(Received 27 January 2014; published 5 May 2014)

The surface of a topological crystalline insulator (TCI) carries an even number of Dirac cones protected by crystalline symmetry. We epitaxially grew high-quality Pb$_{1-x}$Sn$_x$Te(111) films and investigated the TCI phase by in situ angle-resolved photoemission spectroscopy. Pb$_{1-x}$Sn$_x$Te(111) films undergo a topological phase transition from a trivial insulator to TCI via increasing the Sn/Pb ratio, accompanied by a crossover from n-type to p-type doping. In addition, a hybridization gap is opened in the surface states when the thickness of the film is reduced to the two-dimensional limit. The work demonstrates an approach to manipulating the topological properties of TCI, which is of importance for future fundamental research and applications based on TCI.

Recently, topological classification of quantum matter has been extended to a new class of matter, namely, topological crystalline insulators (TCI) [1]. A TCI consists of a bulk gap and an even number of robust surface Dirac cones. Different from the well-known topological insulators [2–4], the topological surface states of TCI are protected by crystalline symmetry instead of time-reversal symmetry; i.e., any perturbations preserving mirror symmetry cannot gap the surface states. Compared with a topological insulator, TCI offers a platform exploring broader topology-related phenomena, for example, spin-filtered edge states with an electrically tunable gap [5] and large Chern number quantum anomalous Hall phases [6]. First-principles calculation demonstrates that TCI can be realized in SnTe [7]. In contrast, PbTe, another IV–VI semiconductor with a similar structure as SnTe, is topologically trivial. Therefore, the Pb$_{1-x}$Sn$_x$Te compound is expected to undergo a topological phase transition at a certain value of $x$. Here we report on the observation of topological surface states and the phase transition from a trivial insulator to a TCI in high-quality Pb$_{1-x}$Sn$_x$Te(111) films prepared by molecular beam epitaxy (MBE). In addition, we observed that the (111) surface of topological Pb$_{1-x}$Sn$_x$Te harbors Dirac cones at the so-called time-reversal-invariant momenta (TRIM) [8]. Its observation has been a challenge owing to the difficulty in sample preparation. The thin film also enables us to investigate the thickness-dependent band structure of TCI. A hybridization gap is clearly seen when the thickness is reduced to a few nanometers.

Figures 1(a) and 1(b) show the rock-salt structure of Sn(Pb)Te and the Brillouin zone of this narrow-gap semiconductor. The fundamental band gaps are located at four equivalent $L$ points in the Brillouin zone. The lattice constant and electronic structure are altered by the substitution of Sn for Pb in Pb$_{1-x}$Sn$_x$Te. As a result, the band gaps close at a critical composition and reopen with increasing Pb content [9,10]. The order of conduction and valence bands at the $L$ points is inverted at the critical composition. The band inversion changes the mirror Chern number $n_M$ [11] from −2 to 0 ($|n_M|$ indicates the number of Dirac points along the $\hat{M} - \bar{\Gamma} - \hat{M}$ direction), giving rise to the topological phase transition as schematically shown in Fig. 1(c).

The nontrivial surface states of topological Pb$_{1-x}$Sn$_x$Te exist on the high-symmetry surfaces, such as {001}, {110}, and {111} that preserve the mirror symmetry with respect to the{110} planes. Here the notation (hkl) refers to the (hkl) plane and all those equivalent ones under symmetry transformation. Depending on the surface orientation, there are two types of surface states with qualitatively different properties: they are either located at TRIM or non-TRIM. More specifically, the (111) surface states of topological Pb$_{1-x}$Sn$_x$Te consist of totally four Dirac cones centered at TRIM $\hat{\Gamma}$ and $\hat{M}$ points, respectively [see Fig. 1(b) for the (111) surface Brillouin zones]. The (111) surface states are topologically much more unusual compared with those on the (001) surface [15,16]. The degeneracy of Dirac points at the TRIM points is not only protected by the mirror
symmetry, but also by the time-reversal symmetry. The Dirac points on (111) surface are robust against translational symmetry breaking \[17\]. So far most of the experiments \[15,16,18–23\] on Pb\(_{1-x}\)Sn\(_x\)Te have been performed on the (001) surface, which is the natural cleavage plane of IV–VI semiconductors. The (111) surface is a polar surface and difficult to obtain in single crystal growth. To meet the challenge, we prepared Pb\(_{1-x}\)Sn\(_x\)Te(111) thin films by using MBE. The lattice constant of SnTe (PbTe) along the [111] crystallographic direction is 1.82 (1.86) Å and that on the hexagonal (111) plane is 4.45 (4.56) Å. The in-plane lattice constant of Pb\(_{1-x}\)Sn\(_x\)Te(111) is very close to that of Bi\(_2\)Te\(_3\). We therefore choose Bi\(_2\)Te\(_3\) thin film grown on Si(111) as the substrate in epitaxial growth \[24\].

The experiments were performed in an ultrahigh vacuum system that consists of a MBE growth chamber, a low temperature scanning tunneling microscope (STM) (omnicron) and an angle-resolved photoemission spectrometer (VG-scienta) with a base pressure better than 1 × 10\(^{-10}\) mbar. The Si(111)-(7 × 7) substrate was prepared by multicycle flashing to 1200 °C. High purity Bi (99.999%), Te (99.9999%), Sn (99.9999%), and Pb (99.999%) were evaporated from standard Knudsen cells. Real-time reflection high-energy electron diffraction (RHEED) was used to monitor the film growth and calibrate the growth rate according to the intensity oscillation of (0,0) diffraction. The film morphology was characterized by STM at 77 K with platinum-iridium tips. In the angle-resolved photoemission spectroscopy (ARPES) measurement, samples were kept at 77 K and a Scienta R4000 analyzer was used to collect the photoelectrons excited by a He-I light source of 21.2 eV. The energy and angular resolution were better than 20 meV and 0.2°, respectively.

The atomically flat surface morphology of the as-grown films is revealed by the sharp streak of a 1 × 1 RHEED pattern along the [110] direction in Fig. 1(d). When the incidence direction of the electron beam in RHEED was turned to the [112] direction, another sharp 1 × 1 RHEED pattern was observed (not shown in the figure), suggesting that the film is (111) oriented and there is no surface reconstruction. In the STM image [Fig. 1(e)], the step height on the film is ∼3.6 Å, corresponding to the thickness of the Sn(Pb)-Te double layer along the (111) direction. The atomic-resolution STM image in the inset of Fig. 1(e) illustrates the hexagonal in-plane lattice structure.
of the Pb$_{1-x}$Sn$_x$Te(111) surface. The high crystal quality and (111) surface orientation are also confirmed by the x-ray diffraction pattern of the film [Fig. 1(f)]. Furthermore, density functional theory calculations (see the Supplemental Material [25]) and previous works [17,26] suggest that the SnTe (111) surface is terminated by Te atoms. If the (111) surface was Sn terminated, it should reconstruct to diminish the surface energy.

Figure 2(a) exhibits the ARPES spectra of SnTe film in the vicinity of the $\Gamma$ point. The observed electronic structure is identified as the valence band based on the tight-binding (TB) calculation [27] [Fig. 2(b)] using Green’s function method [28,29] (see the Supplemental Material [25]). The band bending effect [30,31], which commonly exists on the surface of narrow band semiconductors, has been considered in the calculation. The lower Dirac cone of the topological surface states merges into the valence band and cannot be distinguished.

The Fermi level in Fig. 2(a) intersects the bulk valence band due to the $p$-type Sn vacancy as the dominant dopant in SnTe [32–34]. It is therefore difficult to access the Dirac point of the topological surface states of SnTe in the ARPES measurement [15,16,18,20]. The Fermi level can be tuned by changing the Pb/Sn ratio in Pb$_{1-x}$Sn$_x$Te [15,16,20,35]. With increasing Pb content, the $p$-type cation vacancy becomes more difficult to form and at the same time more $n$-type Te vacancies can be produced. At a low Pb/Sn ratio [Fig. 2(c)], a Dirac-like dispersion becomes visible at the $\Gamma$ point. The Dirac point is located at about 130 meV below the Fermi level and very close to the top of the valence band. The TB calculation [Fig. 2(d)] ascribes this linear dispersion to the topological surface states.

The ARPES measurement and TB calculation [Figs. 2(e)–2(h)] indicate that Pb$_{1-x}$Sn$_x$Te at high Pb content is topologically trivial. The topological phase transition occurs when $x$ is between 0.3 and 0.4. In the case of pure PbTe [Fig. 2(g)], the film is heavily $n$ doped and a bulk electron pocket is clearly visible at the Fermi level. Inside the bulk energy gap of 280 meV, no state with Dirac-like dispersion is observed. Instead, a $W$-shaped band shows up. Based on the TB calculation with band bending [Fig. 2(h)], we attribute this $W$-shaped band to the trivial surface state with Rashba splitting. The (111) plane of IV–VI semiconductors is a polar surface with dangling bonds, leading to the observed surface states. The band bending effect [30,31] and spin-orbit coupling give rise to the Rashba splitting of the surface states at the $\Gamma$ point. The two subbands with different spins shift in the opposite direction along the $k$ axis and degenerate at the $\Gamma$ point, resulting in the $W$-shaped dispersion. The Rashba-type band persists in the nontopological Pb$_{1-x}$Sn$_x$Te compound [for example, see Figs. 2(e) and 2(f) for Pb$_{0.75}$Sn$_{0.25}$Te], and apparently evolves into the topological surface states after the topological phase transition.

One single Dirac cone at the $\Gamma$ point is not enough to establish the notion of TCI. The topological Pb$_{1-x}$Sn$_x$Te is distinct from the $Z_2$ topological insulator and should carry an even number of Dirac points on the high-symmetry crystal surfaces. Further evidence for TCI emerges at the $M$ points. Figures 3(a) to 3(d) exhibit the ARPES intensity maps of Pb$_{1-x}$Sn$_x$Te with various compositions at $M$ points. At a low content of Pb, a Dirac-like band with linear dispersion is clearly resolved. The energy of the Dirac point is estimated to be 180 meV (SnTe) and 36 meV (Pb$_{0.25}$Sn$_{0.75}$Te) above the Fermi level by linear extrapolation. Together with the topological surface states at the $\Gamma$ point, there are totally four Dirac cones on the (111) surface as predicted by theory [8]. With an increasing content of Pb, Pb$_{1-x}$Sn$_x$Te becomes topologically trivial and there is no more topological surface state inside the bulk energy gap [Figs. 3(c) and 3(d)]. In addition, the bulk gap of PbTe at the $M$ point is larger than that of Pb$_{0.75}$Sn$_{0.25}$Te, which is consistent with the scenario that the gap closes at the critical composition and gradually reopens with increasing Pb content after the topological phase transition.

Different from previous band calculations [8,10], the location of the Dirac point at $M$ [Fig. 3(b)] is much higher than that at $\Gamma$ [Fig. 2(c)]. The discrepancy can be resolved by taking into account the effect of band bending as shown in the TB calculation [Figs. 3(e)–3(h)]. Finally, if the film thickness becomes thin enough, the coupling of topological states from the opposite surfaces...
should open an energy gap in the spectra[14]. The gap opening (∼170 meV) for a 1.1 nm Pb$_{0.25}$Sn$_{0.75}$Te film is clearly demonstrated in Fig. 4(a). The vertically nondispersive feature between the upper and lower cones may stem from the enhanced many-body electronic interaction[36] or film inhomogeneity. For comparison, Figs. 4(b) and S4 in Supplemental Material[25] show the full Dirac cone without the energy gap for a thick film (∼30 nm) and the spectra for a 2.5 nm film, respectively.

In summary, we have investigated the electronic structure of Pb$_{1-x}$Sn$_x$Te(111) thin film by ARPES and TB calculation. The MBE film exhibits a topological phase transition with increasing Pb content and an even number of Dirac cones in the TCI phase. Together with the property of high electronic mobility and a large mean-free path for the (111)-oriented IV–VI semiconductors[37–39], the quasi-two-dimensional thin film with exotic surface states paves the road for searching new quantum phases in TCI near the topological phase transition and achieving high-efficiency electrical spin manipulation.
