Aggregation of misfolded proteins is characteristic of a number of neurodegenerative diseases, including Huntington disease (HD). The CCT/TRiC (chaperonin containing TCP-1/TCP-1 ring) chaperonin complex can inhibit aggregation and cellular toxicity induced by expanded repeat Huntington (mHtt) fragments. The substrate-binding apical domain of CCT/TRiC subunit CCT1, ApiCCT1, is sufficient to inhibit aggregation of expanded repeat mHtt fragments in vitro, providing therapeutic promise for HD. However, a key hurdle in considering ApiCCT1 as a potential treatment is in delivery. Because ApiCCT1 has a region of similarity to the HIV Tat protein cell-transduction domain, we tested whether recombinant ApiCCT1 (ApiCCT1) protein could enter cells following exogenous delivery and modulate an established panel of mHtt-mediated cell-based phenotypes. Cell fractionation studies demonstrate that exogenous ApiCCT1 can penetrate cell membranes and can localize to the nucleus, consistent with a strategy that can target both cytosolic and nuclear pathogenic events in HD. ApiCCT1, application does indeed modulate HD cellular phenotypes by decreasing formation of visible inclusions, fibrillar oligomers, and insoluble mHtt derived from expression of a truncated mHtt exon 1 fragment. ApiCCT1, also delays the onset of inclusion body formation as visualized by live imaging. ApiCCT1, reduces mHtt-mediated toxicity in immortalized striatal cells derived from full-length knock-in HD mice, suggesting that therapeutic benefit may extend beyond effects on aggregation. These studies provide the basis for a potentially robust and unique therapeutic strategy to target mHtt-mediated protein pathogenesis.

Huntington disease (HD) is a devastating neurodegenerative disorder that strikes in midlife and is characterized by movement abnormalities, psychiatric symptoms, and cognitive deficits, as well as by the accumulation of pathogenic proteins and peptides (1–3). Currently no disease-modifying therapy is available. The disease is caused by an abnormal CAG repeat expansion in the HD gene, leading to the production of an expanded polyglutamine repeat in the amino terminal domain of the Huntington protein (Htt) (2, 3). A hallmark of HD is the propensity for the mutant protein (mHtt) to misfold and aggregate (1). While the connection between large fibrillar deposits and neurodegeneration is not clear, accumulation and aggregation of mHtt is likely to result from a deficit in cellular quality control machinery and can be used as a surrogate outcome measure for disease progression.

Molecular chaperones, which are colocalized within mHtt inclusion bodies, suppress neurodegeneration in several animal models of protein misfolding diseases, including HD (4–7). For instance, overexpression of Hsp70 and Hsp40 suppresses neurodegeneration in animal models of polyglutamine diseases (8, 9). In parallel, deletion of Hsp70 markedly worsens pathogenesis in a mouse model of HD (10). Chaperones are thought to suppress the toxicity of disease-associated proteins through direct effects on their misfolding and clearance; however, the mechanisms are not well understood.

The 1MDa CCT/TRiC (TCP1-ring complex) chaperonin is an ATP-dependent, ring-shaped hetero-oligomeric chaperone that slows and folds newly translated polypeptides (11). A genome-wide RNAi screen in Caenorhabditis elegans identified six of the eight subunits of CCT (1, 2, 4–7) as suppressors of polyglutamine aggregation (12). CCT/TRiC expression also prevents mHtt aggregation in cell and yeast models of HD (13–16). Further, overexpression of one subunit of the TRiC/CCT complex, CCT1, is sufficient to inhibit aggregation and reduce mHtt-mediated toxicity in mouse N2a neuronal cells (15). CCT/TRiC also can suppress aggregation in vitro, using purified components (15). Reduction to just the 20 kDa substrate-binding apical domain of yeast CCT1 (ApiCCT1) inhibits aggregation of recombinant mHtt in vitro, potentially through its ability to bind to the N-terminal 17 amino acid domain of Htt. This domain is involved in multiple Htt functions and in aggregation kinetics of mHtt (15). However, the efficacy of this apical domain has not yet been tested in HD cell models.

Given the potential of ApiCCT1 as a therapeutic for the treatment of HD, we tested if recombinant yeast ApiCCT1 (ApiCCT1) protein could alter the aggregation and neurotoxicity of mHtt in selected proof-of-concept assays when purified protein was directly added to the culture media of cellular models of HD. We hypothesized that ApiCCT1 could be directly taken up by cells given the potential similarity of a positively charged region in ApiCCT1 to the protein transduction domain of the HIV protein Tat. We establish here that exogenously delivered ApiCCT1 can penetrate cell membranes, supporting the idea that ApiCCT1 has potential therapeutic application without necessitating intracellular expression. Of note, ApiCCT1 can cofractionate with nuclear fractions, which is significant in the context of nuclear accumulation and toxicity mediated by mHtt (1, 12, 17, 18). Application of just the apical domain of recombinant yeast CCT1 to rat pheochromocytoma-derived PC12 cells stably expressing truncated mutant Htt exon 1 protein (mHttex1p) (14A2.6 cells) decreased the formation of oligomeric and insoluble mHtt and slowed the kinetics of inclusion body formation in 14A2.6 cells. Finally, ApiCCT1 rescued mHtt-mediated toxicity in mouse striatal STHdhQ109/HdhQ109 cells derived from a knock-in mouse model of HD. Together these results provide a rationale for further development of ApiCCT1 as a therapeutic strategy for HD.

for future testing of extracellular infusion of ApiCCT1, or cell-based delivery of secreted forms of ApiCCT1 to ameliorate HD phenotypes in vivo.

Results

Purified ApiCCT1, Is Taken Up by Cells Following Exogenous Delivery. Chaperones target proteins, homeostasial cellular processes and have significant potential to modulate the protein misfolding and accumulation that appears key to many neurodegenerative diseases (19). Previous in vitro results suggest that expression of ApiCCT1 in neurons might reduce the misfolding and accumulation of mHtt. However, extensive molecular manipulations would be required for intracellular expression of ApiCCT1 in cells in the brain; therefore, strategies to deliver ApiCCT1 extracellularly and be taken up by cells could be highly beneficial (Fig. L4). It is a well-established phenomenon that some exogenously delivered proteins, specifically cell-penetrating peptides (CPPs), can cross membranes to enter cells and even nuclei (20, 21). There are no specific primary sequences common to all CPPs; however, many have a high abundance of positively charged amino acids or an alternating pattern of charged and hydrophobic residues (22, 23). This includes one of the first and most highly studied CPPs, the transactivator of transcription (TAT) protein of HIV (20, 21). To evaluate the possibility of directly introducing ApiCCT1 into cells expressing mHtt, we compared the sequence of yeast ApiCCT1, and TAT. Fortuitously, we find that ApiCCT1 does contain a region with a similar abundance of positively charged amino acids (Fig. 1B), providing a rationale to test exogenous application of ApiCCT1.

To test the hypothesis that ApiCCT1 can enter cells, a biochemical approach was used to determine whether ApiCCT1 cofractionated with cytosolic or nuclear cellular fractions. ApiCCT1 was added to the media of PC12 cells, Htt14A2.6, that inducibly express a truncated form of expanded repeat Htt exon 1 protein fused at the C terminus to enhanced green fluorescent protein (EGFP) (24), and cell fractions performed. 14A2.6 cells induced with Ponasterone A were simultaneously treated with a single application of 1 μM ApiCCT1, for 48 h. Before lysis, cells were treated with 90 μg/mL proteinase K (PK) to digest any extracellular protein associated with the cell surface. Following lysis, the total extract (T) was fractionated into cytoplasmic (C) and nuclear (N) fractions. Intact nuclei were again treated with PK before lysis to remove any proteins bound to the exterior of the nuclear membrane. All fractions were analyzed by SDS-PAGE followed by Western analysis (Fig. 1C). Blots were probed with anti-His antibody (ApiCCT1), anti-GAPDH (cytoplasmic marker), anti-p84 (nuclear marker), and anti-EGFP (mHtt). As expected, the majority of the ApiCCT1, remains in the media and a significant fraction appears trapped in the cell membrane as ApiCCT1 levels are lower upon PK treatment. This finding precluded analysis of cellular localization by immunofluorescence using available antibodies. However, ApiCCT1 is clearly visible in the PK-treated sample, indicating that theApiCCT1 does enter cells (red box). Moreover, ApiCCT1 appears to localize within both the cytosolic and nuclear fractions, suggesting the availability of ApiCCT1 to act in both compartments. Although levels of ApiCCT1 appear to be higher in nuclear versus cytoplasmic fractions, this may be due to the fact that ApiCCT1 makes up a smaller percentage of the total protein in the cytoplasm. To ensure that the ApiCCT1, was not bound to aggregated mHtt or trapped within aggregates, the experiment was repeated using uninduced cells, where mHtt aggregates are absent. ApiCCT1 is still found within the cytoplasm and nuclei of these cells (Fig. S1), indicating that the entry of ApiCCT1 into cells is independent of the presence of mHtt aggregates.

Exogenous Delivery of ApiCCT1, Reduces Multiple Aggregation Species in PC12 Cells Stably Expressing Truncated HttEx1p. To evaluate the therapeutic potential of exogenous delivery of ApiCCT1, a panel of established cell-based assays was used to monitor effects on specific aggregation species and cellular toxicity. We first tested whether ApiCCT1 could modulate visible inclusion formation, which is a highly utilized first assessment of altered aggregation. Exogenous delivery to 14A2.6 cells significantly decreased the number of visible inclusions following induction and ApiCCT1 application (one-way ANOVA: F = 3.933, P = 0.0037; Dunn’s multiple comparison test: 0 μM vs. 0.5 μM, P < 0.05; 0 μM vs. 1 μM, P < 0.01; and 0 μM vs. 2.5 μM, P < 0.05) (Fig. 2A and B). To determine whether this reduction is accompanied by a concomitant increase in monomeric, soluble Htt, Htt monomer levels from the same experiments were examined by Western analysis. ApiCCT1 does not appear to alter monomer levels (one-way ANOVA: F = 0.1908, P = 0.9604) or expression levels (Fig. 2 C and D and qPCR), suggesting that ApiCCT1 does not interfere with Htt expression and does not alter the steady-state levels of monomeric mHtt and no obvious differences in cell numbers following ApiCCT1 delivery, were observed.

Insoluble Htt aggregates and mHtt oligomers are hallmarks of HD (1, 17, 25). In particular, oligomeric mHtt species are thought
to be a major source of toxicity in affected neurons (25). Accordingly, mHtt oligomers and insoluble Htt species were next evaluated to determine whether exogenous delivery of ApiCCT1 reduces mHtt-mediated toxicity in a knock-in cell model of HD. Protein homeostasis mechanisms and protein accumulation is impacted in HD and other neurodegenerative diseases and targeted modulation of the chaperone network has been considered an attractive therapeutic target (19). Previous studies demonstrated that overexpression of CCT1 can alter HD phenotypes in cell models of HD and that the apical subunit of yeast CCT1 (ApiCCT1) alone interacts with recombinant mHtt in vitro and inhibits aggregation (15, 16). Therefore, if exogenous delivery of ApiCCT1 to cells could modulate intracellular aggregation and toxicity, striatal STHdhQ109/HdhQ109 cells were used. These are striatal progenitor cells immortalized by a knock-in mouse model of expanded polyglutamines (30) and expressing full-length mHtt within the endogenous mouse locus. Upon temperature shift and serum withdrawal, mHtt lines show decreased viability and increased cell death compared with the same cells at time 0 immediately before this shift (31). This control is used instead of comparing to a line expressing wild-type HTT due to clonal variability between lines. Cell viability was measured using an XTT (sodium 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-(phenylamino)-carbonyl]-2H-tetrazolium inner salt) colorimetric cell proliferation assay to detect altered cellular metabolic activities. Results are presented as percent relative to cells not treated with ApiCCT1, following shift to nonpermissive conditions. Exogenous delivery of ApiCCT1 reduced mHtt-mediated toxicity in STHdhQ109/HdhQ109 cells, depicted graphically as an increase in cell viability following shift to nonpermissive conditions. Interestingly, this effect persists after 48 h, suggesting that the exogenous ApiCCT1 may have a sustained effect on cell survival.

**Discussion**

Protein homeostasis mechanisms and protein accumulation is impacted in HD and other neurodegenerative diseases and targeted modulation of the chaperone network has been considered an attractive therapeutic target (19). Previous studies demonstrated that overexpression of CCT1 can alter HD phenotypes in cell models of HD and that the apical subunit of yeast CCT1 (ApiCCT1) alone interacts with recombinant mHtt in vitro and inhibits aggregation (15, 16). Therefore, if exogenous delivery of ApiCCT1 to cells could modulate intracellular aggregation and toxicity, striatal STHdhQ109/HdhQ109 cells were used. These are striatal progenitor cells immortalized by a temperature-sensitive large T antigen, derived from a knock-in mouse model of expanded polyglutamines (30) and expressing full-length mHtt within the endogenous mouse locus. Upon temperature shift and serum withdrawal, mHtt lines show decreased viability and increased cell death compared with the same cells at time 0 immediately before this shift (31). This control is used instead of comparing to a line expressing wild-type HTT due to clonal variability between lines. Cell viability was measured using an XTT (sodium 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-(phenylamino)-carbonyl]-2H-tetrazolium inner salt) colorimetric cell proliferation assay to detect altered cellular metabolic activities. Results are presented as percent relative to cells not treated with ApiCCT1, following shift to nonpermissive conditions. Exogenous delivery of ApiCCT1 reduced mHtt-mediated toxicity in STHdhQ109/HdhQ109 cells, depicted graphically as an increase in cell viability following shift to nonpermissive conditions. Interestingly, this effect persists after 48 h, suggesting that the exogenous ApiCCT1 may have a sustained effect on cell survival.

**ApiCCT1, Delays Inclusion Body Formation in 14A2.6 Cells.** To investigate whether kinetics of aggregation could be affected, a live-cell imaging assay system was used to determine whether altered kinetics is observed, specifically targeting the lag phase in inclusion formation (28). Strikingly, ApiCCT1 delays the formation of visible inclusions in the 14A2.6 cells (one-way ANOVA: F = 4.548, P = 0.0047; Dunnett’s multiple comparison test: 0 μM vs. 0.5 μM, P < 0.05; 0 μM vs. 1 μM, P < 0.01; 0 μM vs. 2.5 μM, P < 0.01) (Fig. 3 A and B) and the amount of SDS-insoluble mHtt (one-way ANOVA: F = 17.91, P < 0.0001; Dunnett’s multiple comparison test: 0 μM vs. 1 μM, P < 0.01; 0 μM vs. 10 μM, P < 0.001) (Fig. 3 C and D). These data indicate that exogenous ApiCCT1 application is able to reduce the formation of oligomeric and insoluble mHtt as well as large visible inclusions, suggesting that ApiCCT1 may have effects on both protein misfolding and/or protein accumulation and that exogenous application is sufficient to modulate these readouts.

**Exogenous ApiCCT1, Reduces mHtt-Mediated Toxicity in a Knock-in Cell Model of HD.** Overexpression of the CCT1 subunit can reduce mHtt-mediated toxicity in mouse neuronal N2a cells (15). We next determined if the apical domain of CCT1 alone could also ameliorate mHtt-mediated toxicity in cells and whether exogenous application of this would be sufficient. To test neurotoxicity, striatal STHdhQ109/HdhQ109 cells were used. These are striatal progenitor cells immortalized by a temperature-sensitive large T antigen, derived from a knock-in mouse model of expanded polyglutamines (30) and expressing full-length mHtt within the endogenous mouse locus. Upon temperature shift and serum withdrawal, mHtt lines show decreased viability and increased cell death compared with the same cells at time 0 immediately before this shift (31). This control is used instead of comparing to a line expressing wild-type HTT due to clonal variability between lines. Cell viability was measured using an XTT (sodium 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-(phenylamino)-carbonyl]-2H-tetrazolium inner salt) colorimetric cell proliferation assay to detect altered cellular metabolic activities. Results are presented as percent relative to cells not treated with ApiCCT1, following shift to nonpermissive conditions. Exogenous delivery of ApiCCT1 reduced mHtt-mediated toxicity in STHdhQ109/HdhQ109 cells, depicted graphically as an increase in cell viability following shift to nonpermissive conditions. Interestingly, this effect persists after 48 h, suggesting that the exogenous ApiCCT1 may have a sustained effect on cell survival.

**Figure 2.** ApiCCT1, reduces the number of cells containing visible inclusions but does not increase levels of monomeric mHtt in 14A2.6 cells. (A and B) The 14A2.6 cells were treated with ApiCCT1, at the concentrations listed for 48 h. Cells were then fixed, imaged at 20× magnification, and the number of cells containing inclusion bodies was counted by fluorescence microscopy. (A) Representative images used for quantification. Scale bar, 20 μm. (B) ApiCCT1, significantly decreases the number of visible inclusions in the 14A2.6 cells (Dunnett’s multiple comparison test, *P < 0.05, **P < 0.01). Error bars represent group means ± SEM. (C and D) The 14A2.6 cells were treated with ApiCCT1, at the concentrations listed for 48 h. SDS/PAGE analysis of lysates shows no significant differences in monomeric mHtt levels with ApiCCT1, treatment. Blots were probed with anti-EGFP (mHtt) and anti-actin (loading control). Error bars represent group means ± SEM.
toxicity, the need for overexpression of the protein inside the cell would be circumvented and provide a rational option for delivery to the brain. We investigated this possibility in a series of targeted proof-of-concept assays and find that exogenous delivery of ApiCCT1 can enter cells and modulate cellular phenotypes.

There is established precedence for exogenous proteins crossing cell membranes and entering cells by several different mechanisms direct penetration, pore formation, endocytosis, and transporter-mediated cell entry (20, 21). Experiments are ongoing to determine the mechanism of ApiCCT1 cell entry with the goal of optimizing the amount of protein that can enter cells in culture and ultimately in brain. These experiments will include mutating the positive charged amino acid domain of yeast ApiCCT1 to determine if this domain is required. Additionally, testing whether exogenous application of human ApiCCT1 also results in cell entry and phenotypic modulation is in progress. As ApiCCT1 does not contain a known nuclear localization signal (32), perhaps the ability to penetrate membranes similar to CPPs might explain the ability of ApiCCT1 to cofractionate with nuclear proteins. Alternatively, the small size of this chaperone domain would allow it to passively diffuse through the nuclear pore (33). The finding that exogenous ApiCCT1 delivery can be taken up by cells and localizes to both the cytosol and nucleus are highly significant given that both compartments appear to contribute to pathogenic effects mediated by chronic mHtt expression (34), in particular nuclear accumulation of mHtt exerts toxic effects (1, 12, 17, 18).

ApiCCT1 may be directly interacting with mHtt to alter aggregation and toxicity, consistent with the previous finding that ApiCCT1 can by itself suppress formation of insoluble mHtt aggregates and interacts with the first 17 amino acids of Htt, which regulates aggregation kinetics and other Htt functions (16). Given that toxicity is ameliorated in a cell model expressing full-length mHtt in which inclusions are not observed, it is likely that ApiCCT1 exerts direct effects on mHtt-mediated phenotypes beyond interference with aggregation. Experiments to evaluate whether there is a direct association between mHtt and exogenously delivered ApiCCT1, as anticipated and whether ApiCCT1 selectively binds to specific aggregation intermediates of mHtt are in progress. It is also possible that ApiCCT1, also exerts extracellular effects. Further study is required to elucidate the mechanism of action of this chaperone protein upon cellular mHtt-mediated phenotypes.

When a cell-based assay designed to screen for altered inclusion body formation was performed (24), exogenous ApiCCT1 protein reduced the formation of visible aggregates, consistent with previous in vitro results. Using this assay, ApiCCT1 was also found to significantly delay the formation of inclusion bodies. While it is not yet known if this delay is protective, it is encouraging that ApiCCT1 might be able to slow the onset of HD phenotypes.

ApiCCT1, decreased oligomeric and insoluble mHtt in an inducible cell model of HD. It is of interest to compare these findings with previous work demonstrating that the entire TRiC/CCT complex increased the formation of nontoxic, SDS-soluble mHtt oligomers (13). Additionally, Hsp70 and Hsp40 were required
for the assembly of the nontoxic oligomers, suggesting that for this system, increased expression of both of these chaperones might be necessary for the formation of the nontoxic oligomeric species. Of note, the SDS-AGE technique used here specifically resolves fibrillar SDS-resistant oligomers, raising the possibility that SDS-resistant and SDS-soluble oligomers, respectively, represent toxic and benign oligomeric species.

The decrease in both oligomeric and insoluble mHtt is important as it is not currently known whether insoluble or oligomeric mHtt induce toxicity in HD. Given that oligomeric mHtt levels are decreased, ApiCCT1 appears to be intervening at the initiating events in the aggregation pathway. Further, ApiCCT1 does not alter the steady-state levels of monomeric mHtt or the expression of the transgene. Because there is no accumulation of monomeric mHtt, which might be expected given the decreased inclusion body formation, it is possible that clearance of the protein might be increased. Alternatively, ApiCCT1 might be remodeling mHtt conformation to either refold misfolded mHtt or produce nontoxic species that are off-pathway to the formation of fibrillar and amyloid species. Further studies to determine the effect of ApiCCT1, on protein folding, conformation, and clearance, such as misfolding of sensor proteins such as dihydrofolate reductase (35), proteasomal activity, or autophagic flux (36) assays will be necessary to understand the mechanisms by which ApiCCT1 alters aggregation and toxicity.

While mechanisms underlying ApHCCT1 cell uptake and modulation of mHtt aggregation have yet to be determined, the data described here provide proof-of-concept evidence that exogenous delivery of just the 20 kDa apical domain of CTT1 is sufficient to alter a panel of cellular mHtt phenotypes and could have profound therapeutic potential without the need to create approaches for intracellular expression of the protein. Indeed, there is support for the feasibility of direct protein delivery in vivo with administration of DJ-1 protein to the brains of 6-Hydroxydopamine (6-OHDA) lesioned rat models of Parkinson’s disease resulting in neuroprotective outcomes (33, 37). Further optimization to increase the efficiency of ApHCCT1 transduction into cells and nuclei might also increase the potency of ApHCCT1, as a therapeutic reagent and is under current investigation. Given the data presented here, the efficacy of in vivo delivery into striatum of HD mouse models can now be investigated and optimized, including cell transplantation-based secretion of ApHCCT1, viral injections of cDNAs encoding secreted forms of ApHCCT1, and direct protein delivery of recombinant protein.

Materials and Methods

Inducible PC12 Cells. The Htt14A2.6 PC12 line was generated and propagated as described in ref. 24.

Protein. The 6x-his tagged ApiCCT1 (MYPGYALNCVSQAMPKRIAGNKV-IACLDDLQKARMVGONIDPEQIRKREAGVLVRKIIDAGAOVQLTT-KGIDDLCLEFKVEAKIMVRCKKEDLRRARIATGATLVSSMLSINEGTEFESSLYLG-LCDEVQAKFSDEDLCKTGSSAAALHIFHNLH) was used as a stock of 87 μM in apical buffer (50 mM Hapes, pH 7.5, 300 mM NaCl, 10% (v/v) glycerol, 1 mM DTT). Apical buffer was used as a vehicle control. Purification was conducted as previously described (15, 16). Cellular Fractionation. Cell fractionation was adapted from ref. 38, but the procedure was performed as described in ref. 39. Briefly, 14A2.6 cells were grown as described above. At 24 h after plating, cells were induced with Ponasterone A (PA) and treated with 6x-His-tagged ApiCCT1. Cells were then allowed to grow for 48 h without additional treatment with ApiCCT1. Cells were harvested and spun down at 1,000× g for 5 min at 4 °C. A small volume of media was retained to determine the amount of ApiCCT1 present in the media. A reference volume (RV) of cells was determined and cells were resuspended in 15 RV of cold buffer (10 mM Tris, pH 7.4, 10 mM NaCl, and 1 mM MgCl2). The samples were divided in half, and 90 μg/mL was added to one set, while the other set was treated with a buffer control (10 mM Tris-HCl, pH 7.5). After 30 min of incubation on ice, the protein was inactivated by addition of 500 μg/mL PMSF. The samples were lysed by adding Nonidet P-40 to a final concentration of 0.3% and homogenized in a glass homogenizer. Crude total cell lysate was then removed for future analysis (T). Remaining lysates were centrifuged at 120,000× g for 5 min at 4 °C, and the supernatant (cytoplasmic fraction) was collected. The nuclear pellet was centrifuged at 120,000× g for 40 min at 4 °C through this sucrose cushion. The purified nuclear pellet was resuspended in 10 RV of 340 mM sucrose solution containing 5 mM MgCl2. A total of 450 RV of 880 mM sucrose solution containing 5 mM MgCl2 was added under the nuclear fraction, and nuclei were purified by centrifuging at 120,000× g for 10 min at 4 °C through this sucrose cushion. The purified nuclei were resuspended in 10 RV of 340 mM sucrose solution containing 5 mM MgCl2. PK treatment was performed as described on the samples previously treated with PK. After stopping the PK reaction, protease inhibitor (Roche) was added to each sample, and the nuclei were lysed by sonicating 3x for 30 s at 40 V with 5 min on ice in between pulses. SDS/PAGE analysis was performed on all samples as above except samples were run on a 15% Criterion gel (BioRad), and because the ApiCCT1 was so abundant in the media, only 10 μg of protein was loaded from the media to avoid extreme overexposure. All other samples were 30 μg of total protein. Samples were then analyzed by SDS/PAGE as described below.

Immunocytochemistry and Quantitation of Inclusion Bodies. 14A2.6 cells were grown as described above on UV-treated coverslips for 24 h and then induced for mHtt expression with 2.5 μM PA for 48 h. Cells were then fixed in 2% paraformaldehyde, permeabilized with 0.1% Triton X-100 in PBS, and nuclei were stained with 4,6-diamidino-2-phenylindole. Fluorescent microscopy was performed using Axiovision software and a Zeiss AxioObserver.Z1 microscope. A minimum of 500 cells were counted from ~5–6 fields in three independent experiments for each data point at 20× magnification. Aggregation is expressed as the percentage of cells with visible inclusions versus total number of cells.

SDS/PAGE of PC12 Cell Homogenates. mHtt expression was induced with 2.5 μM PA and simultaneously treated with listed concentrations of ApiCCT1 for 48 h with no subsequent addition of ApiCCT1. Three independent experiments were performed. At 48 h postinduction, cells were lysed in radio-immune precipitation assay buffer [10 mM Tris, pH 7.5, 150 mM NaCl, 1 mM EDTA (pH 8.0), 1% Nonidet P-40, 0.5% SDS] containing Complete Protease Inhibitor (Roche Diagnostics). A DC protein assay (Bio-Rad) was performed to determine protein content. A total of 250 μl of crude total cell lysate was added in a 1:1 ratio to loading buffer (125 mM Tris, pH 6.8, 20% glycerol, 4% SDS, 10% β-mercaptoethanol, 0.004% bromophenol blue) and loaded onto a 10% Criterion gel (Bio-Rad). The gel was then run at 25 V until the dye front reached the bottom of the gel. It was then wet-transferred to a nitrocellulose membrane, blocked for 1 h in startingBlock T20 (TBS) Blocking Buffer (Pierce) at room temperature and probed with anti-sixEFP (Clontech, 1:1,000), anti-Ahx-Actin (Sigma, 1:1,000), anti-Ahx antibody (Sigma, 1:1,000), anti-GAPDH (Invitrogen, 1:1,000), or anti-p84 (AbCam, 1:1,000). Peroxidase-conjugated AffiniPure goat anti-rabbit or anti-mouse secondary antibodies (Jackson ImmunoResearch Materials and Methods

Fig. 4. ApiCCT1 reduces mHtt-mediated toxicity in a knock-in cell model of HD. ApHCCT1 increases survival of SNca10/TgHdhQ10 cells at both 24 and 48 h after treatment and temperature shift (Dunnett’s multiple comparison test, ∗P < 0.05, ***P < 0.001) by XTT assay. Samples were normalized to the vehicle control. Values over 100% indicate higher o.d. and therefore increased respiration likely due to increased cell survival. Error bars represent group means ± SEM.
Laboratories) were used at 1:20,000 for 1 h at room temperature. Blots were detected using PICO detection reagent (Pierce).

SDS-AGE of PC12 Cell Homogenates. The analysis of mHtt by SDS-AGE with Western analysis was performed as previously described (26–29).

Filter Retardation Analysis of PC12 Cell Homogenates. The same lysates used in the SDS/PAGE and SDS-AGE assays were also analyzed for SDS-insoluble mHtt by filter-retardation assays as described in refs. 27, 28, 40.

Quantification of Western Blots. Densitometry of the autoradiographs was performed using Image software (National Institutes of Health). Measurements were normalized to control samples treated with vehicle in all of the assays as there is no loading control for SDS-AGE or filter-retardation assays.

Live Cell Imaging. Time-lapse microscopy was performed as described in ref. 28. The 1A4.2.6 cells were grown as above, and 5 × 10^5 cells were plated onto collagen-coated glass-bottom microwell dishes (MatTek, P35-1.5–14-C). Cells were induced with 2.5 μM PA and simultaneously treated with listed concentration of ApiCCT1 at 24 h postplating and allowed to equilibrate in the imaging system. The amount of equilibration time was variable between experiments, and this difference in time was accounted for in the time elapsed for analysis. Cells were then allowed to grow for 48 h in a VivaView live cell imaging system ( Olympus). Cells were imaged every 10 min for 48 h at 20X magnification every nine different locations per well to allow for sufficient cell numbers in analysis. Three independent experiments were performed. The "lag phase" of inclusion formation is shown as the number of hours before the appearance of the first inclusion body.

Knock-In Cell Line. Homozygous mutant STRh455/451Hdh109/109 cell lines (gift from E. Cattaneo, University of Milano, Milan) were plated in 24-well plates (0.75 × 10^5 cells/well) in complete medium (DMEM / 5% glucose, 10% FBS) at 33°C as described previously (31). Experiments were plated to have five technical replicates per concentration per experiment, with each independent experiment repeated three times. Cells were treated with listed concentrations of ApiCCT1, concurrently with the addition of low serum medium and temperature shift with no subsequent treatments through the duration of the study.

Cell Survival Assay. Cells were treated as described above. XTT (sodium 2,3-bis[2-methoxy-4-nitro-5-sulphophenyl]-2H-tetrazolium inner salt) assays were performed at 24 and 48 h after the temperature shift. At those time points, cells were incubated for 4 h with XTT and phenazine methosulfate (0.2 μg/mL and 0.1 μg/mL, respectively; Sigma-Aldrich), and absorbance was read at 450 nm. Higher values in the treated groups indicate increased cellular respiration suggestive of increased cell survival.

Statistical Analysis. All statistical analyses were performed using GraphPad Prism 5.04 software. All data are expressed as mean ± SE of measure. P < 0.05

ACKNOWLEDGMENTS. We thank Dr. Jack Reiliding for helpful discussions of the manuscript and Dr. Christopher Sontag and Dr. Brian Cummings for advice and technical assistance with live cell imaging. Funding was provided by National Institutes of Health Grants P01-NS051625 and NS52789 (to L.M.T.) and AG00538 (to C.G.G.) and the Hereditary Disease Foundation and Huntington’s Disease Society of America (to L.M.T.).
