(Received 19 April 2012; published 23 October 2012)

The low-energy \( n\Sigma^- \) interactions determine, in part, the role of the strange quark in dense matter, such as that found in astrophysical environments. The scattering phase shifts for this system are obtained from a numerical evaluation of the QCD path integral using the technique of lattice QCD. Our calculations, performed at a pion mass of \( m_\pi \sim 389 \text{ MeV} \) in two large lattice volumes and at one lattice spacing, are extrapolated to the physical pion mass using effective field theory. The interactions determined from lattice QCD are consistent with those extracted from hyperon-nucleon experimental data within uncertainties and strengthen model-dependent theoretical arguments that the strange quark is a crucial component of dense nuclear matter.

The interactions between hyperons and nucleons are important for understanding the composition of dense nuclear matter. In high-density baryonic systems, the large values of the Fermi energies may make it energetically advantageous for some of the nucleons to transform into hyperons via the weak interactions, with the increase in rest mass being more than compensated for by the decrease in combined Fermi energy of the baryon-lepton system. This is speculated to occur in the interior of neutron stars, but a quantitative understanding of this phenomenon depends on knowledge of the hyperon-nucleon (YN) interactions in the medium. In this Letter, we use \( n\Sigma^- \) scattering phase shifts in the \( ^1S_0 \) and \( ^3S_1 \) spin channels calculated with lattice QCD (LQCD) to quantify the energy shift of the \( \Sigma^- \) hyperon in dense neutron matter, as might occur in the interior of a neutron star. Our results strongly suggest an important role for strangeness in such environments.

Precise nucleon-nucleon (NN) interactions constrained by experiment and chiral symmetry, together with numerically small but important three-nucleon interactions, have served as inputs to refined many-body techniques for studying the structure of nuclei, such as Green’s function Monte Carlo calculations [1], the no-core shell model [2], and lattice effective field theory [3], which have led to remarkably successful calculations of the ground states and excited states of light nuclei, with atomic number \( A < 14 \). By contrast, the YN potentials, which are essential for a first-principles understanding of the hypernuclei and dense matter, are only very approximately known. Therefore, gaining a quantitative understanding of YN interactions—on a par with knowledge of the NN interactions—through experimental and LQCD methods is a fundamental goal of nuclear science.

Existing experimental information about the YN interaction comes from the study of hypernuclei [4,5], the analysis of associated \( \Lambda \)-kaon and \( \Sigma^- \)-kaon production in \( NN \) collisions near threshold [6–11], hadronic atoms [12], and from charge-exchange production of hyperons in emulsions and pixelated scintillation devices [13]. There is only a small set of cross section measurements of the YN processes, and, not surprisingly, the extracted scattering parameters are not accurately known. The potentials developed by the Nijmegen [14–16] and Jülich [17–19] groups are just two examples of phenomenological models based on meson exchange, but the couplings in such models are not completely determined by the \( NN \) interaction and are instead obtained by a fit to the available YN data. In Refs. [14,15], for example, six different models are
constructed, each describing the available YN cross section data equally well but predicting different values for the phase shifts. Effective field theory (EFT) descriptions have also been developed [20–24] and have the advantage of being model independent.

In the absence of precise experimental measurements, LQCD calculations can be used to constrain the YN interactions. Several years ago, the NPLQCD Collaboration performed the first $n_f = 2 + 1$ LQCD calculations of YN interactions [25] (and $NN$ interactions [26]) at unphysical pion masses. Quenched and dynamical calculations were subsequently performed by the HALQCD Collaboration [27] and by NPLQCD [28]. Recent work by NPLQCD [29–31] and HALQCD [32,33] has shown that the $S = -2$ H dibaryon is bound for pion masses larger than those of nature, and NPLQCD [31] has shown that the same is true for the $\Xi^-$ with $S = -4$. In this Letter, we use the results of LQCD calculations to determine leading-order (LO) couplings of the YN EFT (using Weinberg power counting [24]), which in turn allow for a determination of YN interactions at the physical pion mass.

In LQCD, Lüscher’s method [34–37] can be employed to extract two-particle scattering amplitudes below inelastic thresholds. For a single scattering channel, the deviation to extract two-particle scattering amplitudes below inelastic thresholds, $e^{-\gamma^2}$, where $\gamma$ is the binding momentum [35–37]. The range of nuclear interactions is determined by the pion mass, and therefore the use of Lüscher’s method requires that $m_{\pi}L \gg 1$ to strongly suppress the contributions that depend exponentially upon the volume, $e^{-m_{\pi}L}$ [39]. However, corrections of the form $e^{-\gamma^2}$, where $\gamma^{-1}$ is approximately the size of the bound state, must also be small for the infinite-volume extrapolation to rapidly converge.

Our results are from calculations on two ensembles of $n_f = 2 + 1$ anisotropic clover gauge-field configurations [40,41] at a pion mass of $m_\pi \sim 389$ MeV, a spatial lattice spacing of $b_s \sim 0.123(1)$ fm, and an anisotropy of $\xi = b_s/b_t \sim 3.5$, with spatial extents of 24 and 32 lattice sites, corresponding to spatial dimensions of $L \sim 3.0$ and $3.9$ fm, respectively, with temporal extents of 128 and 256 lattice sites, respectively. A detailed analysis demonstrates that the single-baryon masses in these lattice ensembles are effectively in the infinite-volume limit [42] and that exponential volume corrections can be neglected in this work. Lüscher’s method assumes that the continuum single-baryon energy-momentum relation is satisfied over the range of energies used in the eigenvalue equation in Eq. (1). As discussed in Refs. [29,31], the uncertainties in the energy-momentum relation translate to a 2% uncertainty in the determination of $q^2$.

We focus on $^1S_0$ and $^3S_1 n\Sigma^-$ interactions, $N\Sigma$ in the $I = 3/2$ channel, and do not consider the $I = 1/2 N\Sigma^-N\Lambda$ coupled channels. Calculations in the $I = 1/2$ channel are complicated by the proximity in energy of the ground and first excited levels in the finite volume. Moreover, while the $\Sigma$ is more massive than the $\Lambda$, the presence of $\Lambda$’s in dense matter does not lower the electron Fermi energy. In the limit of SU(3) flavor symmetry, the $^1S_0$ channels are in symmetric irreducible representations of $8 \otimes 8 = 27 \oplus 10 \oplus \bar{10} \oplus 8 \oplus \bar{8} \oplus \bar{1}$, and hence the $n\Sigma^-$ (along with the $\Xi^-\Xi^-$, $\Sigma^-\Sigma^-$, $nn$, and $\Sigma^-\Xi^-$) transforms in the 27. YN and $NN$ scattering data, along with the leading SU(3) breaking effects, arising from the light-meson and baryon masses, suggest that all of these channels are attractive at the physical pion mass and that $\Xi^-\Xi^-$ and $\Sigma^-\Sigma^-$ are bound [43–45]. By contrast, the $^3S_1$ channel of $n\Sigma^-$ scattering transforms in the 10 in the limit of SU(3) symmetry and is therefore unrelated to $NN$ interactions. Hence, this channel is quite uncertain, with disagreements among hadronic models as to whether the interaction is attractive or repulsive.

The low-energy $n\Sigma^-$ interactions can be described by an EFT of nucleons, hyperons, and pseudoscalar mesons ($\pi$, $K$, and $\eta$), constrained by chiral symmetry [20,23,24]. At LO in the expansion, the $n\Sigma^-$ interaction is given

\[ q \cot \delta(q) = \frac{1}{\pi L} \lim_{\lambda \to \infty} \left[ \sum_{|j| < \Lambda} \frac{1}{|j|^2 - q^2} - 4\pi \Lambda \right]. \tag{1} \]
by one-meson exchange together with a contact operator that encodes the low-energy effect of short-distance interactions. As these contact operators are independent of the light-quark masses, at LO the quark-mass dependence of the $n\Sigma^-$ interactions is dictated by the meson masses. Therefore, in each partial wave, a single lattice datum at a sufficiently low pion mass determines the coefficient of the contact operator, thereby determining the LO interaction, including energy-independent and local potentials, wave functions, and phase shifts, at the physical pion mass.

We find that our LQCD calculations in the $^1S_0$ $n\Sigma^-$ channel are consistent with the SU(3) symmetry expectations. At $m_\pi \sim 389$ MeV, using a volume extrapolation as discussed above, we find that this channel has a bound state, with binding energy $B = 25 \pm 9.3 \pm 11$ MeV. The quality of the LQCD data in the $^1S_0$ $n\Sigma^-$ channel is comparable to that of its $27$-plet partner $\Xi^- \Xi^-$, analyzed in detail in Ref. [31] (see also [46]). In the EFT, the coefficient of the LO contact operator in this channel is determined by tuning it to reproduce the LQCD-determined binding energy. We find that this channel becomes unbound at $m_\pi \approx 300$ MeV, in agreement with Ref. [47], which constrained the LO contact operator using experimental data. In Fig. 1, we show the predicted $^1S_0$ $n\Sigma^-$ phase shift at the physical pion mass—(very dark, light) (blue) bands correspond to (statistical, systematic) uncertainties—and compare with the EFT constrained by experimental data [24], the Nijmegen NSC97f model [14], and the Jülich 2004 model [19]. The systematic uncertainties on our predictions include those arising from the LQCD calculation (see [46]) as well as estimates of omitted higher-order effects in the EFT.

The $^3S_1^-D_1^n \Sigma^-$ coupled channel is found to be highly repulsive in the $s$ wave at $m_\pi \sim 389$ MeV, requiring interactions with a hard repulsive core of extended size. Such a core, if large enough, would violate a condition required to use Lüscher’s relation, namely, $R \ll L/2$, where $R$ is the range of the interaction. We have determined the EFT potential directly by solving the three-dimensional Schrödinger equation in finite volume to reproduce the energy levels obtained in the LQCD calculations. The repulsive core, whose size is set by the contact operator at LO in the EFT, is found to be strongly enhanced over the meson-exchange contributions. This formally precludes the use of Lüscher’s relation, but both methods lead to phase shifts that agree within uncertainties, indicating that the exponential corrections to Lüscher’s relation are small. In Fig. 2, we show the predicted $^3S_1^n \Sigma^-$ phase shift at the physical pion mass.

The $n\Sigma^-$ interactions presented here are the crucial ingredient in calculations that address whether $\Sigma^-$’s appear in dense neutron matter. As a first step, and in order to understand the competition between attractive and repulsive components of the $n\Sigma^-$ interaction, we adopt a result due to Fumi for the energy shift due to a static impurity in a noninteracting Fermi system [48]:

$$\Delta E = -\frac{1}{\pi \mu} \int_0^\infty dk k \left[ \frac{3}{2} \delta \Sigma^-(k) + \frac{1}{2} \delta S_0(k) \right],$$

where $\mu$ is the reduced mass in the $n\Sigma^-$ system. Using our LQCD determinations of the phase shifts, and allowing for a 30% theoretical uncertainty, the resulting energy shift and uncertainty band are shown in Fig. 3. At neutron number density $\rho_n \sim 0.4$ fm$^{-3}$, which may be found in the interior of neutron stars, the neutron chemical potential is $\mu_n \sim M_N + 150$ MeV due to neutron-neutron interactions and the electron chemical potential is $\mu_e \sim 200$ MeV [49]. Therefore, $\mu_n + \mu_e \sim 1290$ MeV, and, consequently, if $\mu_{\Sigma^-} = M_{\Sigma^-} + \Delta E \lesssim 1290$ MeV, that is, $\Delta E \leq 100$ MeV, then the $\Sigma^-$, and hence the strange quark, will play a role in the dense medium. We find using
Fumi's theorem that $\Delta E = 46 \pm 13 \pm 24$ MeV at $\rho_n = 0.4$ fm$^{-3}$. Corrections due to correlations among neutrons are difficult to estimate and will require many-body calculations which are beyond the scope of this study. Despite this caveat, the results shown in Fig. 3 indicate that the repulsion in the $n\Sigma^-$ system is inadequate to exclude the presence of $\Sigma^-$'s in neutron star matter, a conclusion that is consistent with most of the previous phenomenological modeling (for a recent review, see Ref. [50]). The present uncertainty in the hadronic interactions, and their transcription into many-body calculations of dense matter, have led to a large uncertainty in the composition of dense matter, particularly the precise role of the strange quark (see, for instance, Refs. [51,52]). Our present calculations provide a step towards eliminating the uncertainties arising from the interactions among hadrons.

In this Letter, we have presented the first LQCD predictions for hypernuclear physics, the $^1S_0$ and $^3S_1$ $n\Sigma^-$ scattering phase shifts shown in Figs. 1 and 2. While the LQCD calculations have been performed at a single lattice spacing, lattice-spacing artifacts are expected to be smaller than the other systematic uncertainties. We anticipate systematically refining the analysis presented in this Letter as greater computing resources become available. The $n\Sigma^-$ interaction is critical in determining the relevance of hyperons in dense neutron matter, and we have used the LQCD predictions of the phase shifts to estimate the $\Sigma^-$ energy shift in the medium. Our calculation suggests that hyperons are important degrees of freedom in dense matter, consistent with expectations based upon the available experimental data and hadronic modeling. It is important that more sophisticated many-body techniques be combined with the interactions determined in this work to obtain a more precise determination of the energy shift of the $\Sigma^-$ in a medium. This will refine the prediction for the role of strange quarks in astrophysical environments and, in particular, will quantitatively address questions posed by the recent observation of a $1.9M_\odot$ neutron star [53].
