Measurement of polarization amplitudes and CP asymmetries in $B^0 \rightarrow K^{*}(892)^0$
Measurement of polarization amplitudes and $CP$ asymmetries in $B^0 \rightarrow \phi K^*(892)^0$

The LHCb collaboration

E-mail: dlambert@cern.ch

Abstract: An angular analysis of the decay $B^0 \rightarrow \phi K^*(892)^0$ is reported based on a $pp$ collision data sample, corresponding to an integrated luminosity of $1.0 \text{fb}^{-1}$, collected at a centre-of-mass energy of $\sqrt{s} = 7 \text{TeV}$ with the LHCb detector. The P-wave amplitudes and phases are measured with a greater precision than by previous experiments, and confirm about equal amounts of longitudinal and transverse polarization. The S-wave $K^+\pi^-$ and $K^+K^-$ contributions are taken into account and found to be significant. A comparison of the $B^0 \rightarrow \phi K^*(892)^0$ and $\bar{B}^0 \rightarrow \phi K^*(892)^0$ results shows no evidence for direct $CP$ violation in the rate asymmetry, in the triple-product asymmetries or in the polarization amplitudes and phases.

1 Introduction

The decay $B^0 \rightarrow \phi K^{*0}$ has a branching fraction of $(9.8 \pm 0.6) \times 10^{-6}$ [1]. In the Standard Model it proceeds mainly via the gluonic penguin diagram shown in figure 1. Studies of observables related to CP violation in this decay probe contributions from physics beyond the Standard Model in the penguin loop [2–4]. The decay was first observed by the CLEO collaboration [5]. Subsequently, branching fraction measurements and angular analyses have been reported by the BaBar and Belle collaborations [6–11].

The decay involves a spin-0 $B$-meson decaying into two spin-1 vector mesons ($B \rightarrow VV$). Due to angular momentum conservation there are only three independent configurations of the final-state spin vectors, a longitudinal component where in the $B^0$ rest frame both resonances are polarized in their direction of motion, and two transverse components with collinear and orthogonal polarizations. Angular analyses have shown that the longitudinal and transverse components in this decay have roughly equal amplitudes. Similar

1 In this paper $K^{*0}$ is defined as $K^*(892)^0$ unless otherwise stated.
results are seen in other $B \to VV$ penguin transitions $[12–15]$. This is in contrast to tree-level decays such as $B^0 \to \rho^+ \rho^-$, where the $V-A$ nature of the weak interaction causes the longitudinal component to dominate. The different behaviour of tree and penguin decays has attracted much theoretical attention, with several explanations proposed such as large contributions from penguin annihilation effects $[16]$ or final-state interactions $[17, 18]$. More recent calculations based on QCD factorization $[19, 20]$ are consistent with the data, although with significant uncertainties.

In this paper, measurements of the polarization amplitudes, phases, $CP$ asymmetries and triple-product asymmetries are presented. In the Standard Model the $CP$ and triple-product asymmetries are expected to be small and were found to be consistent with zero by previous experiments $[6–10]$. The studies reported here are performed using $pp$ collision data, corresponding to an integrated luminosity of $1.0 \, \text{fb}^{-1}$, collected at a centre-of-mass energy of $\sqrt{s} = 7 \, \text{TeV}$ with the LHCb detector.

2 Analysis strategy

In this analysis the $B^0 \to \phi K^{*0}$ decay is studied, where the $\phi$ and $K^{*0}$ mesons decay to $K^+ K^-$ and $K^+ \pi^-$, respectively (the study of the charge conjugate $B^0$ mode is implicitly assumed in this paper). Angular momentum conservation, for this pseudoscalar to vector-vector transition, allows three possible helicity configurations of the vector-meson pair, with amplitudes denoted $H_{+1}$, $H_{-1}$ and $H_0$. These can be written as a longitudinal polarization, $A_0$, and two transverse polarizations, $A_\perp$ and $A_\parallel$,

$$
A_0 = H_0, \quad A_\perp = \frac{H_{+1} - H_{-1}}{\sqrt{2}} \quad \text{and} \quad A_\parallel = \frac{H_{+1} + H_{-1}}{\sqrt{2}}. \quad (2.1)
$$

In addition to the dominant vector-vector (P-wave) amplitudes, there are contributions where either the $K^+ K^-$ or $K^+ \pi^-$ pairs are produced in a spin-0 (S-wave) state. These amplitudes are denoted $A_{S KK}$ and $A_{S K \pi}$, respectively. Only the relative phases of the amplitudes are physical observables. A phase convention is chosen such that $A_0$ is real. The remaining amplitudes have magnitudes and relative phases defined as

$$
A_\parallel = |A_\parallel| e^{i\delta_\parallel}, \quad A_\perp = |A_\perp| e^{i\delta_\perp}, \quad A_{S K \pi} = |A_{S K \pi}| e^{i\delta_{S K \pi}} \quad \text{and} \quad A_{S KK} = |A_{S KK}| e^{i\delta_{S KK}}. \quad (2.2)
$$
To determine these quantities, an analysis of the angular distributions and invariant masses of the decay products is performed. It is assumed that the contribution from $B^0 \to K^+K^-K^+\pi^-$, where both the $K^+K^-$ and $K^+\pi^-$ are non-resonant, is negligible.

In the following sections the key elements of the analysis are discussed. First, the conventions used in the angular analysis are defined together with the form of the differential cross-section. Next, the parameterization of the $K^+\pi^-$ and $K^+K^-$ mass distributions is discussed. Finally, the triple-product asymmetries that can be derived from the angular variables are defined.

2.1 Angular analysis

The angular analysis is performed in terms of three helicity angles ($\theta_1, \theta_2, \Phi$), as depicted in figure 2. The angle $\theta_1$ is defined as the angle between the $K^+$ direction and the reverse of the $B^0$ direction in the $K^*0$ rest frame. Similarly, $\theta_2$ is the angle between the $K^+$ direction and the reverse of the $B^0$ direction in the $\phi$ rest frame. The angle $\Phi$ is the angle between the decay planes of the $\phi$ and $K^*0$ mesons in the $B^0$ rest frame.

The flavour of the decaying $B^0$ meson is determined by the charge of the kaon from the $K^*0$ decay. To determine the polarization amplitudes, the $B^0$ and $B^0$ decays are combined. For the study of $CP$ asymmetries, the $B^0$ and $B^0$ decays are separated.

Taking into account both the P- and S-wave contributions and their interference, the differential decay rate [8] is given by the sum of the fifteen terms given in table 1,

$$d^5\Gamma = \frac{9}{8\pi} \sum_{i=1}^{15} h_i f_i(\theta_1, \theta_2, \Phi) M_i(m_{K\pi}, m_{KK}) d\Omega(KKK\pi).$$  \hspace{1cm} (2.3)

The $h_i$ factors are combinations of the amplitudes, $f_i$ are functions of the helicity angles, $M_i$ are functions of the invariant mass of the intermediate resonances and $d\Omega(KKK\pi)$ is a four-body phase-space factor,

$$d\Omega(KKK\pi) \propto q_\phi q_{K^-} q_{B^0} dm_{K\pi} dm_{KK} d\cos \theta_1 d\cos \theta_2 d\Phi,$$  \hspace{1cm} (2.4)
\begin{align}

\hline
\end{array}
\end{align}

Table 1. Definition of the $h_i$, $f_i$ and $\mathcal{M}_i$ terms in eq. (2.3). Note that the P-wave interference terms $i = 4$ and $i = 6$ take the imaginary parts of $A_{1\|} A_{1\perp}^\dagger$ and $A_{1\perp} A_{1\|}^\dagger$, while $i = 5$ takes the real part of $A_{1\|} A_{1\perp}^\dagger$. Similarly the S-wave interference terms $i = 9$ and $i = 13$ take the imaginary parts of $A_{1\perp} A_{1\|}^\dagger M_{1\perp}^* M_{1\perp}^*$, and the terms $i = 8, 10, 12, 14$ take the real parts of $A_{1\|} A_{1\perp}^\dagger M_{1\perp}^* M_{1\perp}^*$ and $A_{1\perp} A_{1\|}^\dagger M_{1\perp}^* M_{1\perp}^*$.

where $q_A$ is the momentum of the daughter particles in the mother’s ($A = B^0, \phi, K^{*0}$) centre-of-mass system.

The differential decay rate for $B^0 \to \phi K^{*0}$ is obtained by defining the angles using the charge conjugate final-state particles and multiplying the interference terms $f_4, f_6, f_9, f_{13}$ by $-1$. To allow for direct $CP$ violation, the amplitudes $A_j$ are replaced by $\bar{A}_j$, for $j = 0, ||, \perp, S$. The rate is normalized separately for the $B^0$ and $\bar{B}^0$ decays such that the P- and S-wave fractions are

\[ F_P = |A_0|^2 + |A_{||}|^2 + |A_{\perp}|^2, \quad F_S = |A_{S\pi}|^2 + |A_{S\pi}^K|^2, \quad F_P + F_S = 1, \]  
and

\[ F_P = |\bar{A}_0|^2 + |\bar{A}_{||}|^2 + |\bar{A}_{\perp}|^2, \quad F_S = |\bar{A}_{S\pi}|^2 + |\bar{A}_{S\pi}^K|^2, \quad F_P + F_S = 1. \]  

In addition, a convention is adopted such that the phases $\delta_{S\pi}^{K\pi}$ and $\delta_{S\pi}^{KK}$ are defined as the difference between the P- and S-wave phases at the $K^{*0}$ and $\phi$ meson poles, respectively.

### 2.2 Mass distributions

The differential decay width depends on the invariant masses of the $K^+ \pi^-$ and $K^+ K^-$ systems, denoted $m_{K\pi}$ and $m_{KK}$, respectively. The P-wave $K^+ \pi^-$ amplitude is parameterized using a relativistic spin-1 Breit-Wigner resonance function,

\[ M_{K\pi}^{+s} \left( m_{KK} \right) = \frac{m_{K\pi}}{q_{K\pi}} \frac{m_{K\pi}^2 \Gamma_{1\perp}^{K\pi} \left( m_{KK} \right)}{\left( m_{KK}^2 - m_{K\pi}^2 - im_{K\pi}^* \Gamma_{1\perp}^{K\pi} \left( m_{KK} \right) \right)}, \]  

where $q_{K\pi}$ is the momentum of the daughter particles in the mother’s ($A = B^0, \phi, K^{*0}$) centre-of-mass system.
where $m_0^{K^*} = 895.81$ MeV/$c^2$ [1] is the $K^{*0}$ mass. The mass-dependent width is given by

$$\Gamma_1^{K\pi}(m_{K\pi}) = \frac{\Gamma_0^{K^*} m_0^{K^*}}{m_{K\pi}} \left[ 1 + r^2 \frac{q_0^2}{q_{K^*}} \right] \left( \frac{q_{K^*}}{q_0} \right)^3,$$

where $q_0$ is the value of $q_{K^*}$ at $m_0^{K^*}$, $r = 3.4 \ h c / \text{GeV}$ [21] is the interaction radius and $\Gamma_0^{K^*} = 47.4$ MeV/$c^2$ is the natural width of the $K^{*0}$ meson [1]. The P-wave $K^+K^-$ amplitude, denoted $M_0^{KK}(m_{KK})$, is modelled in a similar way using the values $m_0^\phi = 1019.455$ MeV/$c^2$ and $\Gamma_0^{KK} = 4.26$ MeV/$c^2$ [1]. In the case of the $\phi$ meson the natural width is comparable to the detector resolution of 1.2 MeV/$c^2$, which is accounted for by convolving the Breit-Wigner with a Gaussian function.

As the $K^{*0}$ is a relatively broad resonance, the S-wave component in the $K^+\pi^-$ system, denoted $M_0^{K\pi}(m_{K\pi})$, needs careful treatment. In this analysis the approach described in ref. [8] is followed, which makes use of the LASS parameterization [21]. This takes into account an $L = 0$ $K_0^*(1430)$ contribution together with a non-resonant amplitude. The values used for the LASS parameterization are taken from ref. [8].

Finally, an S-wave in the $K^+K^-$ system is considered. This is described by the Flatté parameterization of the $f_0(980)$ resonance [22],

$$M_0^{KK}(m_{KK}) = \frac{1}{m_f^2 - m_{KK}^2 - i m_f (g_{\pi\pi} \rho_{\pi\pi} + g_{KK} \rho_{KK})},$$

where the $g_{KK,\pi\pi}$ are partial decay widths and the $\rho_{KK,\pi\pi}$ are phase-space factors. The values $m_f = 939$ MeV/$c^2$, $g_{\pi\pi} = 199$ MeV/$c^2$ and $g_{KK}/g_{\pi\pi} = 3.0$ were measured in ref. [23].

The Flatté distribution is convolved with a Gaussian function to account for the detection resolution. Other approaches to modelling the mass distributions for both the $K^+\pi^-$ and $K^+K^-$ S-wave are considered as part of the systematic uncertainty determination.

### 2.3 Triple-product asymmetries

The amplitudes and phases can be used to calculate triple-product asymmetries [2, 4, 24]. Non-zero triple-product asymmetries arise either due to a $T$-violating phase or a $CP$-conserving phase and final-state interactions. Assuming $CPT$ symmetry, a $T$-violating phase, which is a true asymmetry, implies that $CP$ is violated.

For the P-wave decay, two triple-product asymmetries are calculated from the results of the angular analysis [4],

$$A_T^1 = \frac{\Gamma(s_1, s_2 \sin \Phi > 0) - \Gamma(s_1, s_2 \sin \Phi < 0)}{\Gamma(s_1, s_2 \sin \Phi > 0) + \Gamma(s_1, s_2 \sin \Phi < 0)} \quad \text{and} \quad A_T^2 = \frac{\Gamma(\sin 2\Phi > 0) - \Gamma(\sin 2\Phi < 0)}{\Gamma(\sin 2\Phi > 0) + \Gamma(\sin 2\Phi < 0)},$$

where $s_1, s_2 = \text{sign} (\cos \theta_1 \cos \theta_2)$. These asymmetries can be rewritten in terms of the interference terms between the amplitudes [4], $h_4$ and $h_6$ in table 1,

$$A_T^1 = -\frac{4}{\pi} \text{Im}(A_4^*) \quad \text{and} \quad A_T^2 = -\frac{2\sqrt{2}}{\pi} \text{Im}(A_6^*).$$

Since the decay products identify the flavour at decay, the data can be separated into $B^0$ and $\bar{B}^0$ decays and the triple-product asymmetries calculated for both cases. This allows
a determination of the true asymmetries, \( A_T^k(\text{true}) = (A_T^k + A_T^{k'})/2 \), and so called fake asymmetries, \( A_T^k(\text{fake}) = (A_T^k - A_T^{k'})/2 \), where \( k = 1, 2 \). In the Standard Model the value of \( A_T^k(\text{true}) \) is predicted to be zero and any deviation from this would indicate physics beyond the Standard Model. Non-zero values for \( A_T^k(\text{fake}) \) reflect the importance of strong final-state phases [4].

The S-wave contributions allow two additional triple-product asymmetries to be defined from \( h_9 \) and \( h_{13} \) in table 1,

\[
A_3^T = \frac{\Gamma(s_{\theta_1} \sin \Phi > 0) - \Gamma(s_{\theta_1} \sin \Phi < 0)}{\Gamma(s_{\theta_1} \sin \Phi > 0) + \Gamma(s_{\theta_1} \sin \Phi < 0)}
\]

\[
= -\frac{\sqrt{3}}{2} \int |M^K_{KK}(m_{KK})|^2 \text{Im}(A_{\perp} A_{S}^{K\pi} M_{1}^{K\pi}(m_{K\pi}) M_{0}^{K\pi}(m_{K\pi})) dm_{KK} dm_{K\pi},
\]

and

\[
A_4^T = \frac{\Gamma(s_{\theta_2} \sin \Phi > 0) - \Gamma(s_{\theta_2} \sin \Phi < 0)}{\Gamma(s_{\theta_2} \sin \Phi > 0) + \Gamma(s_{\theta_2} \sin \Phi < 0)}
\]

\[
= -\frac{\sqrt{3}}{2} \int |M_{KK}^{K\pi}(m_{K\pi})|^2 \text{Im}(A_{\perp} A_{S}^{KK} M_{1}^{KK}(m_{KK}) M_{0}^{KK}(m_{KK})) dm_{KK} dm_{K\pi},
\]

where \( s_{\theta_i} = \text{sign} (\cos \theta_i) \) for \( i = 1, 2 \).

\section{Detector and dataset}

The LHCb detector [25] is a single-arm forward spectrometer covering the pseudorapidity range \( 2 < \eta < 5 \), designed for the study of particles containing \( b \) or \( c \) quarks. The detector includes a high-precision tracking system consisting of a silicon-strip vertex detector surrounding the \( pp \) interaction region, a large-area silicon-strip detector located upstream of a dipole magnet with a bending power of about 4 Tm, and three stations of silicon-strip detectors and straw drift tubes placed downstream. The polarity of the dipole magnet is reversed at intervals corresponding to roughly 0.1 fb\(^{-1}\) of collected data, in order to minimize systematic uncertainties associated with detector asymmetries. The combined tracking system provides a momentum measurement with relative uncertainty that varies from 0.4\% at 5 GeV/c to 0.6\% at 100 GeV/c, and impact parameter resolution of 20 \( \mu \)m for tracks with high transverse momentum (\( p_T \)). Charged hadrons are identified using two ring-imaging Cherenkov detectors [26]. Photon, electron and hadron candidates are identified by a calorimeter system consisting of scintillating-pad and preshower detectors, an electromagnetic calorimeter and a hadronic calorimeter. Muons are identified by a system composed of alternating layers of iron and multiwire proportional chambers.

The trigger [27] consists of a hardware stage, based on information from the calorimeter and muon systems, followed by a software stage, which applies a full event reconstruction. In this analysis two categories of events that pass the hardware trigger stage are considered: those where the signal \( b \)-hadron products are used in the trigger decision (TOS) and those
where the trigger decision is caused by other activity in the event (TIS) [27]. The software trigger requires a three-track secondary vertex with large transverse momenta of the tracks and a significant displacement from the primary \( pp \) interaction vertices (PVs). At least one track should have \( p_T > 1.7 \text{ GeV/c} \) and \( \chi^2_{\text{IP}} \) with respect to any primary interaction greater than 16, where \( \chi^2_{\text{IP}} \) is defined as the difference in \( \chi^2 \) of a given PV reconstructed with and without the considered track. A multivariate algorithm [28] is used for the identification of secondary vertices consistent with the decay of a \( b \) hadron.

Simulated data samples are used to correct for the detector acceptance and response. In the simulation, \( pp \) collisions are generated using Pythia 6.4 [29] with a specific LHCb configuration [30]. Decays of hadronic particles are described by EvtGen [31], in which final-state radiation is generated using Photos [32]. The interaction of the generated particles with the detector and its response are implemented using the GEANT4 toolkit [33, 34] as described in ref. [35].

4 Event selection

The selection of events is divided into two parts. In the first step a loose selection is performed that retains the majority of signal events, whilst reducing the background by a large fraction. Following this, a multivariate method is used to further reduce the background.

The selection starts from well reconstructed charged particles with a \( p_T > 500 \text{ MeV/c} \) that traverse the entire spectrometer. Fake tracks, not associated to actual charged particles, are suppressed using the output of a neural network trained to discriminate between these and real particles [36]. Further background suppression is achieved by exploiting the fact that the products of \( b \)-hadron decays have a large impact parameter (IP) with respect to the nearest PV. The IP of each track with respect to any primary vertex is required to have a \( \chi^2_{\text{IP}} > 9 \).

To select well-identified pions and kaons, the difference in the logarithms of the likelihood of the kaon hypothesis relative to the pion hypothesis (DLL\( K\pi \)) is provided using information from the ring-imaging Cherenkov detectors. The kaons that form the \( \phi \to K^+K^- \) candidate are required to have DLL\( K\pi \) > 0. To reduce background from \( \pi^+\pi^- \) pairs, a tighter requirement, DLL\( K\pi \) > 2, is applied to the kaon in the \( K^+\pi^- \) pair. For the pion in the \( K^+\pi^- \) pair the requirement is DLL\( K\pi \) < 0.

The resulting charged particles are combined to form \( \phi \) and \( K^{*0} \) meson candidates. The invariant mass of the \( K^+K^- \) \( (K^+\pi^-) \) pair is required to be within \( \pm 15 \text{ MeV/c}^2 \) \( (\pm 150 \text{ MeV/c}^2) \) of the known mass of the \( \phi \) \( (K^{*0}) \) meson [1]. Finally, the \( p_T \) of the \( \phi \) and \( K^{*0} \) mesons should both be greater than 900 MeV/c, and the fit of their two-track vertices should have a \( \chi^2 < 9 \).

Candidate \( B^0 \) meson decays with \( K^+K^-K^+\pi^- \) invariant mass in the range \( 5150 < m_{KKK\pi} < 5600 \text{ MeV/c}^2 \) are formed from pairs of selected \( \phi \) and \( K^{*0} \) meson candidates. A fit is made requiring all four final-state particles to originate from a common vertex and the \( \chi^2 \) per degree of freedom of this fit is required to be less than 15. To remove \( B^0 \to \phi\phi \) decays where a kaon has been incorrectly identified as a pion, the invariant mass of the \( K^+\pi^- \) pair is recalculated assuming that both particles are kaons. If the resulting invariant mass
is within ±15 MeV/c² of the known φ mass, the candidate is rejected. Finally, the decay vertex of the B⁰ meson candidate is required to be displaced from the nearest PV, with a flight distance significance of more than 5 standard deviations, and the B⁰ momentum vector is required to point back towards the PV with an impact parameter less than 0.3 mm and χ² IP < 5.

Further background suppression is achieved using a geometric likelihood (GL) method [15, 37, 38]. The GL is trained using a sample of simulated B⁰ → φK*⁰ signal events together with background events selected from the upper mass sideband of the B⁰ meson, m_{KKKπ} > 5413 MeV/c², and the φ mass sidebands, |m_{KK} − m_φ⁰| > 15 MeV/c². These sidebands are not used in the subsequent analysis. Six discriminating variables are input to the GL: the IP of the B⁰ candidate with respect to the PV, the distance of closest approach of the φ and K*⁰ meson candidate trajectories, the lifetime of the B⁰ candidate, the transverse momentum of the B⁰ candidate, the minimum χ² IP of the K⁺K⁻ pair and the minimum χ² IP of the K⁺π⁻ pair. As a figure of merit the ratio S/√S + B is considered, where S and B are the yields of signal and background events in the training samples, scaled to match the observed signal and background yields in the data. The maximum value for the figure of merit is found to be 24.6 for GL > 0.1, with signal and background efficiencies of 90% and 21%, respectively, compared to the selection performed without the GL. This reduces the sample size for the final analysis to 1852 candidates.

5 K⁺K⁻K⁺π⁻ mass model

The signal yield is determined by an unbinned maximum likelihood fit to the K⁺K⁻K⁺π⁻ invariant mass distribution. The selected mass range is chosen to avoid modelling partially reconstructed B decays with a missing hadron or photon. In the fit the signal invariant mass distribution is modelled as the sum of a Crystal Ball function [39] and a wider Gaussian function with a common mean. The width and fraction of the Gaussian function are fixed to values obtained using simulated events. A component is also included to account for the small contribution from the decay Bₙ⁰ → φK*⁰ [38]. The shape parameters for this component are in common with the B⁰ signal shape and the relative position of the Bₙ⁰ signal with respect to the B⁰ signal is fixed using the known mass difference between B⁰ and Bₙ⁰ mesons [1]. The invariant mass distribution is shown in figure 3, together with the result of the fit, from which a yield of 1655 ± 42 B⁰ signal candidates is found.

After the selection the background is mainly combinatorial and is modelled by an exponential. Background from Bₙ⁰ → φφ decays, with one of the kaons misidentified as a pion is reduced by the veto applied in the selection. The number of candidates from this source is estimated to be 6 events using simulation. These are distributed across the K⁺K⁻K⁺π⁻ mass range, and are considered negligible in the fit. A potential background from B⁰ → D⁺K⁻(D⁺ → φπ⁺) decays, which would peak in the signal region, is also found to be negligible. Possible background from the yet unobserved decay Λ_b⁰ → φpK⁻ with a misidentified proton is considered as part of the systematic uncertainties.
Figure 3. Invariant mass distribution for selected $K^+K^-K^+\pi^-$ candidates. A fit to the model described in the text is superimposed (red solid line). The signal contribution is shown as the blue dotted line. The contribution from combinatorial background is shown in green (dotted line). A contribution from $B_s^0 \rightarrow \phi K^{*0}$ (purple dot-dashed line) decays is visible around the known $B_s^0$ meson mass.

6 Angular fit

The physics parameters of interest for this analysis are defined in table 2. They include the polarization amplitudes, phases and amplitude differences between $B^0$ and $\bar{B}^0$ decays from which the triple-product asymmetries are calculated.

The correlation between the fit variables and $m_{KKK\pi}$ is found to be less than 3%. Therefore, the background can be subtracted using the sPlot method [40], with $m_{K^+K^-K^+\pi^-}$ as the discriminating variable. The results of the invariant mass fit discussed in section 5 are used to give each candidate a signal weight, $W_n$, which is a function of $m_{K^+K^-K^+\pi^-}$. The weight is used to subtract the background contributions from the distributions of the decay angles and intermediate resonance masses, which are fit using a signal-only likelihood that is a function of $\theta_1, \theta_2, \Phi, m_{K\pi}$ and $m_{KK}$. The angular fit minimizes the negative log likelihood summed over the $n$ selected candidates

$$-\ln L = -\alpha \sum_n W_n \ln S_n,$$

where $\alpha = \sum_n W_n / \sum_n W_n^2$ is a normalization factor that includes the effect of the weights in the determination of the uncertainties [41, 42], and $S$ is the signal probability density function (eq. (2.3)) convolved with the detector acceptance.

The acceptance of the detector is not uniform as a function of the decay angle of the $K^+\pi^-$ system ($\theta_1$) and the $K^+\pi^-$ invariant mass. This is due to the 500 MeV/c criterion applied on the $p_T$ of the pion from the $K^{*0}$ meson decay. In contrast, the acceptance is
relatively uniform as a function of the decay angles $\theta_2$ and $\Phi$, and the invariant mass of the $K^+K^-$ system.

The detector acceptance is modelled using a four-dimensional function that depends on the three decay angles and the $K^+\pi^-$ invariant mass. The shape of this function is obtained from simulated data. As the quantities relating to the $p_T$ of the decay products are used in the first-level hardware based trigger, the acceptance is different for candidates that have a TIS or TOS decision at the hardware trigger stage \cite{27}. Consequently, the trigger acceptance is calculated and corrected separately for the two categories. The 17\% of candidates that fall in the overlap between the two categories are treated as TOS, and the remaining TIS candidates are labelled ‘not TOS’. The projections of the acceptance are shown in figure 4. In the subsequent analysis the data set is divided into the two categories and a simultaneous fit is performed.

7 Angular analysis results

Figure 5 shows the data distribution for the intermediate resonance masses and helicity angles with the projections of the best fit overlaid. The goodness of fit is estimated using a point-to-point dissimilarity test \cite{43}, the corresponding $p$-value is 0.64.

The fit results are listed in table 2. The value of $f_L$ returned by the fit is close to 0.5, indicating that the longitudinal and transverse polarizations have similar size. Significant S-
wave contributions are found in both the $K^+\pi^-$ and $K^+K^-$ systems. The $CP$ asymmetries in both the amplitudes and the phases are consistent with zero.

Using eqs. (2.11)–(2.13), the values for the triple-product asymmetries are derived from the measured parameters and given in table 3. The true asymmetries are consistent with zero, showing no evidence for physics beyond the Standard Model. In contrast, all but one of the fake asymmetries are significantly different from zero, indicating the presence of final-state interactions.

The systematic uncertainties on the measured amplitudes, phases and triple-product asymmetries are summarized in table 4. The largest systematic uncertainties on the results of the angular analysis arise from the understanding of the detector acceptance. The
angular acceptance function is determined from simulated events as described in section 6. An uncertainty, labelled ‘Acceptance’ in the table, is assigned to account for the limited size of the simulation sample used. This is estimated using pseudo-experiments with a simplified simulation.

A difference is observed in the kinematic distributions of the final-state particles between data and simulation. This is attributed to the S-wave components, which are not included in the simulation. To account for this, the simulated events are reweighted to match the signal distributions as expected from the best estimate of the physics parameters from data (including the S-wave). In addition, the events are reweighted to match the observed distributions of the $B^0$ candidate and final-state particle transverse momenta. The reweighting is done separately for the two trigger categories and the nominal results are recalculated using the reweighted simulation to determine the angular acceptance. The difference between the weighted and unweighted results is taken as a systematic uncertainty (labelled ‘Data/MC’ in the table).

A further uncertainty arises from the $K^+K^-K^+\pi^-$ mass model used to determine the signal weights for the angular analysis. The fit procedure is repeated using different signal and background models. For the signal component a double Gaussian model is used instead of the sum of a Gaussian and a Crystal Ball function. Similarly, the influence of background modelling is probed using a first-order polynomial instead of an exponential function. Other changes to the background model are related to the possible presence of additional backgrounds. A possible small contribution from misidentified $\Lambda_b \rightarrow pK^-K^+K^-$ and $\Lambda_b \rightarrow p\pi^-K^+K^+$ decays is added and the fit repeated. Finally, the lower bound of the fit range is varied and the contribution from partially reconstructed $B$ decays modelled. The largest difference compared to the central values is assigned as an estimate of the systematic uncertainty (labelled ‘Mass model’ in the table).

Alternative models of the S-wave contributions in both the $K^+K^-$ and $K^+\pi^-$ system are considered. The default fit uses the LASS parameterization to model the $K^+\pi^-$ S-wave. As variations of this, both a pure phase-space model and a spin-0 relativistic Breit-Wigner with mean and width of the $K^*_0(1430)$ resonance are considered [1]. For the $K^+K^-$ S-wave a pure phase-space model is tried in place of the Flatté parameterization. The largest observed deviation from the nominal fit is taken as a systematic uncertainty (column labelled ‘S-wave’ in the table).

Various consistency checks of the results are made. As a cross-check candidates that are in the overlap between the trigger categories are treated as TIS for the angular correction in the fit rather than TOS. The dataset is also divided according to the magnetic field polarity. The results obtained in these studies are consistent with the nominal results and no additional uncertainty is assigned.

8 Direct CP rate asymmetry

The raw measurement of the rate asymmetry is obtained from

$$A = \frac{N(\bar{B}^0 \rightarrow \phi K^0) - N(B^0 \rightarrow \phi K^0)}{N(\bar{B}^0 \rightarrow \phi K^0) + N(B^0 \rightarrow \phi K^0)}.$$  

(8.1)
The numbers of events, \( N \), are determined from fits to the \( m_{KK\pi} \) invariant mass distribution performed separately for \( B^0 \) and \( \bar{B}^0 \) decays, identified using the charge of the final-state kaon. The dilution from the S-wave components is corrected for using the results of the angular analysis.

The candidates are separated into the TIS and TOS trigger categories. In this study, candidates that are accepted by both trigger decisions are included in both categories and

\[
\begin{align*}
\text{Asymmetry} & \quad \text{Measured value} \\
A_1^1 & \quad -0.007 \pm 0.012 \pm 0.002 \\

</tbody>
</table>

A possible bias to the central value is treated as a systematic uncertainty. The obtained raw asymmetries for the two trigger types are

$$A_{\phi K^{*0}}^{\text{TOS}} = +0.014 \pm 0.043 \quad \text{and} \quad A_{\phi K^{*0}}^{\text{TIS}} = -0.002 \pm 0.040 .$$

The direct CP asymmetry is related to the measured $A$ by

$$A_{CP} = A - \delta \quad \text{with} \quad \delta = A_D + \kappa_d A_P , \quad (8.2)$$

where $A_D$ is the detection asymmetry between $K^+\pi^-$ and $K^-\pi^+$ final-states, $A_P$ is the asymmetry in production rate between $B^0$ and $\bar{B}^0$ mesons in $pp$ collisions, and the factor $\kappa_d$ accounts for the dilution of the production asymmetry due to $B^0 - \bar{B}^0$ oscillations.

The decay $B^0 \to J/\psi K^{*0}$ is used as a control channel to determine the difference in asymmetries

$$\Delta A_{CP} = A_{CP}(\phi K^{*0}) - A_{CP}(J/\psi K^{*0}) , \quad (8.3)$$
Since the detector and production asymmetries cancel in the difference. Assuming $A_{CP}$ to be zero for the tree-level $B^0 \to J/\psi K^{*0}$ decay, $\Delta A_{CP}$ is the $CP$ asymmetry in $B^0 \to \phi K^{*0}$. The sample of $B^0 \to J/\psi K^{*0}$ decays, where the $J/\psi$ meson decays to a muon pair, are collected through the same trigger and offline selections used for the signal decay mode. Candidates are placed in the TOS trigger category if the trigger decision is based on the decay products from the $K^{*0}$ meson only. Where the decay products from the $J/\psi$ meson influences the trigger decision, the candidate is rejected. The raw asymmetries obtained separately for the two trigger types are

$$A_{J/\psi K^{*0}}^{TOS} = -0.003 \pm 0.016 \quad \text{and} \quad A_{J/\psi K^{*0}}^{TIS} = -0.016 \pm 0.008.$$ 

After averaging the trigger categories based on their statistical uncertainty, the measured value for the difference in $CP$ asymmetries is

$$\Delta A_{CP} = (+1.5 \pm 3.2 \pm 0.5)\%,$$

where the uncertainties are statistical and systematic, respectively. Systematic uncertainties arise from the differences between the event topologies of the $B^0 \to J/\psi K^{*0}$ and $B^0 \to \phi K^{*0}$ decays. Differences in the behaviour of the events in the TIS trigger category between the signal and control modes lead to an uncertainty of 0.25%. A further uncertainty of 0.4% arises from the differences in kinematics of the daughter particles in the two modes. The double counting of candidates in the overlap region leads to a possible bias on the central value, estimated to be less than 0.1%.

### 9 Conclusions

In this paper measurements of the polarization amplitudes and strong phase differences in the decay mode $B^0 \to \phi K^{*0}$ are reported. The results for the P-wave parameters are shown in Table 5; these are consistent with, but more precise than previous measurements. All measurements are consistent with the presence of a large transverse component rather than the naïve expectation of a dominant longitudinal polarization.
It is more difficult to make comparisons for the S-wave components as this is the first measurement to include consistently the effect of the S-wave in the $K^+K^-$ system, and because the $K^+\pi^-$ mass range is different with respect to the range used in previous analyses. The measurements of the polarization amplitude differences are consistent with CP conservation.

The results of the angular analysis are used to determine triple-product asymmetries. The measured true asymmetries show no evidence for CP violation. In contrast, large fake asymmetries are observed, indicating the presence of significant final-state interactions. The difference in direct CP asymmetries between the $B^0 \to \phi K^{*0}$ and $B^0 \to J/\psi K^{*0}$ decays is also measured,

$$\Delta A_{CP} = (+1.5 \pm 3.2 \pm 0.5) \%,$$

where the first uncertainty is statistical and the second systematic. This is a factor of two more precise than previous values reported by BaBar and Belle [8, 11] and is found to be consistent with zero.

Acknowledgments

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. We thank the technical and administrative staff at the LHCb institutes. We acknowledge support from CERN and from the national agencies: CAPES, CNPq, FAPERJ and FINEP (Brazil); NSFC (China); CNRS/IN2P3 and Region Auvergne (France); BMBF, DFG, HGF and MPG (Germany); SFI (Ireland); INFN (Italy); FOM and NWO (The Netherlands); SCSR (Poland); MEN/IFA (Romania); MinES, Rosatom, RFBR and NRC “Kurchatov Institute” (Russia); MinECo, XuntaGal and GENCAT (Spain); SNSF and SER (Switzerland); NASU (Ukraine); STFC (United Kingdom); NSF (USA). We also acknowledge the support received from EPLANET and the ERC under FP7. The Tier1 computing centres are supported by IN2P3 (France), KIT and BMBF (Germany), INFN (Italy), NWO and SURF (The Netherlands), PIC (Spain), GridPP (United Kingdom). We are indebted to the communities behind the multiple open source software packages on which we depend. We are also thankful for the computing resources and the access to software R&D tools provided by Yandex LLC (Russia).
