In the presence of time-reversal symmetry, quantum interference gives strong corrections to the electric conductivity of disordered systems. The self-interference of an electron wave function traveling time-reversed paths leads to effects such as weak localization and universal conductance fluctuations. Here, we investigate the effects of broken time-reversal symmetry in a driven artificial two-level system. Using a superconducting flux qubit, we implement scattering events as multiple Landau-Zener transitions by driving the qubit periodically back and forth through an avoided crossing. Interference between different qubit trajectories gives rise to a speckle pattern in the qubit transition rate, similar to the interference patterns created when coherent light is scattered off a disordered potential. Since the scattering events are imposed by the driving protocol, we can control the time-reversal symmetry of the system by making the drive waveform symmetric or asymmetric in time. We find that the fluctuations of the transition rate exhibit a sharp peak when the drive is time symmetric, similar to universal conductance fluctuations in electronic transport through mesoscopic systems.

At low temperatures, the conductivity of disordered systems is strongly influenced by quantum interference effects such as weak localization and universal conductance fluctuations (UCF) [1,2]. Weak localization is due to constructive self-interference of an electron wave function traversing time-reversed paths, leading to an enhanced probability of backscattering and therefore a reduction of the conductance. UCF describe the strong fluctuations in conductance that occur as a function of any parameter that changes the scattering configuration [3–5]. The interference effects are highly sensitive to anything that breaks time-reversal symmetry, such as a magnetic field applied perpendicularly to the motion of the charge carriers. Studies of weak localization and UCF thus provide a method for investigating effects related to phase coherence, which has been used in a wide variety of systems ranging from metals [6] and semiconductors [7] to quantum dots [8–10] and graphene [11] and even for the scattering of light off disordered media [12–14].

The presence of weak localization and UCF in such widely varying systems shows the universality of the effect, occurring independently of the sample size, dimensionality, and the degree of disorder. In mesoscopic systems, there are typically a large number of scatterers, giving millions of interfering paths that contribute to the electron transport. In this Letter, we investigate the effect of time-reversal symmetry on a driven artificial two-level system in the few-scatterer limit. The scattering events are implemented as Landau-Zener transitions by driving a qubit multiple times through an avoided crossing. With both the number of scattering events and the time-reversal symmetry imposed by the driving protocol, we have control over the number of possible paths in the system. In a configuration with only four scatterers, we measure a sharp increase in the fluctuations of the qubit transition rate when the drive waveform is made symmetric in time.

We use a superconducting flux qubit [15,16], which consists of a niobium loop interrupted by three Josephson junctions [17], with a magnetic flux \( \Phi \) threading the loop. The clockwise and counterclockwise persistent currents \( \pm I_p \), corresponding to the qubit’s diabatic states, are tunnel coupled with strength \( \Delta \). The two-level Hamiltonian

\[
H = (-1/2)(\Delta \sigma_x + \varepsilon \sigma_z)
\]

describes the qubit dynamics, where \( \varepsilon = 2I_p f, f = \Phi - \Phi_0/2 \) is the flux detuning, \( \Phi_0 = h/2e \) is the superconducting flux quantum, and \( \sigma_x \) and \( \sigma_z \) are Pauli matrices. The qubit energy separation \( E_{01} = \sqrt{\varepsilon^2 + \Delta^2} \) is therefore controlled by the flux \( \Phi \) in the loop [Fig. 1(a)].

We first discuss the concept of scattering events in a driven two-level system. Starting at negative flux detuning and with the qubit in its ground state, we apply a large-amplitude flux signal that drives the qubit through an avoided crossing and back again [Fig. 1(a)]. At the first avoided crossing, the ground state \( |0\rangle \) undergoes a Landau-Zener transition and splits into a coherent superposition of \( |0\rangle \) and \( |1\rangle \). The states evolve independently until the second time they reach the avoided crossing, where they interfere constructively or destructively depending on the relative phase \( \varphi \) acquired between the two transitions.

The Landau-Zener transitions and the qubit evolution can be thought of as a phase-space analog of an optical Mach-Zehnder interferometer [17]. Figure 1(b) shows the energy evolution of the qubit during the drive, where the
interference phase $\varphi = \frac{1}{\hbar} \int_{t_1}^{t_2} E_{01}(t) dt$ is given by the shaded area between the two scattering events. The setup is similar to the mesoscopic system of Fig. 1(c) in the limit of very few scatterers. The qubit phase space of Fig. 1(b) contains only two scatterers, two possible trajectories, and one interference phase. The problem can be solved analytically, with the resulting qubit transition rate showing oscillations as a function of the interference phase $\varphi$ [18].

We can increase the number of trajectories in our system by driving the qubit back and forth through the avoided crossing several times for each cycle of the driving waveform. This allows us to increase the complexity of the system and move closer to the mesoscopic case while still having a controlled, nonchaotic phase space. Figure 1(d) shows the qubit being driven through the avoided crossing two additional times, giving a total of four scatterers, three interference phases, and $2^3 = 8$ possible paths. Note that the drive waveform is symmetric in time. Qubit trajectories that are related by the temporal symmetry will pick up the same phase during the driven evolution, and they will therefore interfere constructively. Examples of time-reversed paths are plotted in red (dashed) and blue (solid) in Fig. 1(d). When the waveform is symmetric in time, the trajectories acquire the same phases (since $\varphi_1 = \varphi_3$) and will interfere constructively. (e) Without time-reversal symmetry, $\varphi_1 \neq \varphi_3$.

We implement the drive protocol using a biharmonic signal [19]:

$$f(t) = f_{dc} + A_1 \cos(\omega t + \alpha) - A_2 \cos(2\omega t).$$  \hspace{1cm} (1)$$

We fix the frequency $\omega/(2\pi) = 125$ MHz, the amplitude $A_1 = 3 m\Phi_0$, and the amplitude ratio $A_2/A_1 = 0.55$, while the parameter $\alpha$ controls the waveform’s asymmetry. The waveform is plotted in Fig. 2(a) for a few different values of $\alpha$, with Fig. 1(b) showing a magnification around the
time \( t = 0 \). Note that the function is symmetric in time for \( \alpha = 0 \) and becomes increasingly asymmetric as \( \alpha \) is increased.

The waveform’s period \( 2\pi/\omega = 8 \text{ ns} \) is comparable to the qubit’s dephasing time \( T_\phi = 10 \text{ ns} \). This puts the dynamics in the quasiclassical regime \([18]\), where coherence is preserved within one period of the drive but where multiphoton processes due to coherence over many periods are not resolved \([17]\). However, since the energy-relaxation time \( T_1 = 20 \mu\text{s} \) is much longer, consecutive periods of the drive signal will lead to a buildup of excited-state population. The process of reaching the steady-state population follows an exponential time dependence, which we characterize by a transition rate \( \Gamma \). In the relevant regime (\( \Gamma \gg 1/T_1 \)), we have \( \Gamma = 2W \), where \( W \) is the probability (per unit time) of inducing a qubit transition from \( |0\rangle \) to \( |1\rangle \) after one period of the drive waveform \([18]\).

The measurement procedure consists of three steps: First, the qubit is cooled to its ground state by using a 3-\( \mu\text{s} \) cooling pulse \([20]\); next, we apply the drive signal to induce qubit transitions; finally, the qubit state is read out by using a superconducting quantum interference device. By changing the length of the drive pulse and fitting the measured qubit population versus pulse duration to an exponential decay, we extract the transition rate \( \Gamma \) from the measured qubit population versus pulse duration to an exponential time dependence, which we characterize by a transition rate \( \Gamma \). In the relevant regime (\( \Gamma \gg 1/T_1 \)), we have \( \Gamma = 2W \), where \( W \) is the probability (per unit time) of inducing a qubit transition from \( |0\rangle \) to \( |1\rangle \) after one period of the drive waveform \([18]\).

For positive \( f_{dc} \), only the negative dip of the biharmonic signal reaches the avoided crossing. This section of the wave will generate two Landau-Zener transitions just like in Fig. 1(a), resulting in a transition rate \( \Gamma \) that oscillates as a function of the interference phase \( \varphi \) picked up between the scattering events [shaded area in Fig. 2(e)]. At the maximum of \( \Gamma \) marked by I in Fig. 2(c), the drive just barely reaches the avoided crossing, giving a phase pickup of \( \varphi = \pi \). As \( f_{dc} \) is decreased, the flux excursion between scattering events gets longer and the phase pickup increases. The next maximum (point II) corresponds to \( \varphi = 3\pi \), and successive maxima occur whenever the interference phase equals odd integers of \( \pi \). In this simplified picture, we do not consider the phase accumulation during the positive part of the flux sweep, which has a smaller influence on the resulting transition rate due to the qubit’s comparatively short dephasing time \( T_\phi = 10 \text{ ns} \).

For negative \( f_{dc} \), the positive part of the biharmonic signal reaches the avoided crossing, as illustrated in Fig. 2(g). Depending on parameters, the waveform may drive the qubit through the avoided crossing up to four times per cycle, giving three interference phases. The phase accumulation and the interference conditions vary strongly with waveform shape, and this is the origin of the clear fluctuations in \( \Gamma \) around point III in Fig. 2(c). Coming back to the trajectories discussed in Figs. 1(d) and 1(e), we can interpret the fluctuations in \( \Gamma \) as interference from all possible paths generated by the scattering events. Note that the drive waveform is periodic in time, so the number of possible scattering events is not restricted to the four events discussed in Figs. 1(d) and 1(e). Rather, interference occurs between all trajectories that retain phase coherence, and the maximal number of paths is ultimately set by the coherence time of the qubit.

Figure 3(a) shows a magnification of the region around point III in Fig. 2(c). Despite involving only a few scattering events, the plot shows a rich interference pattern as a function of \( f_{dc} \) and \( \alpha \). To make the connection to charge transport in mesoscopic systems, we identify the qubit’s transition rate \( \Gamma \) with the electric conductance, whereas the time-symmetry breaking parameter \( \alpha \) corresponds to the magnetic field. We calculate the mean and the standard deviation of \( \Gamma \) by averaging over \( f_{dc} \) in the range \(-4 m\Phi_0 < f_{dc} < 0 m\Phi_0 \). Since the parameter \( f_{dc} \) controls the timing of the scattering events, this averaging effectively corresponds to averaging over different scattering configurations. In mesoscopic systems, the averaging over different scattering configurations is typically done by tuning a gate voltage or the in-plane magnetic field. We choose this particular drive protocol and implementation of scattering configurations because the transition rate averaged over detuning is expected to satisfy a sum rule \([17,18]\), and we can therefore directly attribute any deviations to the breaking of the time-reversal symmetry \([21]\).

Figures 3(b) and 3(c) show the average transition rate \( \langle \Gamma \rangle \) and the standard deviation of \( \Gamma \), respectively, as a function of drive waveform asymmetry. We note that \( \langle \Gamma \rangle \) is independent of \( \alpha \). This is in contrast to mesoscopic...
systems, which typically show a dip in the conductance due to weak localization in the presence of time-reversal symmetry. Weak localization is thus not present in our experiments. On the other hand, the sharp peak in the standard deviation of $\Gamma$ at $\alpha = 0$ [Fig. 3(c)] corresponds to the UCF peak of phase-coherent electron transport.

In Fig. 3, the scattering configuration is altered by tuning the static flux detuning $f_{dc}$. A different way of changing the configuration is to randomize the drive waveform; this is more closely related to the random, chaotic trajectories present in mesoscopic systems, but a drawback is that such randomization will not produce a clean interference pattern as the one shown in Fig. 3(a). For completeness, we have performed numerical simulations of the qubit transition rate with randomized drive waveforms, and we get a very similar sharp peak in the fluctuations of $\Gamma$ at $\alpha = 0$ (see Supplemental Material [22]).

The existence of UCF-like features without weak localization is related to the specific scattering configuration in our system. In mesoscopic electron transport, weak localization is dominated by the backscattering from time-reversed paths originating at the first scattering center of the incoming electrons. Looking at the sketches in Figs. 1(a) and 1(c), we notice that, in our few-scatterer setup, the first scattering center can scatter in both the forward and the backward directions. Constructive interference from time-reversed paths thus leads to enhanced scattering in both the backward and the forward directions, and the average transmission probability will not be affected. However, interference effects are still visible as an increase of fluctuations in the transmission probability. In mesoscopic systems, there are many more scatterers, and the incoming and outgoing leads are far enough separated that direct scattering from the first incoming scattering center to the outgoing lead becomes negligible.

So far, we have discussed only variations in $\Gamma$ due to the phase pickup between scattering events. Changing the drive waveform will also affect the transition probabilities of the individual Landau-Zener transitions, but we expect such variations to average out when measured over many configurations. This is consistent with the average transition rate being independent of $\alpha$, as seen in Fig. 3(c) and in Fig. 1(c) S1(c) in the Supplemental Material [22].

Measurements of weak localization and universal conductance fluctuations are normally used to determine coherence lengths in two-dimensional systems. For our driven qubit, where the interfering trajectories are in phase space rather than real space, we can employ the technique to investigate the coherence time $T_2 (= T_\phi)$ of the device. To this end, we have simulated the qubit’s transition rate numerically by using the same model as in Ref. [18] for different values of $T_2$ under the drive defined by Eq. (1). Figure 4(a) shows the result of such a simulation, with qubit parameters $\Delta/h = 19$ MHz ($h$ is Planck’s constant), $T_1 = 20$ $\mu$s, and $T_2 = 10$ ns, in striking agreement with the measured data in Fig. 3(a).

In Fig. 4(b), we plot the standard deviation of the transition rate, calculated by repeating the simulation for different values of $T_2$. The peak around zero asymmetry is very broad for small values of $T_2$ but becomes sharper and stronger as $T_2$ is increased. This is very similar to how features due to weak localization and UCF in mesoscopic systems depend on the coherence lengths. For long $T_2$, there are extra structures appearing in Fig. 4(b), away from the main peak at $\alpha = 0$, which are an effect of the small number of possible trajectories in our setup. In mesoscopic systems, the large number of scattering possibilities averages out such configuration-specific structures and leaves only broad features related to the breaking of time-reversal symmetry. We note that the simulations give good agreement with the data for $T_2 = 10–20$ ns, consistent with previous results [18].

In conclusion, we have investigated effects due to time-reversal symmetry in a driven two-level system where both the scattering events and the time-reversal symmetry are imposed by the driving protocol. This setup allows us to perform experiments in the regime of few scatterers, with a finite and controllable number of possible trajectories. We find that effects similar to universal conductance fluctuations, normally associated with chaotic systems with a large number of scattering events, persist even in the few-scatterer limit. In addition, our work shows an example of how a well-controlled, well-understood device like a qubit can be used to simulate more complex quantum systems.

[21] To obtain the average transition rate, we integrate the perturbative expression for the transition rate \( \Gamma = 2W \) in Ref. [18] over flux detuning: \( \langle \Gamma \rangle = (2\pi/2\Omega) \times \int_0^\infty df \frac{d\Gamma}{df} = (2\pi/2\Omega) \times \pi(\Delta/h)^2/2 \approx 0.15 \text{ Mrad/s} \). The normalization \( \Omega = 2m_0 |f_{\text{max}}| \) includes the slope of the lowest energy level, \( m_0 = dE_0/df_{\text{max}} = 1.44 \text{ GHz}/m\Phi_0 \), and \( f_{\text{max}} = -4 \text{ m}\Phi_0 \). The UCF \( \langle \Gamma^2 \rangle \) does not have a simple analytic form.
