $W$ and $Z$ bosons [2]. The Higgs boson ($H$) represents the remaining degree of freedom after the symmetry is broken and also allows fermions to acquire mass through Yukawa couplings. The SM does not predict the mass of the Higgs boson, $m_H$, but the combination of precision electroweak measurements [3], including recent top quark and $W$ boson mass measurements from the Tevatron [4,5], constrains $m_H < 152$ GeV/c$^2$ at the 95% confidence level. Direct searches at LEP2 [6], the Tevatron [7], and the LHC [8] exclude all possible masses of the SM Higgs boson at the 95% confidence level or the 95% credibility level (C.L.), except within the ranges $116.6 - 119.4$ GeV/c$^2$ and $122.1 - 127$ GeV/c$^2$. A SM Higgs boson in this mass range would be produced in the $\sqrt{s} = 1.96$ TeV $p\bar{p}$ collisions of the Tevatron, and would have a branching fraction to $b\bar{b}$ greater than 50% [9–11]. In these currently allowed regions, $H \to b\bar{b}$ is the dominant decay mode, but large QCD multijet backgrounds overwhelm searches in the exclusive $b\bar{b}$ final state. Searches for $H$ produced in association with a vector boson, $VH$ ($V=W$ or $Z$), where the vector boson decays leptonically, access final states with significantly higher signal-to-background ratios than those resulting from $gg \to H \to b\bar{b}$.

This Letter presents a search for $VH$ production in events with missing transverse energy ($E_T$) [12]—a signature of neutrinos escaping detection—and $b$ jets in a data set corresponding to an integrated luminosity of 9.45 fb$^{-1}$ collected using the CDF II detector at the Fermilab Tevatron. This analysis considers $Z(\to \nu\bar{\nu})H$ production, where the neutrinos ($\nu$) escape detection, or $Z(\to \ell^+\ell^-)H$ when neither charged lepton is identified or they are reconstructed as jets. We are also sensitive to $WH$ events where $W \to e\nu$ or $W \to \tau\nu$ and the charged lepton is

reconstructed as a jet, or where it is not identified. By building upon techniques used for the observation of single-top-quark production [13], we significantly increase the signal acceptance with respect to previous Tevatron searches in this final state [14,15].

CDF II is a multipurpose collider detector described in Ref. [16]. A three-level online selection system (trigger) is used to select events for analysis. Events are selected via Boolean OR of two trigger paths [17] requiring either the presence of large $E_T$, or large $E_T$ and two jets [18]. The efficiency associated to this selection is obtained from data and is applied to the Monte Carlo (MC) simulated samples to reproduce the inefficiencies present in the data. The parametrization of the trigger efficiency [19] significantly improves the modeling of the trigger turn-on outside the fully efficient region, as verified using data control samples. This allows significantly relaxed preselection requirements compared to that of Ref. [14]. The parametrization is done using a neural network (NN) [20] trained from the following inputs: the $E_T$ in the event, its azimuth ($\varphi(\vec{E}_T)$), three variables characterizing the $i$th jet ($j_i$) in the event—$E_T(j_i)$, $\eta(j_i)$, and $\varphi(j_i)$—and the $\eta$-$\phi$ separation of the jets $\Delta R = \sqrt{\Delta \varphi^2 + \Delta \eta^2}$ [12]. We thus have 9 (14) input variables for events with two (three) jets. We use a muon-triggered sample to define the nominal parametrization and derive the trigger systematic uncertainty from a parametrization of an inclusive jet sample with at least one jet with $E_T > 50$ GeV. The efficiency ranges from 0.40 for events having $E_T = 35$ GeV to 1.0 for events with $E_T > 80$ GeV.

We reconstruct jets from energy depositions in the calorimeter towers using a jet clustering cone algorithm [18] with a cone of radius $\Delta R = 0.4$. In addition to the standard jet-energy corrections used by CDF [18], we adjust the energy of the jets according to the measured momentum of the charged particle tracks within the jet cone [21]. We further improve the energy determination using a NN approach to estimate the energies of the initiating quarks. The direction and magnitude of the $\vec{E}_T$ are then recomputed. These jet reconstruction methods improve both the signal acceptance and the relative resolution of the reconstructed invariant mass of the Higgs boson candidate by $\sim$15%. We reject events with an identified $e$ or $\mu$ to maintain statistical independence from other CDF analyses searching for the SM Higgs boson [22,23].

After the events are reconstructed, the following preselection requirements are made: we select events with $E_T > 35$ GeV and two or three jets satisfying $E_T > 15$ GeV and $|\eta| < 2.4$, thus accepting events where partons provide an additional jet candidate, or a lepton ($e$ or $\tau$) is reconstructed as a jet. The two most energetic jets, $j_1$ and $j_2$, are required to have reconstructed transverse energies of at least 25 and 20 GeV, respectively, satisfy $|\eta(j_i)| < 2$, be separated by $\Delta R(j_1,j_2) > 0.8$, and at least one of these two jets must satisfy $|\eta(j_i)| < 0.9$. This selection is relaxed with respect to Ref. [14], and increases the signal acceptance by a factor of 1.4. The cost of this increased signal acceptance is a 10-fold increase of the background acceptance. One of the leading sources of significant $E_T$ in QCD (quantum chromodynamics) production of multi-jet events (QCD MJ) arises from the mismeasurement of jet energies. Neutrinos from semileptonic $b$ decays can also produce significant $E_T$ in QCD MJ events. In both of those cases, the $\vec{E}_T$ is often aligned with $E_T^j$, and such events are rejected by requiring $\Delta \varphi(\vec{E}_T, \vec{E}_T^j) \geq 1.5$ and $\Delta \varphi(\vec{E}_T, E_T^j) \geq 0.4$. This reduces the backgrounds by a factor of 3, while retaining 90% of the signal. The large backgrounds from light-flavor jet production originating from $u, d,$ or $s$ quarks or gluons are reduced by identifying (tagging) jets consistent with the decay of $b$ quarks; $c$ quarks are not explicitly identified.

We use two algorithms to tag $b$-quark jets, SECVTX [24], which attempts to reconstruct the secondary vertex from the $b$ decay (displaced from the interaction point because hadrons containing $b$ or $c$ quarks can travel a few millimeters in the detector before decaying), and JETPROB [25], which determines for each jet the probability that the tracks within the jet are consistent with originating from the primary vertex. We operate SECVTX (JETPROB) at about 40% (50%) efficiency, yielding a rate of light-flavor jets mistakenly identified as $b$ jets (mistags) of about 1% (5%). We exploit the different purities of the selected multitagged events by considering independent tagging categories separately and later combining results. We require that one of the leading jets be tagged by SECVTX and the other be tagged either by SECVTX (SS) or JETPROB (SJ), or be untagged (1S). The tagging process reduces the backgrounds by 2 orders of magnitude while retaining about 50% of the signal. Events satisfying the aforementioned criteria comprise the preselection sample. The signal-to-background ratio ($S/B$) in this sample is estimated to be $S/B \sim 1/400$ in the SS tagging category for $m_H = 125$ GeV/$c^2$, compared to less than $10^{-5}$ for the full sample of triggered events. The relative fraction of events with $Z \rightarrow \nu \bar{\nu}, Z \rightarrow \ell^+ \ell^-$, and $W \rightarrow \ell \nu$ is, respectively, 47, 3, and 50%; of the latter, the fraction with electron ($e$), muon ($\mu$), and tau ($\tau$) decays is, respectively, 30, 20, and 50%.

Backgrounds from top-quark events via pair and electroweak production (top), $V +$ jets events, and diboson events ($VV$) are all modeled via simulation. The ALPGEN generator [26] is used to estimate $V+$ jets (including the ratio of light- to heavy-flavor events), POWHEG [27] for electroweak production of top quarks, and PYTHIA [28] for top-quark pair production and $VV$ events, as well as for the $VH$ signal. The parton showering is performed by PYTHIA. The event generation process includes a simulation of the detector response [29], and the resulting samples are subjected to the same reconstruction and analysis chain as the data. The normalization of the simulated samples is
described in Ref. [7]. Electroweak (EWK) mistags, events with light-flavor jets that are wrongly tagged, are mostly due to $V + \text{jets}$ and are determined from light-flavor simulated samples weighted by a per-event mistag probability, obtained for each algorithm from an orthogonal data sample [24,25].

The background contribution from QCD MJ events is difficult to describe accurately with the simulation, and so is modeled separately from an independent data sample. We predict the QCD MJ contribution from data events with $\Delta \phi(\vec{E}_T, \vec{E}_{T,j}) < 0.4$ and $35 < \vec{E}_T < 70$ GeV. In this sample, we measure the contamination from events with heavy-flavor jets or light-flavor mistags that fall into one of the three previously described tagging categories [19].

Following Ref. [14], we parametrize this category-tagging rate (the ratio of category-tagged events to events satisfying taggability requirements) in bins of the magnitude of the negative vector sum of the transverse momenta of the charged tracks within the jet $(\vec{p}_T)$ [30], the scalar sum of transverse energies of $j_1, j_2,$ and $j_3$ (where applicable) $H_T, Z[j_1], \text{and } Z[j_2]$, where $Z[j] = \sum p_T^j / p_T^T$. We define one four-dimensional matrix ($M_{TR}$) for each tagging category. The large data sample available allows improvement of this model by defining an event-based $M_{TR}$ instead of a jet-based $M_{TR}$. The advantage is that correlations between the jets in each event are properly taken into account. We use the $M_{TR}$ to predict the QCD MJ contribution in the preselection, which has the same flavor composition before tagging requirements as in the region from which the $M_{TR}$ is derived. The QCD MJ background normalization in each tagging category is determined from the corresponding $M_{TR}$ after subtracting the contributions from all other background sources, which are estimated using simulated events. The model is validated in various control regions, defined below.

We employ an artificial neural network, $\text{NN}_{\text{QCD}}$, to discriminate the expected signal from the remaining backgrounds. Seven input variables are used for this purpose: the invariant mass of the two leading jets [$m(j_1, j_2)$], the invariant mass of $\vec{E}_T$ and all jets, the differences $H_T - \vec{E}_T$ and $H_T - \vec{E}_T$ ($H_T$ is the magnitude of the negative vector sum of jet $E_T$), the maximum $\Delta R$ between the jets, the output of $\text{NN}_{\text{QCD}}$, and the output of a NN using tracking information to separate events with intrinsic $\vec{E}_T$ from those with instrumental $\vec{E}_T$ [33].

We avoid potential bias by testing our understanding of the SM backgrounds in several control samples where the expected amount of signal is negligible. We define an EWK region [Fig. 2(a)] by requiring events to have at least one charged lepton in addition to satisfying the preselection criteria. This region is sensitive to top-quark pair, $V + \text{jets}$, and, to a lesser extent, $VV$ and electroweak single-top-quark production, and is used to validate the simulation against the data. We also define the MJ1, MJ2, and MJ3 control regions, which contain no identified lepton and are dominated by QCD processes. MJ1 [Fig. 2(b)] contains events with $\Delta \phi(\vec{E}_T, \vec{E}_{T,j}) < 0.4$ and $\vec{E}_T > 70$ GeV. MJ2 contains events satisfying the preselection requirements and $\text{NN}_{\text{QCD}} < 0.1$ and is the region where the QCD MJ normalization is obtained from the data. MJ3, defined from preselection events with $0.1 \leq \text{NN}_{\text{QCD}} \leq 0.45$, serves as a final consistency check of the overall normalization. Finally, we validate our background model in the preselection region before proceeding with the final fit in the signal region. We check the distribution of multiple kinematic variables, including all inputs to $\text{NN}_{\text{QCD}}$ and to the final discriminant function $\text{NN}_{\text{SIG}}$, defined in the next paragraph, as well as the output of these two networks in all our control samples [19]. We obtain good agreement.

FIG. 1 (color online). The distribution of $\text{NN}_{\text{QCD}}$ for events satisfying the preselection criteria. The signal region is defined by $\text{NN}_{\text{QCD}} > 0.45$. The normalization of the QCD MJ contribution is determined from the data. The uncertainty includes all statistical and systematic contributions (see text).
between the data and our SM background model in all the samples, with only the normalization of the QCD MJ component determined from the fit to data.

The distribution of $N_{\text{NSIG}}$ is validated in our control samples, as shown in Fig. 2 for events with two $b$ tags. Figure 2(c) shows the distribution of $N_{\text{NSIG}}$ in the signal region for events with two $b$ tags. The expected number of events is compared to the observed yields in Table I (see Supplemental Material [34]). For $m_H = 125 \text{ GeV}/c^2$, we expect a total of 21 (16) signal events with one (two) $b$-tagged jets.

We perform a binned likelihood fit to probe for a $VH$ signal in the presence of SM backgrounds. The likelihood is the product of Poisson probabilities over the bins in the $N_{\text{NSIG}}$ distribution. The mean number of expected events in each bin includes contributions from each background source and from the $VH$ processes (assuming a given value of $m_H$). We employ a Bayesian likelihood method [35] with a flat, non-negative, prior probability for the SM Higgs boson production cross section times branching fraction, $\sigma/(VH) \times B(H \rightarrow b\bar{b})$, and truncated Gaussian priors for the uncertainties on the acceptance and shape of the backgrounds. We combine the three tagging categories by taking the product of their likelihoods and simultaneously varying the correlated uncertainties. All systematic uncertainties except those associated with the QCD MJ and the EWK mistags are treated as fully correlated across the tagging categories.

The uncertainties from the simulations statistics and those on the normalizations of top-quark (10%), diboson (6%), $V + \text{jets}$ (30%), QCD MJ (1 to 3%), and EWK mistags (20 to 65%) production are not correlated. The shapes obtained by varying the $M_{\text{TR}}$ (mistag) probabilities by 1 standard deviation from their central values are applied as shape uncertainties for the QCD MJ (EWK mistags). The correlated uncertainties, which apply to both the signal and the EWK backgrounds, include luminosity measurement (6%), $b$-tagging efficiency (5 to 10%), trigger efficiency (3-5%), lepton veto efficiency (2%), parton distribution function (3%), and up to 11% for the jet-energy scale [18]. We also determine the shape uncertainties on $N_{\text{NSIG}}$ due to the jet-energy scale and the trigger efficiency. The latter two also affect the QCD MJ background through the background subtraction procedure described above. Initial- and final-state radiation uncertainties (2 to 3%) are applied only to the $VH$ signal.

![FIG. 2 (color online). The distribution of the final discriminant function, $N_{\text{NSIG}}$, for events with two $b$ tags (SS + SJ categories) in the control samples: (a) EWK, (b) MJ1, (c) signal region ($MN_{\text{QCD}} > 0.45$). Only the normalization of the QCD MJ is fit to the data.](image-url)

### TABLE I. Comparison of the number of expected and observed events in the signal region for different tagging categories. The uncertainties include all statistical and systematic contributions (see text and the Supplemental Material [34]).

Expected Higgs boson signal for $m_H = 125 \text{ GeV}/c^2$

$ZH \rightarrow \nu \nu b\bar{b}$ $7.6$ $9.7$

$WH \rightarrow \ell \nu b\bar{b}$ $8.0$ $10.6$

$ZH \rightarrow \ell \ell b\bar{b}$ $0.4$ $0.6$

We compute 95% C.L. upper limits on $\sigma(VH) \times \mathcal{B}(H \rightarrow b\bar{b})$ for $90 < m_H < 150$ GeV/$c^2$ in 5 GeV/$c^2$ steps using the methodology described in Ref. \[36\]. The expected and observed upper limits are shown in Table II and Fig. 3. We test the consistency of the observed limits with the signal hypothesis by statistical sampling of the signal-plus-background model (assuming $m_H = 125$ GeV/$c^2$). These studies indicate that the median upper C.L. in the SM Higgs scenario is higher (up to 2.5 units in SM cross section) than that of the background-only hypothesis over the 90–150 GeV/$c^2$ range, and is consistent with the observed limits within 1 standard deviation.

In summary, we have performed a direct search for the SM Higgs boson decaying into $b\bar{b}$ pairs using the full CDF II data sample, corresponding to 9.45 fb$^{-1}$ of integrated luminosity accumulated during run II of the Tevatron. Improved techniques increase the sensitivity by roughly 15% with respect to a previous analysis \[14\] in addition to the improvement due to larger integrated luminosity. We set 95% C.L. upper limits on $\sigma(VH) \times \mathcal{B}(H \rightarrow b\bar{b})$ for $90 < m_H < 150$ GeV/$c^2$ with 5 GeV/$c^2$ increments. For a Higgs boson mass of 125 GeV/$c^2$, the observed limit is 6.7 times the SM prediction, consistent with the expected limit of 3.6 within 2 standard deviations.

We thank the Fermilab staff and the technical staffs of the participating institutions for their vital contributions. FIG. 3 (color online). Observed and expected (median, for the background-only hypothesis) 95% C.L. upper limits on $VH$ cross section times $\mathcal{B}(H \rightarrow b\bar{b})$ divided by the SM prediction, as a function of the Higgs boson mass. The bands indicate the 68% and 95% credibility regions where the limits can fluctuate, in the absence of signal.

[12] CDF uses a cylindrical coordinate system with the pseudorapidity 

\[ \eta = -\ln(\tan(\frac{\theta}{2})) \]

where \( \theta \) is the polar angle, and \( \phi \) is the azimuthal angle, while \( p_T = p \sin \theta \) and \( E_T = E \sin \theta \). The \( E_T \) is defined as the magnitude of \( \vec{E}_T = -\sum \vec{E}_i \hat{n}_i \), where \( \hat{n}_i \) is a unit vector perpendicular to the beam axis and pointing at the ith calorimeter tower, and \( E_i \) is the transverse energy therein.

[17] A trigger path is uniquely defined by specifying selection criteria at each of the three trigger levels. The trigger paths and the parametrization of their combined efficiency are described in detail in Ref. [19].

The event sphericity is defined by
\[ S = \frac{1}{2} (\lambda_2 + \lambda_3), \]
where the sphericity tensor is
\[ S^{\alpha\beta} = \frac{(\sum p_i^\alpha p_i^\beta)}{(\sum p_i^\gamma)} \]
and \( \lambda_1 > \lambda_2 > \lambda_3 \) are its three eigenvalues and satisfy \( \lambda_1 + \lambda_2 + \lambda_3 = 1 \). The index \( i \) refers to each jet in the event.

The event centrality is
\[ C = \sqrt{\frac{\sum p_i^x \sum p_i^y}{\sum p_i^x + \sum p_i^y + \sum p_i^z}}. \]
