Abstract

We have exploited a typically undesired elementary step in cross-coupling reactions, β-hydride elimination, to accomplish palladium-catalyzed dehydrohalogenations of alkyl bromides to form terminal olefins. We have applied this method, which proceeds in excellent yield at room temperature in the presence of a variety of functional groups, to a formal total synthesis of (R)-mevalonolactone. Our mechanistic studies establish that the rate-determining step can vary with the structure of the alkyl bromide, and, most significantly, that L2PdHBr (L=phosphine), an often-invoked intermediate in palladium-catalyzed processes such as the Heck reaction, is not an intermediate in the active catalytic cycle.

INTRODUCTION

The elimination of HX to form an olefin is one of the most elementary transformations in organic chemistry (eq 1).1,2 However, harsh conditions, such as the use of a strong Brønsted acid/base or a high temperature (which can lead to poor functional-group compatibility and to olefin isomerization) are often necessary for this seemingly straightforward process. For example, many classical methods for the dehydration of alcohols, such as the Chugaev elimination via a xanthate ester,3 require elevated temperature (e.g., 100–250 °C). More recently, through the development of sophisticated derivatizing agents such as the Burgess4 and Martin5 reagents, some of the deficiencies of the older approaches have been remedied; however, while these particular methods are effective for net dehydrations of secondary and tertiary alcohols, they are not generally useful for primary alcohols.

For the dehydration of primary alcohols, the Sharpless–Grieco reaction, wherein the alcohol is converted into a selenide and then a selenoxide prior to elimination, is a particularly effective approach. Due to the mildness of the conditions (e.g., elimination at room temperature or below), this method has been widely used in organic synthesis. However, drawbacks of this reaction include the generation of a stoichiometric amount of a toxic arylselenol byproduct and difficulties in separating the desired olefin from selenium-based impurities.

With respect to metal-catalyzed methods for HX elimination, Oshima reported in 2008 that CoCl₂/IMes•HCl effects the formation of olefins from alkyl halides (but not sulfonates) in the presence of two equivalents of a Grignard reagent (Me₂PhSiCH₂MgCl). Although this investigation focused on the regioselective synthesis of terminal olefins from secondary alkyl bromides, Oshima also applied his method to two primary alkyl halides, which provided good yields of the terminal olefin (79–96%), along with small amounts of the internal olefin (2–8%). Furthermore, while our study was underway, Frantz reported that Pd(P(t-Bu)₃)₂ catalyzes the elimination/isomerization of certain enol triflates to 1,3-dienes.

The development of mild new methods for the elimination of HX to generate an olefin, a fundamental transformation in organic synthesis, persists as a worthwhile endeavor. In this report, we describe the use of a palladium catalyst to achieve elimination reactions of primary alkyl electrophiles and furnish terminal olefins in excellent yield at room temperature (eq 2).

\[
\text{RBr} \xrightarrow{\text{cat. Pd(P(t-Bu)₃)₂, base, r.t.}} \text{R} = \text{C=C} \text{R}
\]

**RESULTS AND DISCUSSION**

In recent years, we and others have pursued the development of metal-catalyzed cross-coupling reactions of alkyl electrophiles that contain β-hydrogens. Historically, it was believed that two substantial impediments to accomplishing this objective were slow oxidative addition and, if oxidative addition could be achieved, rapid β-hydride elimination in preference to transmetalation (Figure 1).

Having made progress in the development of palladium-based catalysts for cross-coupling alkyl electrophiles, we sought to exploit these advances to devise a mild method for H–X elimination of alkyl electrophiles to form olefins, since the oxidative-addition challenge had presumably been solved, and the “deleterious” β-hydride elimination process (Figure 1) would now be the desired pathway. Indeed, in our earlier efforts to achieve cross-coupling reactions of alkyl electrophiles, we had noted that significant, although not synthetically useful, quantities of the olefin were sometimes observed as undesired side products (e.g., up to 31% in the case of a Suzuki coupling).

Upon examining an array of reaction parameters, we have been able to develop a palladium-catalyzed method for olefin synthesis that accomplishes the dehydrohalogenation of a primary alkyl bromide at room temperature with excellent efficiency (Table 1, entry 1). The ligand of choice is P(t-Bu)₃Me, which we have previously established is useful for palladium-catalyzed Suzuki reactions of alkyl electrophiles. Essentially no 2-dodecene is detected (<1%).
In the absence of Pd(P(\text{-Bu})_2\text{Me})_2, virtually no olefin is formed (Table 1, entry 2). Although KOt-Bu is not necessary (entry 3), a poor yield is obtained in the absence of Cy_2NH (entry 4). Palladium complexes that bear other hindered trialkylphosphines (entries 5 and 6) or PPh_3 (entry 7) are comparatively ineffective, as are other Brønsted bases (entries 8 and 9). An active catalyst can be generated in situ from Pd_2(dba)_3 and P(\text{-Bu})_2\text{Me} (entry 10), and a lower loading of Pd(P(\text{-Bu})_2\text{Me})_2 can be employed with only a small loss in yield (entry 11), terminated via ^1H NMR spectroscopy (is given in brackets). Due to the volatility of allylbenzene, the yield was determined via gas chromatography versus a calibrated internal standard (average of two experiments). KOt-Bu loading: 2.5%. KOt-Bu loading: 20%.

We have determined that this Pd(P(\text{-Bu})_2\text{Me})_2-catalyzed method can be applied to the room-temperature dehydrohalogenation of a range of primary alkyl bromides, furnishing the desired terminal olefins in generally high yields (Table 2; for each reaction essentially no (<2%) product is formed in the absence of Pd(P(\text{-Bu})_2\text{Me})_2). Through the use of a higher catalyst loading (compare entries 1–3), more hindered (\(\gamma\)- and \(\beta\)-branched) electrophiles can be converted to olefins nearly quantitatively. Allylbenzene, too, can be generated in excellent yield and with no isomerization to \(\beta\)-methylstyrene (entry 4). A wide array of functional groups are compatible with this mild method for elimination of HBr, including a silyl ether (entry 5), a carbamate (entry 6), esters (entries 7–12), an aryl chlo-ride (entry 8), heteroaromatic substituents (oxygen, sulfur, and nitrogen; entries 9–13), and a ketone (entry 14); on the other hand, preliminary studies indicate that the presence of a primary alcohol, an aldehyde, or a nitroarene can be problematic. A primary alkyl bromide reacts exclusively in the presence of a secondary bromide (entry 15), a primary tosylate (entry 16), and a primary chloride (entry 17). For most of these elimination processes, virtually no (<2%) isomerization to the internal olefin is observed.

When 1-iodododecane is subjected to the method developed for the dehydrohalogenation of alkyl bromides (Table 1), only a small amount of 1-dodecene (20% yield) is generated; N-alkylation of dicyclohexylamine is the major product. Furthermore, under the same conditions, essentially no elimination is observed with a primary alkyl chloride or tosylate, presumably due to the relatively high barrier to oxidative addition to Pd(P(\text{-Bu})_2\text{Me})_2. On the other hand, at elevated temperature, elimination of a primary tosylate to the desired terminal olefin can proceed in excellent yield (eq 3). It is worth noting that alkyl tosylates are not suitable substrates for Oshima’s cobalt-catalyzed elimination, likely because of difficulty in achieving homolytic cleavage of the C–O bond; in contrast, under our conditions, C–O scission is probably accomplished through an \(\text{S}_2\text{N}_2\) pathway. 

\[\text{Me}(\text{CH}_2)_3\text{OTs} \xrightarrow{6\% \text{Pd}(\text{-Bu})_2\text{Me}} \text{Me}(\text{CH}_2)_3\text{Me} \]

\begin{tabular}{|c|c|}

10% KOt-Bu, 1.2 equiv Cy_2NH, 80 °C & 98\% (5:1) \
6% LiOMe, 1.2 equiv TMP, 80 °C & 98\% (18:1) \
\hline
\end{tabular}

Palladium-catalyzed eliminations of more hindered (\(\gamma\)- and \(\beta\)-branched) primary alkyl tosylates also proceed in excellent yield (Table 3, entries 2 and 3). Interestingly, a secondary alkyl tosylate undergoes elimination, predominantly generating the internal 2-alkene (entry 4; 2:1 internal:terminal). Furthermore, not only an alkyl tosylate, but also a mesylate, can be eliminated to form an olefin with good efficiency (entry 5). Perhaps due in part to the elevated reaction temperature, small amounts of olefin isomerization are sometimes
observed in eliminations of alkyl sulfonates (entries 1 and 5), and preliminary experiments indicate that the functional-group tolerance of the method is limited. For each elimination illustrated in Table 3, essentially no olefin is produced in the absence of Pd(P(t-Bu)₂Me)₂ (<2%).

We have applied our palladium-catalyzed elimination process to a formal total synthesis of (R)-mevalonolactone. Spencer described the preparation of this bioactive compound from nerol via alcohol A, which was transformed into olefin C via a Sharpless–Grieco sequence (top of Figure 2). Spencer noted that the conversion of the alcohol to the selenide “proved to be the only difficult step in the synthesis”. We have applied our palladium-catalyzed elimination process to a formal total synthesis of (R)-mevalonolactone. Spencer described the preparation of this bioactive compound from nerol via alcohol A, which was transformed into olefin C via a Sharpless–Grieco sequence (top of Figure 2).

We have effected the transformation of alcohol A into olefin C in 78% overall yield through our palladium-catalyzed elimination process (bottom of Figure 2). Thus, treatment of A with Ph₃PBr₂ furnishes primary alkyl bromide B. Next, palladium-catalyzed dehydrohalogenation under our standard conditions at room temperature affords the desired olefin in excellent yield (93%). Finally, removal of the 1-ethoxyethyl protecting group generates Spencer’s intermediate C.

**Mechanism**

Our current hypothesis is that these palladium-catalyzed elimination reactions follow the pathway outlined in Figure 3 (throughout this section, L = P(t-Bu)₂Me). Thus, oxidative addition of the alkyl bromide to L₂Pd proceeds via an S₈₂ process to generate L₂Pd(CH₂CH₂R)Br (D). Dissociation of one phosphine furnishes a 14-electron palladium adduct (E), which undergoes β-hydride elimination to provide a palladium olefin–hydride intermediate (F). In the presence of base (Cy₂NH) and L, palladium complex F affords [Cy₂NH]₂Br, the olefin, and L₂Pd.

In order for our mechanistic study to be more tractable, we chose to focus our investigation on palladium-catalyzed dehydrobrominations in the absence of KOt-Bu, a process that also occurs in excellent yield (entry 3 of Table 1). With regard to the oxidative-addition step of the proposed catalytic cycle, we have previously established that L₂Pd reacts with 1-bromo-3-phenylpropane in Et₂O at 0 °C, and we have crystallographically characterized the Pd(II) adduct. We have now examined the reaction of 1-bromododecane with L₂Pd in dioxane at room temperature, and we have determined that oxidative addition is complete within 1.5 hours, affording a mixture of L₂Pd(CH₂CH₂R)Br and L₂PdHBr (eq 4). After an additional 1.5 hours, this mixture has proceeded to form L₂PdHBr quantitatively. Taken together, these data indicate that oxidative addition and then β-hydride elimination are chemically and kinetically competent initial steps of the catalytic cycle.

![Mechanism Diagram](image)

We have investigated the impact of added P(t-Bu)₂Me on the reaction of 1-bromododecane with L₂Pd (eq 5). The rate of consumption of L₂Pd is unaffected by the additional ligand, whereas the rate of formation of L₂PdHBr is inhibited, consistent with the suggestion that...
L\textsubscript{2}Pd (rather than L\textsubscript{1}Pd or L\textsubscript{3}Pd) is the species undergoing oxidative addition and that ligand dissociation precedes \(\beta\)-hydride elimination.\textsuperscript{22}

The rate law for the palladium-catalyzed dehydrobromination of 1-bromododecane is first order in L\textsubscript{2}Pd, fractional (first order at lower concentration, zeroth order at higher concentration) order in the alkyl bromide, and zeroth order in Cy\textsubscript{2}NH. According to \textsuperscript{31}P NMR spectroscopy, L\textsubscript{2}Pd(CH\textsubscript{2}CH\textsubscript{2}R)Br is the predominant resting state of palladium during the early stages of the reaction (small amounts of L\textsubscript{2}Pd and L\textsubscript{2}PdHBr are also present; as the reaction progresses, the proportion of L\textsubscript{2}PdHBr increases). These data are consistent with oxidative addition and a subsequent step each being partially rate-determining.

\end{itemize}

(5)

For the stoichiometric chemistry of L\textsubscript{2}Pd, we have established that \(\beta\)-hydride elimination is impeded by the addition of excess P(\text{t-Bu})\text{Me}\ (eq 5); we have similarly determined that the palladium-catalyzed dehydrohalogenation of 1-bromododecane is inhibited by added P(\text{t-Bu})\text{Me}. Furthermore, we observe a modest kinetic isotope effect when comparing the rate of elimination of 1-bromododecane with that of 1-bromo-2,2-dideuteriododecane (\(k\text{H}/k\text{D} = 1.5\); eq 6). Collectively, these data are consistent with \(\beta\)-hydride elimination being the other partially rate-determining step.

\begin{itemize}

  \item \(\text{X} = \text{n-decyl}\)
  \item \(\text{k (X=H)} = 1.5\quad \text{k (X=D)}\)
\end{itemize}

(6)

In a previous study, we have demonstrated that oxidative addition of a primary alkyl electrophile to Pd/P(t-Bu)\text{Me} preferentially proceeds through an SN\textsubscript{2} pathway.\textsuperscript{12a,c} If oxidative addition is indeed partially rate-determining for the dehydrohalogenation of 1-bromododecane, then one might anticipate that, in the case of a more hindered alkyl bromide, oxidative addition would be entirely rate-determining. The rate law the dehydrobromination of a \(\beta\)-branched primary alkyl bromide and established that the rate law is first order in the alkyl bromide, first order in L\textsubscript{2}Pd, and zeroth order in Cy\textsubscript{2}NH (eq 7). Furthermore, \textsuperscript{31}P NMR spectroscopy reveals that L\textsubscript{2}Pd is the predominant resting state of the catalyst. Taken together, these observations are consistent with oxidative addition being the rate-determining step for the palladium-catalyzed elimination of this more hindered alkyl bromide.
Interestingly, L<sub>2</sub>PdHBr is not an intermediate in the primary catalytic cycle. Thus, treatment of 1-bromododecane with 6% L<sub>2</sub>PdHBr, rather than L<sub>2</sub>Pd, results in essentially no 1-dodecene (eq 8).

We have established that Cy<sub>2</sub>NH is not a sufficiently strong Brønsted base to drive the acid-base equilibrium illustrated in eq 9 to the right, thereby producing L<sub>2</sub>Pd from L<sub>2</sub>PdHBr. Thus, it appears that, during our palladium-catalyzed dehydrobromination process, a palladium–hydride other than L<sub>2</sub>PdHBr is undergoing reductive elimination to regenerate Pd(0).

Because each turnover of catalyst generates [Cy<sub>2</sub>NH]<sub>2</sub>Br, a question arises as to why this ammonium salt does not protonate L<sub>2</sub>Pd to form L<sub>2</sub>PdHBr, thereby deactivating the palladium catalyst. In fact, during the course of the dehydrobromination process, we do observe a slow accumulation of L<sub>2</sub>PdHBr. Fortunately, however, the poor solubility of [Cy<sub>2</sub>NH]<sub>2</sub>Br in dioxane impedes this deleterious protonation, i.e., [Cy<sub>2</sub>NH]<sub>2</sub>Br precipitates faster than it protonates L<sub>2</sub>Pd.<sup>25</sup>

Although we had previously postulated that the formation of a relatively stable L<sub>2</sub>PdHCl (L=PCy<sub>3</sub>) complex could be the origin of low catalyst activity in a Heck reaction of an aryl chloride,<sup>23</sup> we had not fully appreciated the importance of avoiding the formation of L<sub>2</sub>PdHBr in developing a mild Pd/P(t-Bu)<sub>2</sub>Me-catalyzed method for the dehydrohalogenation of alkyl bromides. The fortuitous solubility properties of [Cy<sub>2</sub>NH]<sub>2</sub>Br, combined with the unanticipated regeneration of Pd(0) prior to the formation of L<sub>2</sub>PdHBr (L=phosphine), are likely critical to the success of this process. The latter observation regarding the timing of reductive elimination is worth considering when contemplating the mechanism of Heck reactions.<sup>26</sup>
CONCLUSIONS

Although the elimination of HX to form an olefin is a classic transformation in organic chemistry, there remains a need for mild new methods for accomplishing this fundamental process. Herein, we have exploited a generally undesired elementary step in cross-coupling reactions, β-hydride elimination, to achieve palladium-catalyzed dehydrohalogenations of alkyl bromides. This method, which we have applied to a formal total synthesis of (R)-mevalonolactone, enables the efficient synthesis of terminal olefins at room temperature in the presence of a variety of functional groups, including heterocycles. Our mechanistic studies establish that the rate-determining step can vary with the structure of the alkyl bromide. Most significantly, we have determined that L$_2$PdHBr (L=phosphine), an often-invoked intermediate in palladium-catalyzed processes such as the Heck reaction, is not an intermediate in the active catalytic cycle.

REFERENCES

J Am Chem Soc. Author manuscript; available in PMC 2013 August 29.

13. Isomerization of the initially generated olefin by a palladium–hydride intermediate is a well-established side reaction in Heck couplings. For recent examples of isomerizations of olefins catalyzed by palladium hydrides, including Pd(P(t-Bu)3)2HCl, see: Gauthier D, Lindhardt AT, Olsen EPK, Overgaard J, Skrydstrup T. J. Am. Chem. Soc. 2010; 132:7998–8009. [PubMed: 20481527]

14. The proportion of internal olefin does not increase as the reaction progresses, and treatment of 1-dodecene with L2PdHBr in dioxane at room temperature does not lead to the generation of internal olefins (however, isomerization is observed at elevated temperature).

15. Under our standard conditions (Table 1), in the presence of one equivalent of a primary-amine additive, the dehydrobromination of 1-bromododecane proceeded in ~95% yield. The dehydrobromination was slightly inhibited (55-70% yield, with the balance being unreacted 1-bromododecane) by the addition of one equivalent of an unprotected indole or a nitrile.

16. The relative rate of dehydrobromination of 1-bromododecane vs. 1-bromo-2-methylpentadecane (a β-branched alkyl bromide) is ~13.

17. For a study of the relative rates of oxidative addition of n-nonyl–X (X=I, Br, Cl, F, OTs) to Pd(P(t-Bu)2Me)2 in THF, see Ref. 12c.

19. Spencer also notes that the selenide was “tenaciously contaminated” by a selenium-containing impurity.

20. Due to the slow accumulation of L2PdHBr during the course of the palladium-catalyzed dehydrobromination (vide infra), our mechanistic studies have focused on the early stages of the reaction.

21. Throughout this discussion, L2PdHBr refers to trans-L2PdHBr.

23. Treatment of L2Pd with [Cy2NH2]Br in dioxane at room temperature leads to very slow formation of L2PdHBr. For related observations with a different ligand (PCy3), halide (Cl), and base (Cy2NMe), see: Hills ID, Fu GC. J. Am. Chem. Soc. 2004; 126:13178–13179. [PubMed: 15479044]

24. On the other hand, KOt-Bu does react with L2PdHBr to generate L2Pd in quantitative yield. However, if KOt-Bu, rather than Cy3NH, is employed as the stoichiometric base, then the elimination does not proceed cleanly, and there is a considerable background reaction (E2).

25. The decreased efficiency of Cy2NMe relative to Cy3NH (Table 1, entry 8 versus entry 1) may be due to the greater solubility in dioxane of [Cy2NHMe]Br compared with [Cy2NH2]Br, which leads to more protonation of L2Pd to form inactive L2PdHBr.

<sup>a</sup>The isolated yield (%) is provided (average of two experiments). For eliminations in which >2% of the internal olefin is generated, the ratio of terminal:internal olefins (determined via $^1$H NMR spectroscopy) is given in brackets.
