(Received 29 May 2013; revised manuscript received 11 August 2013; published 23 October 2013)

Motivated by recent photoemission experiments on the surface of topological insulators we compute the spectrum of driven topological surface excitations in the presence of an external light source. We completely characterize the spectral function of these nonequilibrium electron excitations for both linear and circular polarizations of the incident light. We find that in the latter case, the circularly polarized light gaps out the surface states, whereas linear polarization gives rise to an anisotropic metal with multiple Dirac cones. We compare the sizes of the gaps with recent pump-probe photoemission measurements and find good agreement. We also identify theoretically several new features in the time-dependent spectral function, such as shadow Dirac cones.

I. INTRODUCTION

Topological properties of matter usually manifest in the appearance of electronic states at the boundary.1 An especially interesting class of such topological boundary modes arises in three-dimensional (3D) topological insulators (TI) which have now been detected experimentally in several material systems.2–6 The edge states consist of fermions in 2D with linear dispersion relation and where its spin and momenta have a fixed relative orientation. Recently, a new possibility for creating topological band structures in nonequilibrium was suggested,7–9 where an initially topologically trivial semiconductor is converted into a topological insulator via an external irradiation. The resulting state was dubbed a Floquet topological insulator and an analog to such a state was recently realized experimentally in a photonic system.10 In the same vein, other theoretical works11–13 have studied the realization of a lattice quantum Hall state with time-periodic perturbations.

The focus of these previous studies has been on turning an electronic system with a topologically trivial band structure into a topological insulator by subjecting it to a periodic-in-time perturbation. Here, on the contrary, we study the effect of an external irradiation on an initially topological state. The motivation comes from the development of new experimental probes that make it possible to access the time-resolved excitation spectrum of driven electrons at the surface of TIs using time-resolved photoemission spectroscopy.14 Below, we focus specifically on the properties of driven Dirac electrons on the surface of existing 3D topological materials such as Bi2Se3, Bi2Te3, and SbTe3 (Ref. 15). We are particularly interested in describing the modification of the spectrum of the boundary modes due to the irradiation as a function of the parameters of the incident light. The spectrum is composed of Floquet bands of the driven Dirac Hamiltonian, as discussed in the previous related works Refs. 12 and 16–18.

Besides, proving the existence of new dynamical Dirac cones which can be engineered, we also unify and extend previous analysis and apply our results specifically to describe an experiment which observed an induced energy gap in driven surface states of Bi2Se3 using time- and angle-resolved photoemission spectroscopy (TrARPES), Ref. 19. We find that our results fit the data well.

II. MODEL OF DRIVEN SURFACE STATES

We consider noninteracting electrons at the surface of a TI with incident light normal to the surface. The Hamiltonian is

$$H(k, t) = H_0(k) + H_{ext}(t),$$

$$H_0(k) = v(k)\sigma_y - k_x\sigma_x,$$

$$H_{ext}(t) = V\Theta(t - t_0)[a^\dagger_k(t)\sigma_y - a_k(t)\sigma_y].$$

$H_{ext}(t)$ describes the external radiation source. The electrons are minimally coupled by the Peierls substitution $k \rightarrow k + eA(t)$, where $A(t) = \alpha_0a(t)$ is the vector potential. We have set $\hbar = 1$, $c = 1$, the scalar potential to zero, and ignored small magnetic effects. Two polarizations are considered $a(t) = (\pm \cos \Omega t, \sin \Omega t)$ (circular) and $a(t) = (\cos \Omega t, 0)$ (linear), where $T = 2\pi/\Omega$ is the period of the external perturbation.

The energy scale of the perturbation is given by $V = ev\alpha_0 = evE_0/\Omega$, where $E_0$ is the amplitude of the electric field and $v$ the speed of Dirac fermions. The dimensionless coupling constant $V/\Omega$ characterizes the strength of the perturbation. We assume the photon energies are small compared with the bulk gap of the TI ($<300$ meV).

The evolution operator, which is a $2 \times 2$ matrix, obeys the time-dependent Schrödinger equation $i\partial_t U_k(t,t') = H(k,t)U_k(t,t')$, with initial condition $U_k(t) = 1$. Once the evolution operator is known, all other correlators can be calculated in terms of the initial state of the system. We first compute the retarded Green’s function in terms of the evolution operator using the equations of motion for the $c_{k,\alpha}^\dagger$ fields yielding the expression $g_{\alpha\beta}(k, t, t') = \langle f_\alpha(0) c_{k,\beta}^\dagger(t') c_{k,\alpha}(0) \rangle = -i\Theta(t - t')U_{k,\beta}(t, t')$, where $U_{k,\beta}$ is the $(\alpha, \beta)$ matrix element of $U_k$. We can similarly compute the nonequilibrium electron distribution function from the two-time lesser Green’s function which in terms of the evolution operator would read as $g_{\alpha\beta}(k, t, t') = i\langle c_{k,\beta}^\dagger(0) c_{k,\alpha}(t) \rangle U_{k,\beta}(t, t') U_{k,\alpha}(t, t')$, where $U_{k,\alpha}$ is the $(\alpha, \alpha)$ matrix element of $U_k$. The evolution operator is a $2 \times 2$ matrix, and the $c_{k,\alpha}^\dagger$ fields yield the expression $g_{\alpha\beta}(k, t, t') = \langle f_\alpha(0) c_{k,\beta}^\dagger(t') c_{k,\alpha}(0) \rangle = -i\Theta(t - t')U_{k,\beta}(t, t')$, where $U_{k,\beta}$ is the $(\alpha, \beta)$ matrix element of $U_k$. This expression is calculated in terms of the evolution operator using the equations of motion for the $c_{k,\alpha}^\dagger$ fields yielding the expression $g_{\alpha\beta}(k, t, t') = \langle f_\alpha(0) c_{k,\beta}^\dagger(t') c_{k,\alpha}(0) \rangle = -i\Theta(t - t')U_{k,\beta}(t, t')$, where $U_{k,\beta}$ is the $(\alpha, \beta)$ matrix element of $U_k$.
take values \{1,2\}. We now make the simplifying assumption that a quasi-steady-state has been reached, or equivalently that all correlations due to the initial state of the system had been washed away (mathematically we set \(t_0 = -\infty\)). Then the form of the evolution operator can be obtained analytically. Indeed, the evolution operator is \(T\)-periodic \(U_k(t+t',T) = U_k(t',t)\) and hence the retarded Green’s function also becomes \(T\)-periodic in the average time variable \(\bar{t} = (t + t')/2\). This periodic structure allows for a simple analytical expression of the Wigner representation 20 of the nonequilibrium retarded Green’s function in the Wigner representation which in a sense is similar to the Lehmann representation of equilibrium correlators.

III. SPECTRAL FUNCTION

It can be shown that the evolution operator 21
\[
U_{\alpha\beta}(t,t') = \sum_{\gamma\nu m} (\alpha|\phi_{\nu m}^\gamma|\beta) e^{-i\Delta_{\nu m}(t-t')/\Omega_1} e^{-i\epsilon_{\gamma m} \bar{t}}
\]
satisfies the Schrödinger equation where \((\alpha|\phi_{\nu m}^\gamma)\) represents the \((\alpha,n)\) component of the eigenvector \(|\phi_{\gamma m}^\nu\rangle\) of the Floquet Hamiltonian. Hence Fourier transforming in \(\bar{t}\) and relative time \(t - t'\) the Wigner representation of the retarded Green’s function is,
\[
g_{\alpha\beta}^{\text{w}}(k,n,\omega) = \sum_{\gamma m} \frac{(\alpha|\phi_{\nu m}^\gamma|\beta)}{\omega - \epsilon_{\gamma m} + n\Omega/2 + i0^+}. \tag{4}
\]
One can similarly obtain simple expressions for the inverse of the retarded Green’s function by noting that \(U_k(t,t')^{-1} = U_k(t',t)\). Driven systems on a lattice with one band have been studied before.22 The important point is that single-particle excitations, which occur at the poles of the imaginary part of the retarded Green’s function, are given by the quasienergies of the driven Dirac Hamiltonian, Eq. (1). The index \(n\) in Eq. (4) represents the number of photons interacting with the Dirac electron. For example, a one-photon resonant transition creates exited states shifted by \(\pm \Omega/2\) with respect to the original Dirac bands \(\pm \hbar k\) (see Appendix D). This dependence on \(n\) was not considered in Ref. 11.

We are interested in the single-particle excited states which are given by the singularities of the nonequilibrium spectral function. In the Wigner representation it is given by
\[
A(k,n,\omega) = -2\text{Im} Tr[g^{\text{w}}(k,n,\omega)]
\]
\[
= -2\text{Im} \left[ \sum_{\gamma m} \frac{(\alpha|\phi_{\nu m}^\gamma|\beta)}{\omega - \epsilon_{\gamma m} + n\Omega/2 + i0^+} \right]. \tag{5}
\]
Of particular interest is the average over period \(T\) of the driving force which is just the \(n = 0\) term,
\[
A(k,0,\omega) = 2\pi \sum_{\gamma m} |(\alpha|\phi_{\nu m}^\gamma)|^2 \delta(\omega - \epsilon_{\gamma m}). \tag{6}
\]
Using the completeness of the \(|\phi_{\nu m}^\gamma\rangle\) states we can verify that it satisfies the sum rule \(\int d\omega \text{Im} A(k,0,\omega) = 2\). Such property is not shared by any other moment of the nonequilibrium spectral function. In equilibrium, the spectral function does satisfy this sum rule which, in that case, derives from fermion conservation and the factor of two comes from the spin. In this sense, the average calculated above is more physical than the nonequilibrium spectral function by itself.
shift23 observed is an effect beyond the scope of the rotating wave approximation. We consider circular [(a), (c)] and linear [(b), (d)] polarization, with momentum along the \( k_x \) axis [(a), (c)] and \( k_y \) axis [(b), (d)]. In all panels, the horizontal lines correspond to different values of \( k_x \) \((k_y = 0)\) to \( v k_x = \Omega \) \((v k_x = \Omega)\) in steps of 0.05. We see the photoinduced gaps at the Dirac point and finite momentum. An exact crossing occurs at \( k^* \) with linear polarization, panel (d), giving rise to a shadow Dirac point. For \( V/\Omega = 0.52 \), the spectral weight is concentrated near the original Dirac bands but significant weight is still observed at shadow bands which are displaced by multiples of \( \Omega \). From the graphs we can read \( \Delta_0^\text{circ} = 0.43\Omega \), \( \Delta_1^\text{circ} = 0.31\Omega \) and \( \Delta_0^\text{lin} = 0 \), \( \Delta_1^\text{lin} = 0.52\Omega \).

where we used \( H_{\text{ext}}(t) = i V \sigma^- e^{i \Omega t} + \text{h.c.} \) and \( \sigma^\pm = (\sigma_x \pm i \sigma_y)/2 \). In the absence of the external perturbation, the four eigenvalues of the above matrix are \( v k_x, -v k_x, v k_x + \Omega \) and \( -v k_x + \Omega \) corresponding to the eigenvalues of the diagonal terms. Note that for \( V = 0 \) two of these bands cross at \( v k_x = \Omega / 2 \). The effect of a small nonzero \( V/\Omega \) is to open a gap in the spectrum at \( v k_x = (\Omega / 2)\sqrt{(2V^2 + 2\Omega^2)/(2V^2 + 4\Omega^2)} \) of magnitude \( \Delta_1^\text{circ}/\Omega = V/\sqrt{V^2 + \Omega^2} = V/\Omega + O(V^3) \). The magnitude of this gap agrees with previous perturbative calculations using the rotating wave approximation.\(^{16}\) For larger \( V/\Omega \), where the above approximation of retaining just two modes is not valid, the resonance occurs at momenta \( v k_x < \Omega / 2 \) [see Figs. 1(a) and 1(b)]. An exact numerical solution of the time-dependent Schrödinger equation confirms this result as shown in Figs. 2(a) and 2(b). The Bloch-Siegert shift\(^{23}\) observed is an effect beyond the scope of the rotating wave approximation.

Next we consider the Dirac point where a gap is photoinduced\(^{12}\) due to the absorption and subsequent emission of a photon by an electron near the Dirac point. The effective Hamiltonian is

\[
H_{k=0} = \begin{pmatrix} H_0 + \Omega & i V \sigma^- & 0 \\ -i V \sigma^+ & H_0 & i V \sigma^- \\ 0 & -i V \sigma^+ & H_0 - \Omega \end{pmatrix}, \tag{8}
\]

In the limit of \( V/\Omega \ll 1 \) the gap is \( \Delta_0^\text{circ} \approx 2(V^2/\Omega) \) (see Appendix C). Here we provide an alternative derivation, valid to all orders in perturbation theory, by noting that at the Dirac point, the Hamiltonian in Eq. (1) is one of the few analytically solvable driven two-level models,\(^{24}\) formally equivalent to a spin-1/2 in a circularly polarized magnetic field. Explicitly, the evolution operator at \( k = 0 \) is given by \( U_{k=0}(t,t) = e^{-i\sigma_z/2}e^{-iH(t-t)^i\sigma_z/2} \), where \( H = V \sigma_y - \Omega \sigma_z/2 \). Hence the gap at the Dirac point is\(^{12}\)

\[
\Delta_0^\text{circ} = \sqrt{\Omega^2 + 4V^2} \mod \Omega. \tag{9}
\]

IV. SHADOW DIRAC POINTS

In Figs. 1(c) and 1(d), we see band crossings at \( k = 0 \) and at finite momentum. In this section we show that these crossings are protected by a dynamical symmetry of the system in the presence of light with linear polarization. The Floquet operator for polarization along \( x \), in the basis of eigenvectors of \( H_0 \), is

\[
\hat{H}_F^\text{lin} = \begin{pmatrix} |k| \sigma_z + V \cos \phi_k \cos(\Omega t) \sigma_y \\ -V \sin \phi_k \cos(\Omega t) \sigma_y - i \partial_t, \end{pmatrix}
\]

where \( \phi_k \) denotes the angle between the momenta and the \( x \)-axis. If the momentum is along \( k_x \), the external perturbation commutes with \( H_0 \) and produces the trivial spectrum shown in Fig. 1(c) with Dirac points at \( v k_x = n\Omega \). If the momentum is perpendicular to the polarization the Hamiltonian is...
\[ \hat{H}_{F}^\text{lin} = \nu |k_y| \sigma_z - V \cos \Omega t \sigma_y - i \partial_t \] and satisfies

\[ \hat{P} \hat{H}_{F}^\text{lin} \hat{P}^{-1} = \hat{H}_{F}^\text{lin}, \]

where \( \hat{P} = \sigma_z e^{i t/2 \hbar} \) is the “parity” operator. This operator shifts time by \( t \to t + T/2 \) and flips the spin operator \( \sigma_y \to -\sigma_y \). This means that eigenstates \( \phi_{\alpha n} \) can be defined with good parity quantum number according to whether \( \alpha + n \) is even or odd. In other words, the external perturbation does not have matrix elements between states of different symmetries and hence crossings of these bands cannot be gapped; they are symmetry protected. This can be explicitly shown by writing \( \hat{H}_{F}^\text{lin} \) in frequency space, in the basis of eigenvectors of \( H_0 \), and noting that it splits into disjoint blocks \( \hat{H}_{F}^\text{lin} = \hat{H}_{\text{even}} \oplus \hat{H}_{\text{odd}} \) (see Appendix B). One implication is that the \( k = 0 \) point remains gapless,

\[ \Delta_0^\text{lin} = 0, \]

(12)

to all orders in perturbation theory, as the bands \( \epsilon_{k_1,0,} \epsilon_{k_2,0} \) have different parities. Indeed, at this point the Floquet operator vanishes for linear polarization.

Similarly, there are symmetry-protected band crossings at finite momentum between the bands \( \epsilon_{k_1, \text{odd}} \) and \( \epsilon_{k_2, \text{odd}} \). This is made explicit in Fig. (1d), where the bands \( \epsilon_{k_1,-1} \) and \( \epsilon_{k_2,1} \) cross at \( \pm k_y^* \). Including \( n = 0, \pm 1, \pm 2 \) Fourier modes we obtain zero-energy eigenvalues of \( \hat{H}_{F}^\text{lin} \) at momenta \( k_y^*/\Omega = 1 - V^2/3\Omega^2 + O(V^4) \).

For \( V/\Omega = 0.52 \) we have \( k_y^*/\Omega \approx 0.91 \). As momentum increases, with fixed \( V/\Omega < 1 \), the crossings asymptotically move towards \( v k_y^*/\Omega = n \Omega \). On the other hand, the crossing of the \( \epsilon_{k_1,0} \) and \( \epsilon_{k_2,1} \) bands can be gapped because they belong to the same symmetry class. The magnitude of this gap is \( \Delta_0^\text{lin} = V \) for \( V/\Omega \ll 1 \). For arbitrary direction in momentum space, other than \( k_x \) and \( k_y \), the states have no well-defined parity, degeneracies are not symmetry-protected, and gaps develop in the spectrum (see Fig. 3). The above considerations show that band touchings occur only at these special points in momentum space and that the existence and position of these points can be engineered with a properly chosen frequency.

V. DISCUSSION AND CONCLUSION

In a TrARPES experiment, the measured photocurrent is proportional to the two-time (nonequilibrium) lesser Green’s function, which in turn is proportional to the distribution function (generally unknown) and the spectral function. Furthermore, for a system were there is no phase coherence between the pump and probe pulses, we expect the photocurrent to time-average over the period of the driving force. These arguments suggest that the measured spectrum would be characterized qualitatively by the average of the spectral function, Eq. (6) (calculated numerically in Fig. 2). For concreteness, if the electric field is \( E_0 \approx 2.2 \times 10^7 \text{ V/m} \) and the photon energies are 120 meV then using \( v = 5 \times 10^5 \text{ m/s} \) as the speed of Dirac electrons on the surface of Bi2Se3, we obtain a coupling \( V/\Omega = 0.52 \). Using Eq. (9), we obtain a gap \( \Delta_0^\text{circ} = 51 \text{ meV} \), in agreement with our simulation in Fig. 2(a) and the experiment,19 \( \Delta_0^\text{lin} = 37 \text{ meV} \) along \( k_x \) and \( k_y \), and so the spectrum is isotropic [see Figs. 2(a) and 2(b)]. For linear light, we obtain \( \Delta_0^\text{lin} = 0 \) along \( k_x \) and \( k_y \) [Figs. 2(c) and 2(d)]. At finite momenta, \( \Delta_0^\text{lin} = 0 \) along \( k_x \) but \( \Delta_0^\text{lin} = 62 \text{ meV} \) at \( k_y \approx \Omega/2 \), in agreement with the experiment19 \( \Delta_0^\text{lin} = 62 \pm 5 \text{ meV} \). The position of the first shadow Dirac point is \( v k_y^*/\Omega = 109 \text{ meV} \).

In conclusion, we have calculated the nonequilibrium spectral function of electrons at the surface of TIs in the presence of an incident light with circular and linear polarization. Depending on the polarization, the system is an anisotropic metal with multiple Dirac cones or an insulator. This theory along with the experimental technique would allows for optical engineering of nonequilibrium spectra in topological materials.

Note added. After completion of this work we learned about Ref. 27 which contains partial overlap with our work.

APPENDIX A: PERIODICALLY DRIVEN TWO-LEVEL HAMILTONIANS

Here we provide a brief review of periodically driven two-level systems.25 If the Hamiltonian is periodic in time \( H(k,t+T) = H(k,t) \), with period \( T \), the solution of the Schrödinger
where the quasienergy is the representation of Eq.(A3), a linear drive is

\[ \gamma = \frac{k}{\Omega} \]

Substituting into the Schrödinger equation gives the eigenvalue problem

\[ \mathcal{H}_F \phi_{\gamma}(t) = \left( H(k,t) - i \partial_t \right) \phi_{\gamma}(t) = \epsilon_{\gamma} \phi_{\gamma}(t), \quad (A3) \]

where the \( \gamma = \{1,2\} \) distinguishes distinct eigenstates of the Floquet Hamiltonian \( \mathcal{H}_F \). Defining \( \phi_{\gamma}(t) = \sum_n \phi_{\gamma}^n e^{i n \Omega t} \) and \( H(k,t) = \sum_n H^x(k)e^{i n \Omega t} \) we obtain the frequency representation of Eq. (A3),

\[ \sum_{m \beta} \langle \alpha n | \mathcal{H}_F | \beta m \rangle \langle \beta m | \phi_{\gamma}' \rangle = \epsilon_{\gamma} \langle \alpha n | \phi_{\gamma}' \rangle, \quad (A4) \]

where \( \langle \alpha n | \mathcal{H}_F | \beta m \rangle = H^x_{\alpha \beta} + n \Omega \delta_{\alpha \beta} \delta_{nm} \). We omit the momentum label to simplify expressions when there is no danger of confusion. The quasienergies are \( \epsilon_{\alpha n} = \epsilon_{\alpha} + n \Omega \), where \( n \) is an integer. For circular polarization, the external driving can be written as \( H_{ext}(t) = iV \sigma^x e^{-i \Omega t} - iV \sigma^y e^{-i \Omega t} \), where \( \sigma^x = (\sigma_+ \pm i \sigma_-)/2 \). Hence the Floquet matrix corresponding to circular polarization is \( \mathcal{H}_F^{cyc} = \delta_{n,m} H_0 + iV \sigma^x \delta_{n,m-1} - iV \sigma^y \delta_{n,m+1} - \delta_{nm} \Omega \) or explicitly,

\[ \mathcal{H}_F^{cyc} = \begin{pmatrix} \cdots & H_0 + \Omega & 0 & 0 \\ -iV \sigma^+ & 0 & iV \sigma^- \\ 0 & -iV \sigma^+ & H_0 - \Omega & \cdots \end{pmatrix}, \quad (A5) \]

where \( H_0 \) is the unperturbed Dirac Hamiltonian. For linear drive \( A(t) = A_0 (\cos \Omega t, 0) \) and the external drive is

\[ H_{ext}(t) = V \sigma_y \cos \Omega t \]

which leads to

\[ \mathcal{H}_F^{lin} = \begin{pmatrix} \cdots & 0 & 0 & 0 \\ 0 & H_0 + \Omega & V \sigma_y/2 & 0 \\ 0 & V \sigma_y/2 & H_0 & V \sigma_y/2 \\ 0 & V \sigma_y/2 & H_0 - \Omega & \cdots \end{pmatrix}. \]

In Fig. 1 we have truncated the Floquet matrix to six Fourier modes and obtained the spectrum of the driven system for circular and linear polarization.

**APPENDIX B: DYNAMICAL SYMMETRY OF THE SYSTEM**

In the basis of the vectors \( \{1 \ i e^{i \phi})/\sqrt{2}, (-1 \ i e^{i \phi}),\sqrt{2} \) the unperturbed Hamiltonian is diagonal \( H_0 = v|k| \sigma_3 \) and for linear polarization the perturbation takes the form \( H_{ext}(t) = V \cos \phi_0 \cos \Omega t \sigma_3 - V \sin \phi_0 \cos \Omega t \sigma_y \), where \( \phi_0 \) is the angle of the electron momentum with respect to the polarization which is taken to define the \( x \)-axis. For the case of momenta perpendicular to the polarization the Floquet operator is \( \tilde{H}_F^{lin} = |k_1| \sigma_3 - V \cos \Omega t \sigma_y - i \partial_t \) and its frequency representation is \( \tilde{H}_F^{lin} = |k_1| \sigma_3 - V (\delta_{n,m-1} + \delta_{n,m+1}) \sigma_y/2 + n \Omega \delta_{nm} \) or explicitly shown in Eq. (B1). Note that \( \tilde{H}_F^{lin} \) can be divided into two disconnected blocks (symmetry classes). For example, the states \( v|k_1| - \Omega \) and \( -v|k_1| + \Omega \) belong to distinct blocks with no matrix element connecting them to any order in perturbation theory and hence they cross. Similarly, the branches \( v|k_1| \) and \( -v|k_1| \) do not mix to any order in perturbation theory and hence the crossing at \( k = 0 \) is also symmetry-protected as concluded in the main text. Finally we note that an electron in the state \( v|k_1| \) always changes chirality upon interacting with a linearly polarized photon leaving it in the state \( \mp v|k_1| \). This is in contrast to circular polarized photons where there is a finite probability of leaving the electron with the same chirality.

\[ \tilde{H}_F^{lin} = \begin{pmatrix} \cdots & v|k_1| + \Omega & 0 & 0 & 0 \\ 0 & -v|k_1| + \Omega & -iV/2 & 0 & 0 \\ 0 & v|k_1| & 0 & 0 & iV/2 \\ -iV/2 & 0 & 0 & -v|k_1| - iV/2 & 0 \\ 0 & 0 & iV/2 & v|k_1| - \Omega & 0 \\ 0 & 0 & -iV/2 & 0 & -v|k_1| - \Omega \end{pmatrix}. \]
APPENDIX C: GAP AT THE DIRAC POINT FROM PERTURBATION THEORY

In the presence of circularly polarized light a gap at \( k = 0 \) will develop. It can be understood intuitively as arising from renormalization effects due to virtual interactions between the branches \( v k \) and \( v k \pm \Omega \). To see this let us consider the truncated Hamiltonian shown in Eq. (8) which contains three branches with Fourier modes \( n = 0, \pm 1 \). Direct diagonalization involves solving an equation of sixth degree.

To reveal the nature of the gap we proceed in a different way. We are only interested in the renormalization of the \( n = 0 \) mode corresponding to the bands \( \pm v |k| \) near \( k = 0 \). The set of equations to solve is (omitting momentum label)

\[
(H_0 + \Omega)\phi^1_\alpha + iV\sigma^- \phi^0_\alpha = \epsilon_\alpha \phi^0_\alpha, \tag{C1}
\]

\[-iV\sigma^+ \phi^1_\alpha + H_0 \phi^0_\alpha + iV\sigma^- \phi^{-1}_\alpha = \epsilon_\alpha \phi^0_\alpha, \tag{C2}
\]

\[-iV\sigma^+ \phi^0_\alpha + (H_0 - \Omega) \phi^{-1}_\alpha = \epsilon_\alpha \phi^{-1}_\alpha. \tag{C3}
\]

If we assume that \( \Omega \gg \epsilon_\alpha \) then from the first and third equations we solve for \( \phi^1_\alpha \) as \( \phi^1_\alpha = -i(V/\Omega)\sigma^+ \phi^0_\alpha \). Substituting back into Eq. (C2) we obtain an effective equation for the \( n = 0 \) state, \( (H_0 - V^2\sigma_z/\Omega)\phi^0_\alpha = \epsilon_\alpha \phi^0_\alpha \). The eigenvalues of the renormalized Hamiltonian are \( \pm \sqrt{v^2k^2 + (V^2/\Omega)^2} \) with a gap at \( k = 0 \) of magnitude \( \Delta_{\text{inc}} = \Omega/2 \), which is \( O(V^2) \) as expected.

APPENDIX D: RETARDED GREEN’S FUNCTION IN PERTURBATION THEORY

One can write explicitly the form of the retarded Green’s function to first order in perturbation theory. Proceeding in the standard way by first expressing the equation of motion of the evolution operator in the interaction picture and then expanding to first order in \( V/\Omega \) we obtain \( U_k(t,t') \approx e^{-iH_0(t-t')}[1 - i \int_{t'}^t ds H_{\text{ext}}(s,t')] \) where \( H_{\text{ext}} \) is the perturbing Hamiltonian in the interaction picture with respect to \( H_0 \). Using the expression \( g^{(0)}_0(k,t,t') = -i(0-t')U_{k,0}(t,t') \) and expanding the Green’s function in Pauli matrices, \( g^\pm = g^0_0 + g^1_\sigma \), we obtain for circular polarization

\[
g^{(0)}_0(k,\vec{t},t') = -i\Theta(t') \cos(vk \cdot \vec{t}), \\
g^{(1)}_0(k,\vec{t},t') = -2iV/\Omega \Theta(t') \sin(vk \cdot \vec{t}) \sin \left( t' \frac{\Omega}{2} \right) \cos(\Omega \vec{t}),
\]

where \( t = t - t' \) and we have retained only the part proportional to the identity as only this part contributes to the spectral function after taking the trace. We have set \( k_z = 0 \) for simplicity to illustrate our point. After Fourier transforming in \( t \), we note that to zeroth order, we obtain the usual Dirac-like dispersion \( \pm vk \) corresponding to the eigenvalues of \( H_0 \) and to first order the Green’s function is explicitly time periodic in \( \vec{t} \), with sharply defined excitation bands at \( \pm vk \pm \Omega/2 \).
