ABSTRACT

Recent studies have shown that membrane-water partition coefficients of organic chemicals can be used to predict bioaccumulation and type I narcosis toxicity more accurately than the traditional $K_{OW}$-based approach. In this paper, we demonstrate how comprehensive two-dimensional gas chromatography (GC × GC) can be used to estimate such membrane-water partition coefficients ($K_{PLW}$s), focusing in particular on phosphatidyl choline based lipids. This method performed well for a set of 38 compounds, including polycyclic aromatic hydrocarbons, polychlorinated benzenes and biphenyls, and substituted benzenes including some phenols and anilines. The average difference between the estimated and the measured log $K_{PLW}$ values of 0.47 log units is smaller than in the case of a log $K_{OW}$ correlation approach but larger than seen using a polyparameter linear free energy relationship based approach. However, the GC × GC based method presents the advantage that it can be applied to mixtures of chemicals that are not completely identified, such as petroleum hydrocarbon mixtures. At the same time, our application of the GC × GC method suffered larger errors when applied to certain hydrogen bonding compounds due to the inability of the GC × GC capillary columns phases that we used to interact with analytes via hydrogen bond donation/electron acceptance.

Keywords Phospholipid-water partition coefficient ($K_{PLW}$), hydrophobic organic compounds (HOCs), comprehensive two-dimensional gas chromatography (GC × GC)
Color map of log $K_{PLW}$ values across the GC × GC retention space.
INTRODUCTION

The bioaccumulation potential of organic contaminants is a key factor in environmental risk assessment of hydrophobic organic chemicals (HOCs). Compounds, for which the rate of biotransformation is slow compared to uptake, tend to accumulate in the lipids of exposed organisms, as dictated by their lipid-water or lipid-air partition coefficients.\(^1\) One approach for calculating bioaccumulation relies on bioaccumulation/bioconcentration factors, obtained from linear free energy relationship correlations involving the n-octanol-water partition coefficient \((K_{OW})^2\). This approach assumes that the partition properties of all types of lipids are the same, although recent studies\(^3-4\) show that significant differences exist between the partitioning of chemicals into storage- versus membrane-lipids. In general, storage lipids consist of triacylglycerides (i.e., three aliphatic side-chains attached to a glycerol moiety). In contrast, membrane lipids are predominantly diacylglycerides (i.e., only two aliphatic side-chains attached to the glycerol unit), with a polar group attached at the third oxygen (Figure 1). This structural nature helps them form bilayers, a critical feature of biological membranes. For important environmental contaminants such as phenols, Sandermann et al.\(^3\) found that partitioning into storage lipids can be as much as a factor of ten lower than the partitioning into membrane lipids, whereas for dichlorodiphenyltrichloroethane (DDT), partitioning into storage lipids was a factor of ten higher than into membrane lipids. This could be explained, at least in part, by the fact that unlike the triacylglyceride storage lipids, the diacylglycerides have moieties that can function as electron density acceptors. Thus, in order to accurately predict bioaccumulation, both the phospholipid-water and triglyceride-water partition coefficients must be known. This is of particular importance in smaller organisms, such as plankton, in which the proportion of
membrane-to-storage lipids is larger\textsuperscript{3}. In addition, the correlation between the bioconcentration factor (BCF) and $K_{OW}$ has been shown to break down for certain classes of compounds, including highly hydrophobic HOCs ($\log K_{OW}$ greater than 6)\textsuperscript{5}, and recent studies suggest membrane-water partition coefficients are better predictors for BCF than $K_{OW}$\textsuperscript{6}.

The differential affinities of contaminants for the two different lipid classes are also relevant from a toxicological perspective. Membranes have been identified as the target site for nonspecific (or type I) narcosis toxicity\textsuperscript{7}. Therefore, by knowing the partition coefficient of a particular contaminant into membrane lipids, one can calculate its activity at the target site of toxicity and better evaluate the potential for toxic effects. Generally, such baseline toxicity has been obtained, similarly to BCFs, via a correlation against $K_{OW}$\textsuperscript{8}. However, Vaes et al.\textsuperscript{9} found that by using the membrane-water partition coefficient as a predictor instead of $K_{OW}$, (1) the relationship can be extended to a larger set of compounds, and (2) lethal body burdens (LBBs) can be better predicted by considering the differential partitioning into two separate lipid compartments.

Experimentally, determination of phospholipid-water partition coefficients ($K_{PLW}$) has largely focused on phosphatidyl cholines (PCs) with various side chains, as PCs readily form vesicles in water and because PCs are one of the most common components of membrane lipids in higher organisms\textsuperscript{10}. These coefficients have been measured for a wide range of organic compounds including known environmental contaminants such as polychlorinated biphenyls (PCB)\textsuperscript{4,6,12-13}, polycyclic aromatic hydrocarbons (PAHs)\textsuperscript{6,14-15}, chlorobenzenes (CBs)\textsuperscript{6,11,14-17}, and other compound classes\textsuperscript{17}. Unfortunately, for many compounds, there can be significant variability in the available data (e.g., $K_{PLW}$ for PCB congener #155 (2,2',4,4',6,6'-hexachlorobiphenyl) varies by more than two orders of magnitude between ref. 4 and ref. 12). This may be due to
experimental artifacts, but the data variation may also be caused by differences in the composition of aliphatic side chains or experimental temperatures that affect the phase of the lipids in question. At temperatures below the phase transition temperature (i.e., in the rigid gel phase), the aliphatic carbon atoms of the hydrophobic side chains reside primarily in the anti conformation; whereas above the phase transition temperature (i.e., in the liquid crystalline state), the gauche conformation becomes energetically favorable, leading to a more fluid, less well packed membrane. Thus, the ability of the liposome to accumulate contaminants is higher in the liquid crystalline phase than in the rigid gel phase. The value of the phase transition temperature is, in turn, affected by the nature of the lipid side chain, with smaller chains and higher degrees of unsaturation leading to lower transition temperatures.

In this study, we present a new method of estimating the $K_{PLW}$ values of organic chemicals based on their retention behavior on a comprehensive two-dimensional gas chromatography system (GC × GC). Current experimental determinations of $K_{PLW}$ values require phospholipid vesicles to be formed in a reproducible fashion, and incubation experiments to be performed in such a way to ensure liposome stability and enough time for equilibration of highly hydrophobic compounds. In addition, $K_{PLW}$ determinations are subject to variability due to exact nature of lipid and experimental temperature, as mentioned above. The method of estimating $K_{PLW}$ values proposed here bypasses such methodological difficulties, and it can be applied when dealing with compounds for which experimental analysis is difficult.

Furthermore, the GC × GC method can be used to evaluate the potential for baseline (type I) narcosis toxicity of mixtures of chemicals, such as those in petroleum, which are not completely identified. Several studies have shown that components of the unresolved complex mixtures associated with petroleum contamination, can cause baseline narcosis type I toxic effects in
invertebrates, but a method is still needed to evaluate this toxicity. The high separation power given by GC × GC, coupled with the ability to give values of $K_{PLW}$ for each of the mixture’s components, which can in turn help us calculate the concentration of narcosis pollutants at their site of action, makes this technique ideal for estimating the cumulative baseline narcosis toxicity of such a mixture. The focus of this paper will be obtaining the values of $K_{PLW}$ from a GC × GC chromatogram, while the application to mixture toxicity will be addressed in a subsequent paper.

**Background**

The advent of GC × GC has greatly improved our ability to separate and characterize components of complex organic mixtures; and recent studies show that with appropriate training sets, a range of physico-chemical properties can be estimated from the retention behaviors of the analytes including their vapor pressures, and octanol-water partition coefficients\(^\text{19}\). In GC × GC, the effluent from the first column is trapped, focused, and injected onto a second, shorter column at discrete time intervals. The stationary phase of the first dimension column is typically nonpolar (e.g., polydimethylsiloxane), resolving compounds based chiefly on their London dispersive interactions with the stationary phase (interactions dependent on a compound’s molecular volume and polarizability). In the second dimension column, due to the presence of the phenyl groups (stationary phase is 50% phenyl polysilphenylene-siloxane, Figure S1), additional intermolecular interactions are also possible, notably hydrogen bond acceptance/electron density donation by the stationary phase. The apolar nature of the stationary phase mimics the partitioning from gas phase to a lipid phase, whereas the monopolar nature of the second dimension reflects some of the interactions that govern the partitioning from gas phase to water. Since $K_{PLW}$ is a ratio of the lipid/gas and water/gas partition coefficients, then we
expect that log $K_{PLW}$ will be positively correlated with the first dimension retention time, and
negatively with respect to the second dimension. Mathematically this translates into a
relationship of the following form for the calculation of log $K_{PLW}$:

$$\log K_{PLW} = a \times RT_1 + b \times RT_2 + c$$

where $RT_1$ and $RT_2$ are the retention times of compound of interest in the first and second
dimension, respectively.

Determination of partition coefficients, such as log $K_{OW}$, has been previously done using high
pressure liquid chromatography and reverse phase column materials (HPLC). The advantage of
this technique over GC is the presence of an aqueous phase, which directly captures the behavior
of organic chemicals in water. However, in HPLC it takes a very long time to elute most
compounds with only water; and if one uses an organic co-solvent, one has to train the system to
correct for co-solvent effects. Also, compared to GC, LC is not as effective at separating
complex mixtures, thereby limiting one's ability to examine such real world exposures to
mixtures. Further, the detector response (e.g., absorbance or fluorescence) is not anywhere near
as constant from analyte to analyte in HPLC as that seen with a flame ionization detector (FID);
thus HPLC detectors do not allow as dependable a simultaneous quantification of mixture
components as the FID when examining mixtures such as those in petroleum hydrocarbons.
Such contaminant quantification, when combined with key physical chemical properties like
$K_{PLW}$ values of each eluting peak, should allow eventual estimation of integrated membrane
doses from mixtures (the long range goal of our work).

MATERIALS AND METHODS
Preparation of solutions. Most of the compounds used in the training sets were purchased as mixtures or individual compounds from Ultra Scientific, Inc. with the exception of the several benzene derivatives which were purchased as individual compounds from Sigma-Aldrich Co. Neat compounds were dissolved in dichloromethane and stock solutions were diluted to appropriate levels for GC × GC – FID analysis (~1-10 ng/μL).

Selection of training set compounds. We selected known environmental contaminants such as PCBs, PAHs, chlorobenzenes (CBs), as well as several structurally diverse benzene derivatives like phenols, anilines and nitroaromatics previously found to cause narcosis. We chose the values of $K_{PLW}$ for which the experiments were performed at temperatures at which the liposomes were in the liquid crystalline phase, since biological membranes are mostly found in this state at environmental conditions (for example, transition phase temperature of egg phosphatidyl choline is -10±5 °C). Additionally, in the liquid crystalline phase, the $K_{PLW}$ dependence with temperature is small, on the order of 0.1-0.2 log units per 10 °C, whereas a sharp change in partition behavior occurs below the transition phase temperature (e.g., for chlorobenzene there is a 1.6 log units difference in $K_{PLW}$ between the two lipid states). After critically reviewing the available data (see Supplemental Information-1, Table S2) and checking it for consistency, we obtained the training set displayed in Table 1. The average log $K_{PLW}$ was used when multiple $K_{PLW}$ values were available from different experimental setups. The regression of log $K_{PLW}$ values against the two retention times (Eq. 1) was performed using the Data Analysis regression feature in Microsoft Excel 2004.

Analysis by GC × GC. GC × GC analyses were performed on an Agilent 7890A gas chromatograph, equipped with a 7683 split/splitless injector, two capillary gas chromatography columns, a quad jet modulator (LECO Corporation, St Joseph, MI), and flame ionization detector.
(FID). The samples were injected in splitless mode. The inlet temperature was set at 300 °C and the purge valve was opened after 1 min. The carrier gas used was H₂, set at a flow rate of 1 mL/min throughout the run. Using sequential pentane injections at 10 minute intervals, we determined that the breakthrough time through the second dimension column decreased by ~30% throughout the run (from 1.710 seconds to 1.150 seconds), which indicates that the flow rate in fact speeds up throughout the run. First dimension separations were performed using a 100% dimethylpolysiloxane capillary column (Restek, RTX-1, 0.25 mm inner diameter, 0.24 μm film thickness, 27.5 m length), which was ramped from 40 °C (0.5 min hold), to 333 °C at 4.92 °C/min. Compounds exiting the first column were cryogenically trapped and re-injected (modulated) onto the second column at 6 s intervals, via the quad jet modulator. The cold jet was dry liquid N₂. The hot jet was set at 40 °C above the temperature of the first dimension oven. The second column was a 50% phenyl polysilphenylene-siloxane capillary column (SGE BPX-50, 0.10 mm ID, 0.25 μm thickness, 1.5 m length), and it was programmed from 55 °C (0.5 min hold) and ramped to 348 °C at 4.92 °C/min, which maintained a constant offset of 15 °C between the two columns throughout the run. The FID was set at 330 °C and sampled at 100 Hz. This relatively fast temperature program sacrificed part of the separation power, but a wide range of compounds (n-C₈ to n-C₃₄ alkanes in the first dimension) were eluted in a time efficient manner, suited to processing large sample sets as well as complex mixtures such as spilled petroleum. The variability of the GC × GC retention times from run to run was very small (variations of less than 0.01 min in the first dimension and of less than 0.03 s in the second dimension observed throughout all the runs).

RESULTS
In order to test the validity of the GC × GC setup used, we first performed a regression of log $K_{OW}$ against the two retention times. Based on the work done by Arey et al., GC × GC retention indices allow one to estimate log $K_{OW}$ with a standard error of about 0.2 log units, using the same two stationary phases as the ones used in this study. However, we wanted to observe the consequences of using retention times instead of retention indices used by Arey et al. We found that for a comparable training set (Figure S2, Table S1), consisting of only apolar and monopolar compounds (PAHs, PCBs and CBs), there was a good correlation between log $K_{OW}$ and retention times:

$$\log K_{OW} = (0.165\pm0.006)\times RT_1 + (-1.33\pm0.09)\times RT_2 + (3.32\pm0.16)$$ (2)

As shown by Arey et al., retention indices can be reproduced by using two different instrument setups: different column lengths, temperature ramps and gas flows, but that would not be the case for retention times. Thus, we can obtain comparable results by using retention times instead of indices, with the downside that we would have to retrain the relationship if the instrument or the setup (e.g., column lengths or carrier flows) is changed. However, the task of retraining only involves running a set of standard mixtures and performing the two dimensional regression. In contrast, the calculation of retention indices of Arey et al. is significantly more involved mathematically, and requires GC × GC-specific parameters as inputs, such as hold up times or phase ratios of the columns.

The set of compounds used to assess our ability to find a relationship between $K_{PLW}$ and retention times included six PCBs, 13 PAHs, nine CBs and 10 benzene derivatives including...
phenols, nitroaromatic compounds, and anilines (Table 1). The regression using the reported $K_{PLW}$ values of this training set and the GC $\times$ GC retention times was quite good:

$$
\log K_{PLW} = (0.208\pm0.010)\cdot RT_1 + (-1.42\pm0.16)\cdot RT_2 + (2.50\pm0.22)
$$

(3)

$N=38, R^2 = 0.953, SE = 0.45$

The statistics of this regression are clearly better (smaller standard error, and larger $R^2$) than if we use only the first dimension retention times. This can be seen by using the first retention times ($RT_1$ values) of our training set of compounds to find a fit as if we had used a one dimensional GC equipped with the same capillary column as the first dimension of the GC $\times$ GC, and operated in similar flow and temperature program conditions:

$$
\log K_{PLW} = (0.127\pm0.009)\cdot RT_1 + (1.22\pm0.30)
$$

(4)

$N=38, R^2 = 0.843, SE = 0.80$

To evaluate the effectiveness of the GC $\times$ GC-deduced correlation (Eq 3), we re-fit the relationship (Eq. 1) withholding one of the 38 compounds and predicted the log $K_{PLW}$ of the 38$^{th}$ compound, and we repeated this procedure for each compound in our training set. The predicted log $K_{PLW}$ values (Table 1, Figure 2A) had an average deviation from the measured value of 0.47 or a factor of 3 in the $K_{PLW}$ (calculated as the square root of the sum of square deviations divided by number of observations minus 1). We noted that four of the divergent compounds were chlorinated benzenes which were all estimated too low, while three were hydrogen bonding compounds which were all overestimated ($N,N$-dimethylaniline, quinoline, $n$-pentylphenol).

Suspecting that this bias may arise by inclusion of the polar compounds, we refit Eq. 1 excluding these seven compounds and found:

$$
\log K_{PLW} = (0.170\pm0.010)\cdot RT_1 + (-0.984\pm0.146)\cdot RT_2 + (2.71\pm0.16)
$$

(5)

$N=29, R^2 = 0.969, SE = 0.30$
The expression greatly reduced the chlorobenzene's deviations from measured values (error now near 0.2 log unit) at the cost of no longer accurately estimating the polar compounds (error now near 1 log unit).

DISCUSSION

Comparison of GC × GC Method Versus ppLFER and log \( K_{OW} \) Approaches

Two other approaches have commonly been used to estimate \( K_{PLW} \) values. The first involves a correlation with octanol-water partition coefficients and the second entails use of a polyparameter linear free energy relationship (ppLFER). To ascertain the relative accuracy of our new GC × GC approach, we contrasted estimates made in this way with those derived from these other methods. In each case, the \( K_{PLW} \) estimation method was applied, when possible to all the compounds in our GC × GC training set, and an average deviation between the estimated and the measured value of \( K_{PLW} \) was calculated as the square root of the sum of squared deviations divided by number of observations minus 1.

First, we compared the performance of the GC × GC-based method of estimating \( K_{PLW} \) to a linear free energy relationship (LFER) approach based on log \( K_{OW} \). While many such relationships are available in the literature, we chose to use the one of Endo et al.\(^{13} \) because it was developed using the largest number of compounds (log \( K_{PLW} = 1.01 \log K_{OW} + 0.12; N=156, \ SE=0.426, R^2=0.948, \) Table 1). This method of estimating \( K_{PLW} \) showed larger deviations than the GC × GC method (average deviation between estimated and measured log \( K_{PLW} \) of 0.58 vs 0.47). Also the approach using log \( K_{OW} \) increasingly underestimated log \( K_{PLW} \) values for the highly hydrophobic PAHs, while the GC × GC method did not do so (Figure 2A vs. 2B).
addition, the $K_{\text{OW}}$-based method depends on the availability of accurate $K_{\text{OW}}$ values, which for PCBs for example can vary substantially in the literature\textsuperscript{20}.

We also compared the GC × GC-based method with results obtained using a polyparameter solvation model. In the polyparameter solvation model\textsuperscript{21}, the partitioning between two media (log $K$), such as water and phospholipids, can be described in terms of five dimensions of solute-solvent interactions using a relationship of the form:

$$
\log K = e^*E + s^*S + a^*A + b^*B + v^*V + c
$$

The capital letters refer to the solute parameters: $E$ (excess molar refraction and hence polarizability), $S$ (polarity), $A$ (hydrogen bond acidity), $B$ (hydrogen bond basicity), $V$ (solute size) and the small letters reflect the differential interactions of the solutes in the two partitioning phases. Previous investigations\textsuperscript{13} found that the best-fit interaction coefficients for phospholipid/water, olive oil/water and octanol/water partitioning systems have similar signs and magnitudes implying that the same intermolecular interactions govern partitioning in these systems (Table 2).

We applied the polyparameter equation developed for log $K_{\text{PLW}}$ ppLFER by Endo et al.\textsuperscript{13} to all the compounds in our training set (Table 1, Figure 2C) with the exception of 4-$n$-pentylphenol and 2-allylphenol for which solute descriptors were not found in the literature. When we do this, for these 36 compounds, we find an average deviation between the estimated and the measured log $K_{\text{PLW}}$ of 0.38. This is lower than the average deviation of 0.46 obtained when the GC × GC-based method is used, for the same 36 compounds. The polyparameter model is especially able to better characterize the phenols, anilines, and nitroaromatic compounds (average deviation across the miscellaneous group of compounds of 0.23 compared to 0.59 in GC × GC approach).

This is understandable because the polyparameter model takes into account a wider range of
intermolecular interactions, such as the ability of compounds to donate electrons/accept hydrogens, while the stationary phases used in the GC × GC setup do not capture these interactions (Table 2).

This limitation is apparent when one applies the ppLFER approach to explain partitioning behavior in GC systems. For the stationary phases we used, best fit ppLFER coefficients have been determined\textsuperscript{22} (Table 2), and these show similar \( l \) coefficient values reflecting similar London interactions for both stationary phases, but increased \( e \), \( s \), and especially \( a \) coefficients for the 50\% phenyl phase of the second dimension column. However, what is most noteworthy is that for both of our stationary phases, \( b \) is zero (neither of the two stationary phases can donate hydrogens for H-bonding) and this is the case for all commercially available stationary phases at this time. But for phospholipid-water partitioning, \( b \) is nonzero and negative, as this term reflects the differential ability of water and phospholipids to donate protons/accept electrons to/from the compounds of interest. We note however, that even with a stationary phase that is able to function as an H-donor, there will still be some limitations. We would not be able to apply this GC × GC method to compounds that decompose when heated to GC temperatures, nor to compounds whose boiling points are a lot higher than the maximum operating temperature of the stationary phases.

However, both the polyparameter model as well as the GC × GC based method should be able to characterize equally well hydrophobic compounds like PCBs and PAHs. When applied to the PCBs in our training set, the polyparameter equation (c) in Table 2 estimated log \( K_{\text{PLW}} \) with an average deviation of 0.79 log units. In comparison, the average deviation obtained for the \( K_{\text{PLW}} \) of PCBs via the GC × GC method was 0.42. One possible reason for this discrepancy may be the differences in the training sets. Interestingly, for the PCBs used in our training set and
measured by Jabusch and Swackhamer\textsuperscript{4}, there is an average difference of 0.8 log units between the experimental value of log $K_{PLW}$ and the polyparameter model prediction, with the experimental value always being higher. In comparison, Endo et al.\textsuperscript{13} used a different PCB data set in developing their polyparameter model and thus, the differences between the two estimation methods appear to stem from the large variability in the available data on $K_{PLW}$ values of PCBs. As with other partition constants, such as $K_{OW}$, the $K_{PLW}$ values for highly hydrophobic compounds like PCBs are difficult to measure due to low solubilities and long equilibration times.

\textit{Limitations of the GC × GC-Based Method}

With our current choice of stationary phases in the GC × GC, we expected that we would not be able to characterize compounds with a strong electron donating (H$^+$ accepting) character as reflected in the polyparameter $bB$ term. Neither of the two stationary phases can donate hydrogens (Table 2); yet, the correlation is able to predict compounds like PAHs (error 0.28), and PCBs (error 0.42) with non-zero $B$ character, as well as some of the miscellaneous compounds (error 0.59), such as aromatic amines. One explanation could be that the contribution of the $bB$ character to the partitioning into phospholipids is minor compared to the contributions of the other interactions. This applies to PCBs for which $B$ ranges from 0.02 to 0.20\textsuperscript{23} rendering a maximum contribution of 0.8 log units to the value of log $K_{PLW}$. The second possible explanation is that the $B$ character correlates with another descriptor, such as $E$ or $S$, which is true for PAHs (Figure S3). Arey at el.\textsuperscript{19} reached a similar conclusion when trying to investigate which kind of information can be provided from the retention behavior of diesel hydrocarbons on the same stationary phases, as used in this study. Lastly, the compounds that
exhibit large $B$ values that do not correlate with either of the other descriptors, should reflect
large errors in $\log K_{PLW}$. This is true for some of the miscellaneous compounds such as
quinoline (Figure S3). In order to reduce the errors associated with our method, we would need
to employ better stationary phases, which could capture compounds with hydrogen-accepting
character, but such GC phases are not currently available.

Applications of the GC × GC-Based Method: Estimating $K_{PLW}$ values for New Compounds

We applied this method to the prediction of $K_{PLW}$ for a set of PCBs and organochlorine
pesticides (OCPs) for which, to our knowledge, there are no available experimental data on
$K_{PLW}$. We compared our estimate against the polyparameter model of Endo et al.\textsuperscript{13} (Figure 3 and
Table S3). For PCBs, the two methods agree only up to $\log K_{PLW}$ of around 6. Beyond that, the
GC × GC method predicts consistently larger values than the polyparameter method, leading to
an overall positive bias. This could be explained by the inability of the stationary phases to
capture the hydrogen bond donation interaction, which has a negative contribution to $\log K_{PLW}$ or
by the difference in training sets mentioned earlier. A similar trend is observed for the
organochlorine pesticides (Table S3), with the exception of a group of OCPs (heptachlor
epoxide, methoxychlor, dieldrin, eldrin and endosulfan) which all contain one or more oxygen
atoms. For these, the differences between the two predictive methods are on average 2.6 log
units, most likely due to their pronounced hydrogen-bond accepting character ($B$ terms larger
than of all the compounds in the GC × GC training set).

Based on the results presented here, and the discussion on the limitation of the GC × GC
method, we believe that this method can be accurately applied to compound classes such as
petroleum hydrocarbons, PAHs, PCBs and CBs, that is, hydrophobic chemicals commonly
assessed for their likely impacts via type I narcosis toxicity. Larger errors are expected when this
method is applied to compounds which can accept hydrogen bonds (based on our training set, compounds with $B$ values greater than 0.4 tend to have deviations between the estimated and the measured log $K_{PLW}$ greater than 0.5 log units). However, we note that the method may still work for $B$ values greater than 0.4, if the $B$ character is correlated with another descriptor (for example PAHs have $B$ values greater than 0.4, but there is a correlation within the PAH family between the $E$ and $B$ descriptors, as shown also in Figure 3S).

Applications of the $GC \times GC$-Based Method: Estimating Baseline Narcosis Risks

The $GC \times GC$ method of estimating $K_{PLW}$ values can also be applied to calculations of baseline (type I) narcosis toxicity of mixtures, e.g. petroleum hydrocarbon mixtures. For calculating baseline (type I) narcosis toxicity, we rely on two assumptions. First, we assume that all the components of the mixture partition independently into the membrane, contributing in an additive fashion to a type I narcosis effect$^{24}$. Secondly, we assume that all the analytes quantified in the $GC \times GC$ run have virtually the same flame ionization detector (FID) response factor. Consequently, one could start with the $GC \times GC$ chromatogram of a passive sampler extract in which the concentration of each peak/compound can be calculated using the relatively constant response factor of the FID. In addition, at each point in the $GC \times GC$ space, one can calculate the value of the $K_{PLW}$ and the passive sampler-water partition coefficient by using equations such as Eq. 1. The integrated dose of contaminants inside the membrane lipid then becomes a sum across the entire $GC \times GC$ space of all the calculated lipid concentrations of individual compounds. As opposed to other narcosis lipid models, such as the one proposed by McGrath et al.$^{25}$, this approach would have the advantage that it does not require the identification of each single compound, nor specific knowledge about their effect concentrations (i.e. the concentration required to produce a narcosis effect in 50% of the test organisms).
Applications of the GC × GC-Based Method: Estimating Bioaccumulation of Mixtures

For calculations of bioaccumulation, one would additionally require information about the proportion of storage versus membrane lipids, and the value of the partition constant between the triglycerides and water ($K_{TGW}$) at each point in the chromatogram. The values of $K_{TGW}$ could be calculated with a relationship of the form of Eq 1, after running an appropriate training set of compounds with known $K_{TGW}$ values on the GC × GC, and finding the corresponding ppLFER regression coefficients. Then, assuming equilibrium with the environment, one could calculate the concentration of pollutants in each lipid compartment. One limitation of calculating bioaccumulation with this approach is that it would not apply to substances that are biotransformed at rates comparable to, or faster than, biouptake equilibration.

In this present study, we have shown that GC × GC retention behavior can be used to predict $K_{PLW}$ for a series of chemicals within about a factor of 3. The results of the GC × GC-based method compared well with those from two other $K_{PLW}$ prediction methods: a polyparameter LFER model and a log $K_{OW}$-based LFER. The practical advantages of predicting $K_{PLW}$ from GC × GC retention behavior are (1) that it can be used to estimate $K_{PLW}$ for compounds where experimental manipulations and analysis might be difficult, (for example hydrophobic PCBs with long equilibration timescales, like those in our training set and Figure 3) and (2) that it can be applied to mixtures of hydrophobic chemicals that are likely to cause baseline narcosis toxicity (e.g. petroleum hydrocarbon mixtures), and for which separation, and partitioning characterization of all the individual components might not be feasible. Compared to other methods of estimating partition coefficients, such as Arey et al.\textsuperscript{19}, we have shown that GC × GC can be used for other compounds beyond hydrocarbons, such as PCBs, CBs and some weak hydrogen bonding compounds, with the practical added simplification of using retention times
instead of retention indices. Even though the relationship presented here between log $K_{PLW}$ and retention behavior is valid only for the particular GC × GC setup used in this study, the method is easily transferable to other GC × GC systems, as it simply involves (a) running an HOC training set on the system in use at the site, and (b) performing a simple regression on reported $K_{PLW}$ values and the GC × GC retention times.

ACKNOWLEDGMENT

This publication is the result of research sponsored by The MIT Sea Grant College Program, under NOAA grant number NA06OAR4170019, project number 2008-R/RC-109. We also acknowledge funding from CICEET, the Cooperative Institute for Coastal and Estuarine Environmental Technology (award number 015553-001). The authors also acknowledge R. Scott Carr and Marion Nipper for their help with sample collection and useful discussions, and David Griffith for comments on the manuscript.

\(^a\)log \( K = c + e*E + s*S + a*A + b*B + l*L \), the capital letters refer to descriptors of the compounds, previously explained in the text, with the exception of \( L \) which is the log of solute gas-liquid distribution constant on hexadecane at 298 K (also known as Ostwald solubility coefficient).

\(^b\)adapted from ref. 13 to be in the same set of parameters as the pp-LFERs of the two stationary phases.

\(^c\)log \( K = c + e*E + s*S + a*A + b*B + v*V \).
Figure 1. Examples of (left) a triglyceride storage lipid, tripalmitin (C_{51}H_{98}O_{6}, MW 807.34 g/mol), and (right) a membrane phospholipid, dipalmitophosphatidyl choline (DPPC, C_{40}H_{80}NO_{8}P, MW 734.04 g/mol).
Figure 2. Comparison of log $K_{PLW}$ predicted from GC × GC (panel A), using $\log K_{PLW}=1.01 \log K_{OW} + 0.12$ (ref. 13, Panel B), and polyparameter model$^{13}$ (panel C). Symbols represent compound classes: PCBs (diamonds), CBs (triangles), PAHs (square), and miscellaneous (crosses). Also displayed in each panel is the 1:1 line.
Figure 3. Comparison of $K_{PL,W}$ predicted from GC × GC and polyparameter model\textsuperscript{15}. Symbols represent compound classes: PCB (diamonds), OCP (squares), oxygenated-OCP (crosses). Also displayed is the 1:1 line.
