Search for a light Higgs boson decaying to two gluons or $s\bar{s}$ in the radiative decays of $Y(1S)$

1550-7998

PHYSICAL REVIEW D 88, 031701(R) (2013)
We search for the decay $Y(1S) \rightarrow \gamma A^0$, $A^0 \rightarrow gg$ or $s \bar{s}$, where $A^0$ is the pseudoscalar light Higgs boson predicted by the next-to-minimal supersymmetric Standard Model. We use a sample of $(17.6 \pm 0.3) \times 10^6$ $Y(1S)$ mesons produced in the BABAR experiment via $e^+e^- \rightarrow Y(2S) \rightarrow \pi^+\pi^- Y(1S)$. We see no significant signal and set 90%-confidence-level upper limits on the product branching fraction $\mathcal{B}(Y(1S) \rightarrow \gamma A^0) \cdot \mathcal{B}(A^0 \rightarrow gg$ or $s \bar{s})$ ranging from $10^{-6}$ to $10^{-2}$ for $A^0$ masses in the range $0.5$–$9.0$ GeV/c$^2$.

The next-to-minimal supersymmetric standard model (NMSSM), one of several extensions to the Standard Model [1], predicts that there are two charged, three neutral $CP$-even, and two neutral $CP$-odd Higgs bosons. One of the $CP$-odd Higgs bosons, $A^0$, can be lighter than two bottom quarks [2]. If so, a $CP$-odd Higgs boson that couples to bottom quarks could be produced in the radiative decays of an $Y$ meson.

The $A^0$ is a superposition of a singlet and a nonsinglet state. The branching fraction $\mathcal{B}(Y \rightarrow \gamma A^0)$ depends on the NMSSM parameter $\cos \theta_A$, which is the nonsinglet fraction. The final state to which the $A^0$ decays depends on various parameters such as $\tan \beta$ and the $A^0$ mass [3].
BABAR has searched for an $A^0$ decaying into $\mu^+\mu^-$ [4,5], $\tau^+\tau^-$ [6,7], invisible states [8], and hadronic final states [9] and has not seen a significant signal. The CMS Collaboration has also not observed a significant signal in the search for $A^0$ decaying into $\mu^+\mu^-$ [10]. In this paper, we report on the first search for the decay $Y(1S) \rightarrow \gamma A^0$, $A^0 \rightarrow gg$ or $s\bar{s}$. We search for the $A^0$ in the mass range $0.5 < m_{A^0} < 9.0$ GeV/$c^2$. By tagging the dipion in the $Y(2S) \rightarrow \pi^+\pi^- Y(1S)$ transition, this analysis greatly reduces $e^+e^- \rightarrow q\bar{q}$ background, where $q$ is a $u$, $d$, or $s$ quark, which is a dominant background contribution in BABAR’s previous $A^0 \rightarrow$ hadrons analysis [9]. Although this analysis has been motivated by NMSSM, these results are generally applicable to any $CP$-odd hadronic resonances produced in the radiative decays of $Y(1S)$ because we search for the $A^0$ excluding two-body final states. For an $A^0$ mass less than $2m_\tau$, the $A^0$ is predicted to decay predominantly into two gluons if $\tan \beta$ is of order 1, and into $s\bar{s}$ if $\tan \beta$ is of order 10.

This paper uses data recorded with the BABAR detector at the PEP-II asymmetric-energy $e^+e^-$ collider at the SLAC National Accelerator Laboratory. The BABAR detector is described in detail elsewhere [11,12]. For this analysis, we use 13.6 fb$^{-1}$ of data [13] taken at the $Y(2S)$ resonance (“on resonance”). An estimated number of $(98.3 \pm 0.9) \times 10^6$ $Y(2S)$ mesons were produced. The branching fraction $\mathcal{B}(Y(2S) \rightarrow \pi^+\pi^- Y(1S))$ is $(17.92 \pm 0.26)\%$ [14]. Therefore, $(17.6 \pm 0.3) \times 10^6$ $Y(1S)$ mesons were produced via the dipion transition. We also use $1.4 \text{ fb}^{-1}$ of data [13] taken 30 MeV below the $Y(2S)$ resonance (“off resonance”) as a background sample.

Simulated signal events with various $A^0$ masses ranging from 0.5 to 9.0 GeV/$c^2$ are used in this analysis. The EVTGEN event generator [15] is used to simulate particle decays. The $A^0$ is simulated as a spin-0 particle decaying to either $gg$ or $s\bar{s}$. Since the width of the $A^0$ is expected to be much less than the invariant-mass resolution of $=100$ MeV/$c^2$, we simulate the $A^0$ with a 1 MeV/$c^2$ decay width. JETSET [16] is used to hadronize partons, and GEANT4 [17] is used to simulate the detector response.

We select events with two charged tracks as the dipion system candidate, a radiative photon, and a hadronic system, as described later in this paper. We select $Y(2S) \rightarrow \pi^+\pi^- Y(1S)$ candidates based on the invariant mass $m_R$ of the system recoiling against the dipion system:

$$m_R^2 = M^2_{Y(2S)} + m_{\pi\pi}^2 - 2M_{Y(2S)}E_{CM}^\pi\pi,$$

where $M_{Y(2S)}$ is the world average $Y(2S)$ mass [14], $m_{\pi\pi}$ is the measured dipion invariant mass, and $E_{CM}^\pi\pi$ is the dipion energy in the $e^+e^-$ center-of-mass (CM) frame. The recoil mass distribution from an $Y(2S) \rightarrow \pi^+\pi^- Y(1S)$ transition has a peak near the $Y(1S)$ mass of $9.460 \pm 0.000\ 26$ GeV/$c^2$ [14]. The background recoil mass distribution is uniform. We select events with a recoil mass in the range $9.45$–$9.47$ GeV/$c^2$. We further suppress the background with a multilayer perceptron (MLP) neural network [18]. Using simulated $Y(2S) \rightarrow \pi^+\pi^- Y(1S), Y(1S) \rightarrow \gamma A^0$ decays of various $A^0$ masses, $Y(2S)$ decays without dipions in the final state, and $e^+e^- \rightarrow q\bar{q}$ events, we train an MLP using nine dipion kinematic variables [8]. The variables are: opening angle between the pions; absolute value of the cosine of the angle formed between the $\pi^-$ and the direction of the $Y(2S)$ in the dipion frame; dipion momentum perpendicular to the beam axis; dipion invariant mass; distance from the beam spot; the larger momentum of the two pions; cosine of the dipion polar angle; $\chi^2$ probability of the fit of the two pion tracks to a common vertex; and cosine of the polar angle of the more energetic pion. These quantities are calculated in the $e^+e^-$ CM frame unless otherwise specified. Applying all other selection criteria, 99% of the remaining signal events and 80% of continuum events pass our MLP selection. The distribution of the recoil mass against the dipion system in data after applying all selection criteria is shown in Fig. 1.

We reconstruct $A^0 \rightarrow gg$ using 26 channels as listed in Table I. We do not use two-body decay channels because a $CP$-odd Higgs boson cannot decay into two pseudoscalar mesons. Charged kaons, pions, and protons are required to be positively identified. To reduce the number of misreconstructed candidates in an event, we require the number of reconstructed charged tracks in an event to match the number of charged tracks in the corresponding decay mode (including the $\pi^+\pi^-$). For example, we reconstruct ten-track events only as $K^+K^-3\pi^+3\pi^-$, $K^+K^-\pi^+2\pi^+2\pi^-\pi^0$ (two tracks from a $K_{\pi}^0$), or $4\pi^+4\pi^-$. The $\pi^0$ and $\eta$ candidates are reconstructed from two photon candidates. The $K_{\pi}^0$ candidates are reconstructed using two charged pions of opposite charge.

![FIG. 1. Distribution of the recoil mass against the dipion system in on-resonance data (points with error bars) after applying all selection criteria. The histogram is the continuum background recoil mass distribution from off-resonance data normalized to the on-resonance integrated luminosity.](http://example.com/figure1.png)
We define our $A^0 \to s\bar{s}$ sample as the subset of the 26 $A^0 \to gg$ decay channels that include two or four kaons (channels 11–24 in Table I). In simulated $A^0 \to s\bar{s}$ events, there is a negligible contribution from channels that do not include at least two kaons. We form an $A^0$ candidate by adding the four-momenta of the hadrons. Similarly, we form an $\Upsilon(1S)$ candidate by using the $A^0$ candidate and a photon with energy more than 200 MeV in the $e^+ e^-$ CM frame. To improve the $A^0$ mass resolution, we constrain the photon and the $A^0$ candidates to have an invariant mass equal to the $\Upsilon(1S)$ mass and a decay vertex at the beam spot. The $\chi^2$ probability of the constrained fit is required to be greater than $10^{-3}$. This rejects 77% of the misreconstructed $A^0$ candidates, which includes candidates with misidentified charged kaons, pions, and protons. We reject $\Upsilon(1S)$ candidates if the radiative photon, when combined with another photon in the event that is not used in the reconstruction of a $\tau^0$ or $\eta$ candidate, has an invariant mass within 50 MeV/$c^2$ of the $\tau^0$ mass. This removes backgrounds where a photon from a $\tau^0$ decay is misidentified as the radiative photon. We also reject $\Upsilon(1S)$ candidates if the Zernike moment $A_{32}$ [19] of the radiative photon is greater than 0.1. This removes backgrounds where showers from both photons from a $\tau^0$ decay overlap and are mistaken as the radiative photon. If there is more than one $\Upsilon(2S) \to \pi^+ \pi^- \Upsilon(1S)$, $\Upsilon(1S) \to \gamma A^0$ candidate that passes all the selection criteria in an event, the candidate with the highest product of MLP output and $\chi^2$ probability is kept. Of the events with at least one $A^0$ candidate, 16% have more than one candidate. Figure 2 shows the $A^0$ candidate invariant mass spectra for the $A^0 \to gg$ and $A^0 \to s\bar{s}$ channels separately after applying all selection criteria and selecting one candidate per event.

We use our off-resonance sample to estimate the continuum contribution in the on-resonance sample. Fifteen percent of the candidates in the on-resonance sample are determined to come from non-$\Upsilon(2S)$ decays.

We use simulated $\Upsilon(2S)$ events to study the remaining backgrounds, which originate mainly from $\Upsilon(1S) \to ggg$ and $\Upsilon(1S) \to \gamma gg$, where the gluons hadronize to more than one daughter. In $\Upsilon(1S) \to ggg$ decays, a $\pi^0$ from the gluon hadronization is mistaken as the radiative photon. This decay mode contributes most of the background candidates with $A^0$ masses between 7 and 9 GeV/$c^2$. The candidates with $A^0$ masses between 2 and 4 GeV/$c^2$ are mostly $\Upsilon(1S) \to \gamma gg$. CLEO measured the $\Upsilon(1S) \to \gamma f_2(1270)$ [20] and $\Upsilon(1S) \to \gamma f_2(1525)$ [21] branching fractions. We do not expect these decays to be a background to the search for a narrow $A^0$ because they mainly decay to two-body final states and have decay widths of 100 MeV/$c^2$.

To determine the number of signal events, we define a mass window, centered on the hypothesis $A^0$ mass, that contains 80% of simulated signal events at that mass. For example, in simulated 3 GeV/$c^2$ $A^0 \to s\bar{s}$ events, 80% of the events that pass the selection criteria have a reconstructed invariant mass for the $A^0$ within $\pm 170$ MeV/$c^2$ of 3 GeV/$c^2$. The mass windows are estimated for several $A^0$ masses for both $gg$ and $s\bar{s}$ and interpolated for all other masses. A sideband region is defined as half of the mass window size adjacent to both sides of the mass window. Again, for example, the lower sideband for a 3 GeV/$c^2$ $A^0 \to s\bar{s}$ would be from 2.66 to 2.83 GeV/$c^2$, and the upper sideband would be from 3.17 to 3.34 GeV/$c^2$. 

![Figure 2](color online). $A^0$ candidate mass spectra after applying all selection criteria. We reconstruct $A^0 \to gg$ using the 26 channels listed in Table I and $A^0 \to s\bar{s}$ using the subset of the same 26 channels that includes two or four kaons. The $A^0$ candidate mass is the invariant mass of the reconstructed hadrons in each channel. The black points with error bars are on-resonance data for $A^0 \to gg$. The red squares with error bars are on-resonance data for $A^0 \to s\bar{s}$. The thick blue histogram is $A^0 \to gg$ in off-resonance data normalized to the on-resonance integrated luminosity. The thin magenta histogram is $A^0 \to s\bar{s}$ in off-resonance data normalized to the on-resonance integrated luminosity.

FIG. 2 (color online). $A^0$ candidate mass spectra after applying all selection criteria. We reconstruct $A^0 \to gg$ using the 26 channels listed in Table I and $A^0 \to s\bar{s}$ using the subset of the same 26 channels that includes two or four kaons. The $A^0$ candidate mass is the invariant mass of the reconstructed hadrons in each channel. The black points with error bars are on-resonance data for $A^0 \to gg$. The red squares with error bars are on-resonance data for $A^0 \to s\bar{s}$. The thick blue histogram is $A^0 \to gg$ in off-resonance data normalized to the on-resonance integrated luminosity. The thin magenta histogram is $A^0 \to s\bar{s}$ in off-resonance data normalized to the on-resonance integrated luminosity.
Using simulated events, we estimate efficiencies of reconstructing the whole decay chain by taking the number of events in a signal mass window, subtracting the number of events in the sidebands, and dividing the difference by the number of simulated events. We interpolate the efficiencies for all hypothesis $A^0$ masses.

Our efficiency measurements of $gg$ and $s\bar{s}$ into the 26 channels are dependent on the hadronization modeling by JETSET. The accuracies of the simulated branching fractions of $gg$ and $s\bar{s}$ to different final states are difficult to determine. We correct for this by comparing simulations with data in $Y(1S)\rightarrow \gamma gg$ decays. We count the number of events in the 26 channels where the reconstructed $gg$ mass is between 2 and 4 GeV/$c^2$ in data and compare that to simulated $Y(2S)\rightarrow \pi^+\pi^- Y(1S)$, $Y(1S)\rightarrow \gamma gg$ events in the same mass range. The background in this mass region is almost entirely from $Y(1S)\rightarrow \gamma gg$ decays. The number of $Y(1S)\rightarrow \gamma gg$ events is too few at masses above 4 GeV/$c^2$ to allow any meaningful study. For each of the 26 channels listed in Table I, we calculate a weight that is the ratio of the event yields in data and simulation. We apply these weights to our efficiency calculations to determine how much the signal efficiency changes. The efficiencies change by a factor of 0.66 on average for $A^0\rightarrow gg$ and 1.09 for $A^0\rightarrow s\bar{s}$. We correct the efficiencies by multiplying our measured efficiencies by these factors and assign an uncertainty due to hadronization modeling of (1 - 0.66)/0.66 = 50% to all $A^0\rightarrow gg$ and $A^0\rightarrow s\bar{s}$ efficiencies since the correction is based on simulated $Y(1S)\rightarrow \gamma gg$ decays but not $Y(1S)\rightarrow \gamma s\bar{s}$ decays. We do not correct for, or assign hadronization modeling uncertainty to, $A^0\rightarrow gg$ of invariant mass from 0.5 to 0.6 GeV/$c^2$ because a $CP$-odd $A^0$ can decay to only $\pi^+\pi^-\pi^0$ in that mass region. Signal efficiencies range from 0.07 to $4\times10^{-4}$ for $gg$ and 0.04 to $1\times10^{-3}$ for $s\bar{s}$. The efficiencies are lower for higher $A^0$ masses because a more massive $A^0$ decays to more hadrons, which increases the probability of misreconstruction.

An $A^0$ signal would appear as a narrow peak in the candidate mass spectrum. To look for a signal, we scan the mass spectrum in 10 MeV/$c^2$ steps from 0.5 GeV to 9.0 GeV/$c^2$. Our null hypothesis is that the signal rate is 0 in the signal mass window. We use sidebands to estimate the number of background events in the signal region. Using Cousins’ method [22], we calculate a probability ($p$ value) of seeing the observed result or greater in the signal mass region given the null hypothesis. We do this separately for $A^0\rightarrow gg$ and $A^0\rightarrow s\bar{s}$. Figure 3 is the

FIG. 3. The probability of observing at least the number of signal events, assuming a null hypothesis for the existence of the decay $Y(1S)\rightarrow \gamma A^0$, $A^0\rightarrow gg$ (top) and $Y(1S)\rightarrow \gamma A^0$, $A^0\rightarrow s\bar{s}$ (bottom).

![Graph](image-url)

FIG. 4 (color online). The 90%-confidence-level upper limits (thin solid line) on the product branching fractions $B(Y(1S)\rightarrow \gamma A^0) \cdot B(A^0\rightarrow gg)$ (top) and $B(Y(1S)\rightarrow \gamma A^0) \cdot B(A^0\rightarrow s\bar{s})$ (bottom). We overlay limits calculated using statistical uncertainties only (thin dashed line). The inner band is the expected region of upper limits in 68% of simulated experiments. The inner band plus the outer band is the expected region of upper limits in 95% of simulated experiments. The bands are calculated using all uncertainties. The thick line in the center of the inner band is the expected upper limits calculated using simulated experiments.
resulting $p$-value plot for all hypothesis masses. The minimum $p$ value for $A^0 \rightarrow gg$ is 0.003 and occurs at an $A^0$ mass of 8.13 GeV/c$^2$. The minimum $p$ value for $A^0 \rightarrow s\bar{s}$ is 0.002 and occurs at an $A^0$ mass of 8.63 GeV/c$^2$. These results are equivalent to Gaussian standard deviations of 2.7 and 2.9, respectively. We use $10^4$ simulated experiments to calculate how often such a statistical fluctuation might occur. For $A^0 \rightarrow gg$, 86% of the simulated experiments have a minimum $p$ value less than 0.003. For $A^0 \rightarrow s\bar{s}$, 59% of the simulated experiments have a minimum $p$ value less than 0.002. Therefore, we conclude that there is no evidence for the light CP-odd Higgs boson.

The dominant systematic uncertainty on the product branching fraction upper limit is related to the efficiency, which was described earlier in the text. Other systematic uncertainties, which are small compared to the 50% uncertainty due to hadronization modeling, include Monte Carlo statistical uncertainties (1%–7%), efficiency variations in estimating the size of the mass windows (5%), dipion branching fraction (2%), $Y(2S)$ counting (1%), and dipion selection efficiency (1%). The systematic uncertainties are summed in quadrature and total 51%.

We calculate 90%-confidence-level (C.L.) upper limits (Fig. 4) on the product branching fractions $\mathcal{B}(Y(1S) \rightarrow \gamma A^0) \cdot \mathcal{B}(A^0 \rightarrow gg)$ and $\mathcal{B}(Y(1S) \rightarrow \gamma A^0) \cdot \mathcal{B}(A^0 \rightarrow s\bar{s})$ using a profile likelihood approach [23]. We do this by calculating an upper limit of the mean number of signal events in the signal region given the number of events observed in the sidebands, and dividing by the efficiency, dipion branching fraction, and the number of $Y(2S)$ mesons produced. The number of background events is assumed to be Poissonian distributed and the efficiency distribution is assumed to be Gaussian with width equal to the total systematic uncertainty.

In summary, we select dipions in $Y(2S)$ decays to obtain a sample of $Y(1S)$ mesons. We reconstruct the $Y(1S)$ decay using a photon and a hadronic system. We observe no signals in the hadronic invariant mass spectra and set upper limits at 90% C.L. on the product branching fractions $\mathcal{B}(Y(1S) \rightarrow \gamma A^0) \cdot \mathcal{B}(A^0 \rightarrow gg)$ from $10^{-6}$ to $10^{-2}$ and $\mathcal{B}(Y(1S) \rightarrow \gamma A^0) \cdot \mathcal{B}(A^0 \rightarrow s\bar{s})$ from $10^{-5}$ to $10^{-3}$. We do not observe a NMSSM $A^0$ or any narrow hadronic resonance.

We are grateful for the excellent luminosity and machine conditions provided by our PEP-II colleagues and for the substantial dedicated effort from the computing organizations that support BABAR. The collaborating institutions wish to thank SLAC for its support and kind hospitality.
