Measurements of $t\bar{t}$ Spin Correlations and Top-Quark Polarization Using Dilepton Final States in $pp$ Collisions at $\sqrt{s} = 7$ TeV

S. Chatrchyan et al.
(CMS Collaboration)
(Received 15 November 2013; published 5 May 2014)

Spin correlations and polarization in the top quark–antiquark ($t\bar{t}$) system are measured using dilepton final states produced in $pp$ collisions at the LHC at $\sqrt{s} = 7$ TeV. The data correspond to an integrated luminosity of $5.0 \text{ fb}^{-1}$ collected with the CMS detector. The measurements are performed using events with two oppositely charged leptons (electrons or muons), a significant imbalance in transverse momentum, and two or more jets, where at least one of the jets is identified as originating from a $b$ quark. The spin correlations and polarization are measured through asymmetries in angular distributions of the two selected leptons, unfolded to the parton level. All measurements are found to be in agreement with predictions of the standard model.

DOI: 10.1103/PhysRevLett.112.182001 PACS numbers: 14.65.Ha, 13.85.-i, 13.88.+e

Measurements of spin correlations and polarization in the top quark–antiquark ($t\bar{t}$) system provide direct access to the properties of the bare top quark, as well as a test of the validity of perturbative quantum chromodynamics in the $t\bar{t}$ production process [1]. Such measurements are of particular interest given the anomalies in the $t\bar{t}$ forward-backward production process observed at the Tevatron [2,3]. The top-quark lifetime has been measured as $2.9^{+0.90}_{-0.63} \times 10^{-25}$ s [4], much shorter than the spin decorrelation time scale of $m_t/\Lambda_{QCD}^2 \approx 10^{-21}$ s [5], where $m_t$ is the top-quark mass, measured as $173.20 \pm 0.87$ GeV [6], and $\Lambda_{QCD}$ is the QCD scale parameter. Consequently, the information about the spin of the top quark at production is transferred directly to its decay products and can be accessed from their angular distributions. In the standard model (SM), top quarks are produced with a small amount of polarization arising from electroweak corrections to the QCD-dominated production process. For models beyond the SM, couplings of the top quark to new particles can alter the production process [1]. Such measurements are of comparisons between the data and theoretical predictions.

The top-quark polarization $P$ in the helicity basis is given by $P = 2A_P$, where the asymmetry variable $A_P$ is defined as

$$A_P = \frac{N(\cos(\theta^*_\ell) > 0) - N(\cos(\theta^*_\ell) < 0)}{N(\cos(\theta^*_\ell) > 0) + N(\cos(\theta^*_\ell) < 0)}.$$ 

Here the number of events $N$ is counted using the $\theta^*_\ell$ measurements of both positively and negatively charged leptons ($\theta^*_\ell^+ \text{ and } \theta^*_\ell^-$), assuming $CP$ invariance.

For $t\bar{t}$ spin correlations, the variable

$$A_{\Delta \phi} = \frac{N(\Delta \phi_{\ell^+\ell^-} > \pi/2) - N(\Delta \phi_{\ell^+\ell^-} < \pi/2)}{N(\Delta \phi_{\ell^+\ell^-} > \pi/2) + N(\Delta \phi_{\ell^+\ell^-} < \pi/2)}$$

provides excellent discrimination between correlated and uncorrelated $t$ and $\bar{t}$ spins, while the variable

$$A_{c_1c_2} = \frac{N(c_1c_2 > 0) - N(c_1c_2 < 0)}{N(c_1c_2 > 0) + N(c_1c_2 < 0)},$$

where $c_1 = \cos(\theta^*_\ell^+)$ and $c_2 = \cos(\theta^*_\ell^-)$, provides a direct measure of the spin correlation coefficient $C_{heq}$ using the...
The results presented in this Letter are based on data that correspond to an integrated luminosity of 5.0 fb$^{-1}$ of proton-proton ($pp$) collisions at $\sqrt{s} = 7$ TeV, provided by the LHC and recorded by the Compact Muon Solenoid (CMS) detector in 2011.

The central feature of the CMS apparatus is a superconducting solenoid, 13 m in length and 6 m in diameter, which provides an axial magnetic field of 3.8 T. The bore of the solenoid is equipped with a variety of particle detection systems. Charged-particle trajectories are measured with silicon pixel and strip trackers covering the pseudorapidity region $|\eta| < 2.5$, where $\eta = -\ln(\tan(\theta/2))$, with $\theta$ the polar angle of the trajectory of the particle with respect to the counterclockwise-beam direction. A crystal electromagnetic calorimeter and a brass and scintillator sampling hadron calorimeter surround the inner tracking volume and provide high-resolution measurements of energy used to reconstruct electrons, photons, and particle jets. The calorimeter covers the region $|\eta| < 5.0$, thereby providing reliable measurements of momentum imbalance in the plane transverse to the beam. Muons are measured in gas-ionization detectors embedded in the steel flux return yoke of the solenoid. A trigger system selects the most interesting collisions for analysis. A more detailed description of the CMS detector is given in Ref. [17].

For this analysis, $pp$ collisions are selected using triggers that require the presence of at least two leptons with large transverse momentum ($p_T$). Electron candidates [18] are reconstructed by associating tracks from the inner tracker with energy clusters in the electromagnetic calorimeter. Muon candidates [19] are reconstructed by combining information from the outer muon detector with the tracks reconstructed by the inner tracker. Additional lepton identification criteria are applied for both lepton flavors in order to reject hadronic jets that are misidentified as leptons [18,19]. Both electrons and muons are required to be isolated from other activity in the event. This is achieved by imposing a maximum value of 0.15 on the ratio of the scalar sum of supplementary track $p_T$ and calorimeter transverse energy deposits within a cone of $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.3$ around the lepton candidate direction, to the transverse momentum of the candidate [20].

Event selection is applied to reject events other than those from $\bar{t}t$ production in the dilepton final state. Events are required to have exactly two opposite-sign, isolated leptons ($e^+e^-$, $e^\pm\mu^\mp$, or $\mu^+\mu^-$). The electrons (muons) are required to have $p_T > 20$ GeV and to lie within $|\eta| < 2.5$ (2.4). The reconstructed lepton trajectories must be consistent with a common interaction vertex. Events with an $e^+e^-$ or $\mu^+\mu^-$ pair with invariant mass in the $Z$-boson mass “window” (between 76 and 106 GeV) or below 20 GeV are removed to suppress $Z/\gamma^*$ and heavy-flavor resonance production.

The jets and the momentum imbalance in each event are reconstructed using a particle-flow technique [21]. The anti-$k_T$ clustering algorithm [22] with a distance parameter of 0.5 is used for jet clustering. Corrections are applied to the energies of the reconstructed jets, based on the results of simulations and studies using exclusive dijet and $\gamma$ + jets data [23]. At least two jets with $p_T > 30$ GeV and $|\eta| < 2.5$, separated by $\Delta R > 0.4$ from leptons passing the analysis selection, are required in each event. At least one of these jets must be consistent with the decay of heavy-flavor hadrons (a “$b$ jet”), identified by the combined secondary vertex $b$-tagging algorithm [24]. The algorithm is based on the reconstruction of a secondary decay vertex, and gives a $b$-tagging efficiency of about 70% (depending on jet $p_T$ and $\eta$) with misidentification probabilities of approximately 1.5% and 20% for jets originating from light partons ($u$, $d$, and $s$ quarks, and gluons) and $c$ quarks, respectively. The missing transverse energy $E_T^{\text{miss}}$ is defined as the magnitude of the momentum imbalance, which is the negative of the vector sum of the momenta of all reconstructed particles in the plane transverse to the beam. The $E_T^{\text{miss}}$ in the event is required to exceed 40 GeV in events with same-flavor leptons, to further suppress the $Z/\gamma^*$ + jets background.

Simulated $\bar{t}t$ events are generated using MC@NLO 3.41 [25], with $m_t = 172.5$ GeV, and showered and fragmented using HERWIG 6.520 [26]. Simulations with different values of $m_t$ and the factorization and renormalization scales are produced in order to evaluate the associated systematic uncertainties.

The dilepton $\bar{t}t$ selection classifies events with $t$ leptons as signal only when the $t$ decays leptonically. Other $\bar{t}t$ topologies, such as the lepton + jets and all-hadronic decays, are classified as background. The background samples of $W$ + jets, $Z/\gamma^*$ + jets, dijetos, and single-top-quark events are generated using MADGRAPH [27] or POWHEG [28], and showered and fragmented using PYTHIA6.4.22 [29]. Next-to-leading order (NLO) cross sections are used for all background samples.

For both signal and background events, multiple $pp$ interactions in the same or nearby bunch crossings (pileup) are simulated using PYTHIA and superimposed on the hard collision. Events are then simulated using a GEANT4-based model [30] of the CMS detector, and finally reconstructed and analyzed with the same software used to process collision data.

The trigger efficiency for dilepton events that pass the analysis selection criteria is determined using a tag-and-probe method as in Ref. [31]. For the $e^+e^-$, $e^\pm\mu^\mp$, and $\mu^+\mu^-$ channels this gives $p_T$- and $\eta$-dependent efficiencies of approximately 100%, 95%, and 90%, respectively [32]. These efficiencies are used to weight the simulated events to account for the trigger requirement. The lepton selection efficiencies (reconstruction, identification, and isolation) are consistent between data and the simulation [31,33]. To account for the difference between the $b$-tagging
These events are not used in the measurement of no analytic solutions, for both the data and the simulation. Reweighting the top-quark \( p_T \) spectrum modeling is one of the largest sources of uncertainty.

After all weights are applied, a total of 740 background events are expected. There are 9824 events observed in the data, and the remaining 9084 events are assumed to be signal (dileptonic \( t\bar{t} \)). The average acceptance for signal events is 18\%, and describes the fraction of all produced signal events that are expected to be selected.

While the \( \Delta \phi_{\nu^-e^-} \) measurement relies purely on leptonic information, the measurements based on \( \theta_T^e \) require the reconstruction of the entire \( t\bar{t} \) system. Each event has two neutrinos, and there is also ambiguity in combining \( b \) jets with leptons, resulting in up to eight possible solutions for the \( t\bar{t} \) system. The analytical matrix weighting technique [20] is used to find the most probable solution, assuming \( m_t = 172.5 \) GeV. In events with only one \( b \)-tagged jet, the second \( b \) jet is assumed to be the untagged jet with the largest \( p_T \). Solutions are assigned a weight, based on the probability of observing such a configuration, and the \( t\bar{t} \) kinematic quantities are taken from the solution with the largest weight. To improve the efficiency of the technique in the presence of mismeasured jets, the solution for each event is integrated over parametrized jet and \( E_T^{\text{miss}} \) resolution functions. Despite this step, \( \approx 14\% \) of the events still provide no analytic solutions, for both the data and the simulation. These events are not used in the measurement of \( \theta_T^e \), which is accounted for as an additional event selection requirement.

The backgrounds from \( Z/\gamma^* + \text{jets} \) production and events with a jet misidentified as a lepton are estimated using both control data samples and simulation. The results agree within their uncertainties. The \( Z/\gamma^* + \text{jets} \) background outside the \( Z \)-boson mass window is estimated using the ratio of simulated events inside the window to the number outside the window to scale the observed event yield inside the window [20]. The contribution in this region from other processes, where the two leptons do not come from a \( Z \) boson, is estimated from \( e^\pm \mu^\pm \) data and subtracted prior to performing the scaling. The background with at least one misidentified lepton (nondileptonic \( t\bar{t} \), \( W + \) jets, and multijet events) is estimated from control samples in data using a parametrization of the probability for a jet to be misidentified as a lepton, determined using events collected with jet triggers of different energy thresholds. For both electrons and muons, an associated “loose” lepton candidate is defined based on relaxed isolation requirements [35]. The lepton misidentification rates are parametrized as a function of lepton \( p_T \) and \( \eta \), and are applied as weights to events containing exactly one lepton candidate and one or more loose lepton candidates.

The simulation is chosen as the method to predict the background event yields and shapes, with systematic uncertainties based on comparisons with the estimates using data. The backgrounds from single-top-quark and diboson events are estimated from simulation, found in agreement with data in recent CMS measurements [36,37].

The measured distributions are distorted from the true underlying distributions by the limited acceptance of the detector and the finite resolution of the measurements. An unfolding procedure is applied to correct the data for these effects, which yields the parton-level distributions of the variables under study, where the full covariance matrix is used to evaluate the uncertainties and bin-to-bin correlations.

The background-subtracted measured distribution \( \bar{b} \) is related to the underlying parton-level distribution \( \bar{x} \) by the matrix equation \( \bar{b} = S\bar{x} \), where \( A \) is a diagonal matrix describing the acceptance in each bin of the measured distribution and \( S \) is a smearing matrix describing the migration of events between bins due to the reconstruction techniques and finite detector resolution. The \( A \) and \( S \) matrices are modeled using the MC@NLO \( t\bar{t} \) simulation, and the results are available in graphical form in the Supplemental Material [38].

A regularized unfolding algorithm is employed using the singular value decomposition method [39]. The effects of large statistical fluctuations in the algorithm are greatly reduced by introducing a regularization term in the unfolding procedure. The unfolding procedure is validated using pseudoexperiments by verifying the pull distributions and linearity for the observables under study.

Various systematic uncertainties affect the measurements. These are mainly related to the performance of the detector and the modeling of the signal and background processes.

The uncertainty due to the jet energy scale corrections affects the analytical matrix weighting technique \( t\bar{t} \) solutions as well as the event selection. It is estimated by varying the jet energy scale of jets within their uncertainties (typically 1\%–2\%) [23], with propagation to the \( E_T^{\text{miss}} \). The uncertainty in the lepton energy scale, which affects mainly the lepton \( p_T \) distributions, is estimated by varying the energy scale of electrons by 0.5\% (the uncertainty in muon energies is negligible), as estimated from comparisons between data and simulated \( Z \)-boson events.

The uncertainty in the background subtraction is obtained by varying the normalization of each background component by 50\% for single-top-quark and diboson...
production and by 100% for the backgrounds from $Z/\gamma^* +$ jets production and from misidentified leptons.

The $t\bar{t}$ modeling and simulation uncertainties are evaluated by rederiving the $A$ and $S$ matrices using simulated events with variations in the parameter of interest: the factorization and renormalization scales are together varied up and down by a factor of 2; the top-quark mass is varied by $\pm1$ GeV around $m_t = 172.5$ GeV; the parton distribution functions are varied using the PDF4LHC prescription [40]; the jet energy resolution is varied by 5%–10%, depending on the $\eta$ of the jet [23]; the simulated pileup multiplicity distribution is changed within its uncertainty; and the scale factors between data and the simulation for the $b$-tagging efficiency, trigger efficiency, and lepton selection efficiency are varied by their uncertainties. In the simulated $t\bar{t}$ events, the $\tau$ spin is not propagated correctly to its decay products. This affects the angular distributions of the electrons and muons coming from $\tau$ decays. The corresponding systematic effect is estimated by reweighting the $\tau$ decay distributions to reproduce the SM expectations. A 100% systematic uncertainty is applied to the top-quark $p_T$ reweighting, since the origin of the effect is not yet fully understood, and the resulting systematic uncertainty is quoted separately.

Finally, the results of the unfolding linearity tests are used to estimate the systematic uncertainty in the unfolding procedure. The contributions to the total systematic uncertainty (from their sum in quadrature) for each asymmetry variable are presented in Table I.

The background-subtracted and unfolded distributions for $\Delta\phi_{p^{+}c^{-}}$, $\cos(\theta_{c}^{+})\cos(\theta_{c}^{-})$, and $\cos(\theta_{c}^{*})$ are shown in Fig. 1, normalized to unit area so that they represent parton-level differential cross sections in each variable. The data are compared to the predictions of the MC@NLO $t\bar{t}$ sample.

FIG. 1 (color online). Background-subtracted and unfolded differential cross sections for $\Delta\phi_{p^{+}c^{-}}$, $\cos(\theta_{c}^{+})\cos(\theta_{c}^{-})$, and $\cos(\theta_{c}^{*})$. The error bars represent statistical uncertainties only, while the systematic uncertainty band is represented by the hatched area. The bin contents are correlated due to the unfolding.
and to NLO calculations for $t\bar{t}$ production with and without spin correlations [16,41].

The asymmetries determined from the unfolded distributions are also parton-level quantities, and are measured to be $A_{\Delta\phi} = 0.113 \pm 0.010 \pm 0.006 \pm 0.012$, $A_{c_1c_2} = -0.021 \pm 0.023 \pm 0.025 \pm 0.010$, and $A_\rho = 0.005 \pm 0.013 \pm 0.014 \pm 0.008$, where the uncertainties are statistical, systematic, and from top-quark $p_T$ reweighting, respectively. These results are compared to the simulated and theoretical [16,41] values in Table II. The $A_{\Delta\phi}$ result indicates the presence of $t\bar{t}$ spin correlations, and strongly disfavors the uncorrelated case.

In summary, this Letter presents measurements related to $t\bar{t}$ spin correlations and the top-quark polarization in the $t\bar{t}$ dilepton final states ($e^+e^-$, $e^\pm\mu^\mp$, and $\mu^+\mu^-$), using asymmetry distributions unfolded to the parton level. The results are in agreement with the standard model predictions for all three measured variables.

We would like to thank Professor W. Bernreuther and Professor Z.-G. Si for calculating the theoretical predictions of Fig. 1 and Table II for this Letter. We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staff at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: BMWF and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, and FAPERESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES and CSF (Croatia); RPF (Cyprus); MoER, SF0690030s09 and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NIH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); NRF and WCU (Republic of Korea); LAS (Lithuania); MOE and UM (Malaysia); CINVESTAV, CONACYT, SEP, and UASLP-FAI (Mexico); MBIE (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Dubna); MON, RosAtom, RAS, and RFBR (Russia); MESTD (Serbia); SEIDI and CPAN (Spain); Swiss Funding Agencies (Switzerland); NNSF (Taipei); ThEPCenter, IPST, STAR, and NSTDA (Thailand); TUBITAK and TAEK (Turkey); NASU (Ukraine); STFC (United Kingdom); DOE and NSF (U.S.).
